Manipulation of Intrathoracic Pressure Improves Stroke Volume During Exercise in Patients with Heart Failure

Sophie Lalande[1], Andrew D. Miller[2], Bruce D. Johnson[2]. [1]*The University of Texas at Austin, Austin, TX; Mayo Clinic, Rochester, MN.* [2]*Mayo Clinic, Rochester, MN.*

(No relevant relationships reported)

Exercise accentuates within-breath fluctuations in intrathoracic pressure (ITP). The more negative ITP during inspiration increases left ventricular (LV) preload and afterload while the more positive ITP during expiration decreases LV preload and afterload. In healthy individuals, the more negative ITP generated during exercise is necessary to maintain an optimal LV preload and, consequently, stroke volume (SV). Curiously, patients with heart failure avoid breathing at high lung volumes and display large positive expiratory ITPs during exercise. In heart failure, a decreased LV compliance results in an increased sensitivity to changes in LV afterload, a decreased sensitivity to increased LV preload and a resulting inability to augment SV through the Frank-Starling mechanism. It was therefore hypothesized that the shallow breathing adopted by patients with heart failure during exercise preserves or enhances SV through decreases in LV preload and afterload. PURPOSE: To investigate the effect of a less negative inspiratory and a more positive expiratory ITP on SV during moderate-intensity exercise in patients with heart failure and reduced ejection fraction (HFREF) and healthy individuals. METHODS: SV was obtained by echocardiography during 2 min of spontaneous breathing (S), two progressive levels of inspiratory unloading (UL1 and UL2) using a ventilator and during expiratory loads of 5 and 10 cmH_2O produced by a ventilator in 11 patients with HFREF (61 ± 9 years, EF: 32 ± 4 %, NYHA class I-II) and 11 age-matched healthy individuals during exercise at 60% of maximal aerobic capacity on a semi-recumbent cycle ergometer. RESULTS: During exercise, inspiratory unloading decreased SV indexed to body surface area (SVI) in healthy individuals (S: 44 ± 7, UL1: 41 ± 5, UL2: 40 ± 4 ml/m2) while it increased SVI (S: 41 ± 7, UL1: 43 ± 7, UL2: 44 ± 5 ml/m2, p = 0.02) in patients with HFREF. Expiratory loading increased SVI in patients with HFREF (S: 43 ± 6, 5: 45 ± 3, 10: 44 ± 6 ml/m2) but decreased SVI in healthy individuals (S: 44 ± 8, 5: 40 ± 5, 10: 39 ± 5 ml/m2, p = 0.01). CONCLUSION: Inspiratory unloading and expiratory loading elicited increases in SVI during moderate-intensity exercise in patients with HFREF, possibly due to beneficial reductions in LV afterload and preload.

Breathing With Heart Failure: How Hard Can It Be?

Troy J. Cross[1], Surendran Sabapathy[2], Ken C. Beck[3], Norman R. Morris[2], Bruce D. Johnson[3]. [1]*Griffith University, QLD, Australia; Mayo Clinic, Rochester, MN.* [2]*Griffith University, QLD, Australia.* [3]*Mayo Clinic, Rochester, MN.*

(No relevant relationships reported)

The syndrome of heart failure (HF) is often accompanied by numerous derangements in ventilatory function. These pathophysiological changes in ventilatory function are believed to augment the mechanical work required to breathe during exercise (Wb). However, the precise contributions of resistive and elastic work to this overall higher Wb in HF remain unclear. PURPOSE: To quantify the resistive and elastic components of Wb during exercise in HF patients and age-matched, healthy controls at standardized levels of minute ventilation ( ). METHODS: The elastic and resistive Wb were assessed in 9 male HF patients (NYHA class I-III) and 9 age-matched, healthy male controls at minute ventilations of 20, 40, 60 and 80 L·min-1 during graded exercise. The components of Wb were quantified using oesophageal manometry and modified Campbell diagrams. RESULTS: Dynamic lung compliance was lower across all minute ventilations in HF patients (P<0.05). Moreover, the inspiratory and expiratory resistive Wb was higher in HF patients compared with controls at any given (P<0.05). The inspiratory elastic Wb was higher at minute ventilations of 40-60 L·min-1 during exercise in HF patients. (P<0.05). CONCLUSIONS: The findings of this study indicate that the overall higher Wb in HF patients may be more so related to greater amounts of resistive than elastic Wb during exercise.

The Link between Muscle Mass, Afferent Feedback and Ventilatory Control in Heart Failure

Manda L. Keller-Ross[1], Bruce D. Johnson[2], Rickey E. Carter[2], MIchael J. Joyner, FACSM[2], John H. Eisenach[3], Timothy B. Curry[2], Thomas P. Olson, FACSM[2]. [1]*University of Minnesota, Minneapolis, MN.* [2]*Mayo College of Medicine, Rochester, MN.* [3]*Kaiser Permanente, Denver, CO.*

(No relevant relationships reported)

Skeletal muscle afferent feedback modulates ventilatory control during exercise. Skeletal muscle atrophy in patients with heart failure (HF) may contribute to increased

FRIDAY, JUNE 1, 2018

afferent feedback which can lead to high ventilation to carbon dioxide production (VE/VCO2) slope. Low peak oxygen consumption (VO2 peak) and high VE/VCO2 slope are strongly associated with mortality in patients with HF. PURPOSE: This study examined the influence of muscle mass on low VO2 and the change in VE/VCO2 with afferent neural block during exercise in HF. METHODS: 17 participants [9 HF (60±6 yrs, mean±SD) and 8 controls (CTL) (63±7 yrs)] completed 3 experimental sessions. Session 1: peak exercise test on a cycle ergometer to volitional fatigue and dual energy x-ray absorptiometry. Sessions 2 and 3: 5 min of steady-state exercise on a cycle ergometer (65% of peak power) randomized to a lumbar injection of fentanyl (afferent blockade) or placebo. Ventilation (VE) and gas exchange (oxygen consumption, VO2; carbon dioxide production, VCO2) were measured. RESULTS: Peak work and VO2 were lower in HF (p<0.05). Leg fat was greater in HF (34.4±3.0 and 26.3±1.8%) and leg muscle mass was lower in HF (63.0±2.8 and 70.4±1.8%, respectively, p<0.05). VE/VCO2 slope was reduced in HF during afferent blockade compared with CTL (-18.8±2.7 and -1.4±2.0%, respectively, p=0.02). The reduction in VE/VCO2 was positively associated with leg muscle mass (r2=0.58, p<0.01) and negatively associated with leg fat mass (r2=0.73, p<0.01) in HF only. In addition, the reduction in VE/VCO2 was also positively associated with arm, trunk and total muscle mass (p<0.01). Importantly, there was a strong relationship between peak VO2 and the reduction in VE/VCO2 slope in HF (r2=0.87, p<0.01), but not CTL. CONCLUSIONS: HF patients with the highest fat mass, least leg muscle mass and lowest peak VO2 had the greatest improvement in VE/VCO2 with afferent blockade. Both muscle mass and fat mass are important contributors to ventilatory abnormalities and strongly associated to improvements in VE/VCO2 slope with locomotor afferent inhibition in HF. This indicates a strong link between muscle atrophy, skeletal muscle afferent activation and ventilatory control in HF.

Comparison of Firefighters and Instructors Physiological Responses Throughout a Day of Live-fire Training

Andrea Wilkinson, Patricia Fehling, FACSM, Leland Haigh, Denise L. Smith, FACSM. *Skidmore College, Saratoga Springs, NY.*
(No relevant relationships reported)

Approximately 10-12% of firefighter (FF) fatalities occur during training, with a significant proportion (56%) of these due to cardiac events. Although the cardiovascular strain of firefighting drills has been well documented, the cardiac and thermal strain experienced throughout an entire training day has not been well characterized.
Purpose: To compare the physiologic responses of FF and instructors during a day of departmental live-fire training that involved 3 training drills. **Methods:** On a work day, 29 career FF (34.7 ± 9.6 yr) and 6 instructors (36.2 ± 2.9 yr) wore a physiologic status monitor during an entire day of live-fire training (~ 7 hours) to record heart rate (HR) and estimated core temperature (EST T$_{co}$). Three drills (fire attack with ventilation and a multiple floor search; high-rise standpipe drill; ventilation, enter, and search), each lasting around 30 minutes were performed on each training day with debrief and clean-up periods after each drill. **Results:** There were no significant differences between the FF and instructors in any of the physiological responses (p > 0.05; see Table 1). FF and instructors achieved approximately 100% of age-predicted maximal heart rate (APMHR; 220-age) at some point during the day. Over the entire day HR mean was ~62% of APMHR. Additional analysis revealed physiologic strain was high during a single clean-up period (173 ± 16 b·min⁻¹, 37.8 ± 0.2°C).
Conclusions: All participants reached APMHR and had a mean HR throughout the day >60% APMHR. There were no differences in HR or EST T$_{co}$ between instructors or FF. We also found that physical exertion during cleanup activities can be as physically

demanding as the live-fire drills. When considering the physiologic strain of FF training, the physical work associated with set-up and clean-up should be taken into consideration.Supported by FEMA AFG Grant EMW-1015-FP-00731

Table 1. Physiologic Characteristics		
Variable	Instructors (n=6)	FF (n=2)
HR Peak (b·min⁻¹)	183 +/- 15	188 +/- 19
HR Mean (b·min⁻¹)	114 +/- 14	116 +/- 11
EST Tco Peak(°C)	38.3 +/- 0.4	38.6 +/- 0.5
EST Tco Mean (°C)	37.7 +/- 0.4	37.8 +/- 0.3
Values are means +/- SD; EST = estimated

Cardiorespiratory Responses to the USFS Wildland Firefighter Arduous Pack Test
Alfiero CJ, Dumke CL FACSM, Ruby BC FACSM and Bundle MW
University of Montana
US wildland firefighters administer over 30 000 physical tests per year to qualify candidates for the occupational demands of fire suppression. The primary assessment is the arduous pack test (APT) a 4.83 km hike that must be completed in 45 min while wearing a 20.45 kg pack. Delivery of individual feedback to guide the physical training of candidates is hampered by two factors; first, passing the pack test is widely considered the minimum performance level necessary needed for this occupation, and second, the binary nature of the assessment presents candidates with a task representing an unknown and self-selected exercise intensity.
PURPOSE: To determine the cardiorespiratory response elicited by the APT within a subject population whose aerobic capacity and body masses vary. **METHODS**: 63 young (age = 22.8±3.2 yrs) adults (37 males, M$_b$ = 81.2±9.4 kg; 26 females, M$_b$ = 63.6±8.5 kg; study range: 55.6-100.0 kg) performed the APT and subsequently underwent a hiking inclined-treadmill test to VO$_{2peak}$ while wearing a skin mounted heart rate (HR) monitor and 20.45 kg pack. **RESULTS**: 50 of the 63 subjects achieved the 45 min cutoff with a finishing time of 41.8 ± 2.1 min, the non-passers had a mean time of 47.7 ± 2.7 min. Non-passers were 77% female and 23% male. The VO$_{2peak}$ values of the passing and non-passing groups were 49.4 ± 7.2 and 42.6 ± 9.6 mlO$_2$ kg⁻¹ min⁻¹, respectively; the study range was 62.1 to 30.8 mlO$_2$ kg⁻¹ min⁻¹. HR, whether expressed as a fraction of the subject's maximum rate (passers = 81.2 ± 17.1 and non-passers = 79.9 ± 12.7% of HR$_{max}$), or as the fraction of the HR reserve (passers = 68.0 ± 7.9 and non-passers = 67.7 ± 15.3% of HR reserve) were not different between the groups. Regression of VO$_{2peak}$ on completion time yielded a negative relationship (R²=0.45). In contrast, the HR responses and completion time were consistent among the participants (R² < 0.01 for both % of HR$_{max}$ and % of HR reserve). **CONCLUSION**: To successfully complete the APT candidates must achieve a HR reserve of 68% or less while maintaining a walking speed of 1.8 m s⁻¹. These data suggest that monitoring HR during load carriage may be used to identify candidates with adequate and inadequate pre fire season readiness.

[4]Department of Health and Exercise Sciences, Skidmore College, Saratoga Springs, NY. [5]University of Brasília, Harvard T.H. Chan School of Public Health, Boston, MA, and GEAFS, Brasília, Brazil.*
(No relevant relationships reported)

Wildland firefighting is characterized by outdoor duties that include long walks and high physical demands. The Brasilia Fire Department Environmental Protection Brigade (EPB) is a wildland fire suppression specialized unit that also perform other duties, such as rescues. **PURPOSE**: To objectively evaluate the physical activity level (PAL) and sedentary time (ST) of wildland firefighters during a routine 24-hour on-

---

Abstracts were prepared by the authors and printed as submitted.

duty period. **METHODS**: We evaluated 26 firefighters from the EPB with mean age of 35.8±6 yrs, BMI of 25.3±3.2 kg/m² and VO_{2max} of 44.4±3.7 mL(kg.min)⁻¹. Volunteers wore the ActiGraph GT3X+ accelerometer set in 60s epochs, at the right waist during a 24-hour on-duty period. Main duties were reported on a written log. PAL and ST were evaluated using vector magnitude cut-points as follow: ST <200 counts per minute (cpm), light activity: 201-2689 cpm and moderate to vigorous activity (MVPA) ≥2690 cpm. **RESULTS**: Table 1 shows descriptive data. 23 participants (88.5%) accumulated at least 30min of MVPA. 16 firefighters (61.5%) achieved ≥10,000 steps. 20 (77%) reached the MVPA intensity and 6 (23%) the very vigorous one. Of those who participated in wildland fire suppression (50% of the sample), they spent 6% less time in ST (p=0.08) and 4.6% more time in MVPA (p=0.045).

Table 1: Median (min-max) values of ST and PAL during a 24h on-duty period (n = 26)

	Absolute (min)	Relative (%)
Sedentary time	561.5 (210-807)	50.4 (19.9-70.1)
Light PA	450 (277-614)	40.3 (27.7-54.2)
MVPA	98.5 (19-272)	8.4 (2.0-25.8)
Steps/day	13145 (4833-40593) steps	
Wear time	1090 (900-1380) min	

PA: physical activity; MVPA: Moderate to vigorous physical activity

CONCLUSIONS: On average, wildland firefighters spent ≥1h30min during MVPA during a routine 24h shift-work. Including night rests, almost half of on-duty period was of ST. The other 50% of the time was mainly spent on light activities but interspersed with MVPA. Almost 80% of the firefighters had at least one episode of MVPA during a routine work period. Those who responded to an episode of wildland fire accumulated more MVPA than those involved only in other firefighters' routine duties.

The Relationship Between Firefighters' Physical Activity Levels and Cardiorespiratory Fitness

Allison M. Barry[1], Nathan D. Dicks[1], Kassiann D. Landin[1], Tanis J. Walch[2], Kyle J. Hackney[1], Katie J. Lyman[1]. [1]North Dakota State University, Fargo, ND. [2]University of North Dakota, Grand Forks, ND. (Sponsor: Donna J. Terbizan, FACSM)

(No relevant relationships reported)

Improved physical activity (PA) and cardiorespiratory fitness (CRF) levels are necessary for firefighters to adequately perform strenuous occupational demands. These demands have been associated with increased cardiovascular events leading to disability and death. Sudden cardiac death accounted for 44% of all annual on-duty deaths in U.S. firefighters from 1995-2004. Thus, the National Fire Protection Association (NFPA) has made it a priority to emphasize PA levels in order to maintain and increase CRF.
PURPOSE: The purpose of the study was to investigate the relationship between sedentary behavior (SB), light physical activity (LPA), and moderate-to-vigorous physical activity (MVPA) to CRF in career firefighters. **METHODS:** Firefighters wore an accelerometer for eight consecutive on- and off-duty days. The accelerometer was worn on the right hip and tracked SB, LPA, and MVPA. Freedson's (1998) cut point determined PA intensity, while Choi's (2011) algorithm was used to remove non-wear time. Additionally, each participant completed a stage-graded exercise test with submaximal square-wave verification bout to determine maximal oxygen uptake (VO_{2max}). VO_{2max} was also estimated using self-reported physical activity rating and a non-exercise regression equation. Pearson's correlations were performed between the PA components and VO_{2max} as well as between estimated and actual VO_{2max} (ml/kg/min).
RESULTS: Preliminary results (n=9) for total wear time for the accelerometer was 920 (min) with 58.7% SB, 37.7 % LPA, and 3.6% MVPA. There were no significant correlations between VO_{2max} and SB (r = -0.18, P = 0.637) or LPA (r = 0.33, P = 0.388). Further, there was no significant correlation between estimated (45.2 ± 7.5) and actual VO_{2max} (39.2 ± 7.1) (r = 0.52, P = 0.149). There was a statistically significant correlation between VO_{2max} and MVPA (r = 0.74, P = 0.022). **CONCLUSION:** The initial results suggest that firefighters are meeting ACSM's PA guidelines but are not are not meeting the NFPA's minimal CRF recommendation of 42 ml/kg/min. Therefore, further research is necessary in order to make recommendations regarding PA and CRF for active firefighters. Twenty-one additional firefighters are expected to complete the study for a total sample of 30.

2054   Board #5   June 1 9:30 AM - 11:30 AM

Physical Factors Associated with Tower Stair Climbing In Firefighter Recruits

Kyle T. Ebersole[1], Cody S. Tesch[2], Robert J. Flees[1], Michael H. Haischer[1], Edward K. Smith[1], David J. Cornell[1]. [1]University of Wisconsin-Milwaukee, Milwaukee, WI. [2]City of Milwaukee Fire Department, Milwaukee, WI. (Sponsor: Terry Housh, FACSM)

(No relevant relationships reported)

Stair climbing in structural fires is a common task for firefighters. Firefighters also frequently have to ascend the stairs while carrying various equipment. The physical factors related to performance on a timed stair climb task are unclear. As a result, there is a lack of evidence to guide training programs for firefighter recruits that target the development of physical factors associated with performance on this task. **PURPOSE:** To determine the physical factors that are associated with performance during a timed stair climbing task in firefighter recruits. **METHODS:** 17 male firefighter recruits (20.4 ± 0.5 yrs, 178.5 ± 5.5 cm, 83.7 ± 8.7 kg) volunteered to participate. The recruits completed a battery of physical fitness and performance tests including: estimated body fat percentage (%Fat) via skinfold assessment; estimated one-repetition maximum squat (Squat) and bench press (Bench); seated weighted ball chest pass (Pass); 2-minute maximal push-up test (Push); estimated maximal aerobic capacity (VO_{2max}) via a submaximal step-test ; functional movement quality via a movement efficiency screen (MES); and time to complete a 5-story tower climb test ($Tower_{TIME}$). Heart rate (HR) was recorded immediately after the step-test (HR_{STEP}) and the tower climb (HR_{TOWER}). Squat, Bench, and Pass data were normalized to body mass (kg). Push data were normalized to the maximum number possible (80). Bivariate correlations were used to determine the relationship between $Tower_{TIME}$ and all the physical fitness and performance factors measured. **RESULTS:** Statistically significant ($P < 0.05$) correlations were identified between $Tower_{TIME}$ and %Fat ($r = 0.563$, $P = 0.019$), Bench ($r = -0.571$, $P = 0.017$), Pass ($r = -0.549$, $P = 0.023$), Push ($r = -0.532$, $P = 0.028$), VO_{2max} ($r = -0.560$, $P = 0.019$), HR_{STEP} ($r = 0.611$, $P = 0.009$), and HR_{TOWER} ($r = -0.638$, $P = 0.002$). Non-significant ($P > 0.05$) correlations were identified for Squat ($r = 0.448$, $P = 0.072$) and MES ($r = 0.353$, $P = 0.165$). **CONCLUSIONS:** Performance during a maximal tower climb task was related to fitness (%Fat and VO_{2max}), as well as upper body strength (Bench), power (Pass), and endurance (Push), but not lower body strength (Squat) or functional movement quality (MES). Further, those who performed better on the tower climb had a lower HR after the step-test and a higher HR after the tower climb test.

2055   Board #6   June 1 9:30 AM - 11:30 AM

Cardiovascular Risk Factor Characterization and Isokinetic Muscle Strength in Overweight and Obese Male Firefighters

Gena Gerstner[1], Andrew J. Tweedell[2], Craig R. Kleinberg[3], Hayden K. Giuliani[1], Timothy J. Barnette[1], Abbie E. Smith-Ryan, FACSM[1], A. C. Hackney, FACSM[1], Katie R. Hirsch[1], Jacob A. Mota[1], Eric D. Ryan[1]. [1]University of North Carolina at Chapel Hill, Chapel Hill, NC. [2]Army Research Laboratory, Aberdeen Proving Ground, MD. [3]Under Armour, Baltimore, MD. (Sponsor: Abbie E. Smith-Ryan, FACSM)

(No relevant relationships reported)

Sudden cardiac death is the cause of nearly half of on duty fatalities among firefighters. Although firefighters endure strenuous occupational duties, they often have sub-standard levels of fitness, and are at risk for cardiovascular disease (CVD). It is unclear if muscular strength provides a protective effect, independent of cardiorespiratory fitness (CRF). **PURPOSE**: The purpose of this study was to examine the influence of isokinetic strength on CVD risk factor characterization in overweight and obese career firefighters, prior to and after accounting for CRF. **METHODS**: Forty-four overweight and obese male firefighters [Mean ± SD; Age: 36.9 ± 7.1 yrs; Stature: 180.1 ± 7.0 cm; Body mass: 107.9 ± 19.8 kg; BMI: 33.1 ± 4.7 kg·m²] performed three maximal concentric isokinetic leg extensions on a calibrated isokinetic dynamometer at slow (1.05 rad·sec⁻¹; PT_{slow}) and fast (4.19 rad·sec⁻¹; PT_{fast}) velocities, in a randomized order. Peak torque was normalized to body mass for both velocities. Cardiovascular risk was determined based on published cutpoints for systolic blood pressure, total cholesterol, high-density lipoproteins, low-density lipoproteins, triglycerides, and trunk fat/limb fat ratio. Firefighters were characterized into three cardiovascular risk profiles (≤1 [n=14], 2 [n=16], and ≥3 [n=14] risk factors). A non-exercise prediction model including age, percent body fat from dual-energy X-ray absorptiometry, and self-reported exercise status from a questionnaire was used to calculate CRF. Two separate one-way analyses of variance (ANOVA) were used to evaluate potential differences in PT_{slow} and PT_{fast} between the three groups. Two separate analyses of covariance (ANCOVA) were used to examine whether PT_{slow} and PT_{fast}, adjusted for CRF, differed between the three groups. An alpha level was set *a priori* at $P ≤ 0.05$ for all analyses. **RESULTS**: There were no differences between groups for PT_{slow} or PT_{fast} prior to ($P =0.130$; $P =0.337$) or after ($P =0.054$; $P =0.191$) accounting for CRF, respectively. **CONCLUSIONS**: These findings suggest that isokinetic muscular strength does not provide a protective

effect from CVD risk factor characterization in this sample of overweight and obese male firefighters. **FUNDING**: Supported in part by a Junior Faculty Award from UNC-Chapel Hill.

2056   Board #7   June 1 9:30 AM - 11:30 AM
The Influence of Age and Adiposity on Functional Balance Performance in Career Firefighters

Jacob A. Mota[1], Timothy J. Barnette[1], Gena R. Gerstner[1], Andrew J. Tweedell[2], Craig R. Kleinberg[3], Hayden K. Giuliani[1], Eric D. Ryan[1]. [1]*University of North Carolina at Chapel Hill, Chapel Hill, NC.* [2]*Army Research Laboratory, Aberdeen Proving Ground, MD.* [3]*Under Armour, Baltimore, MD.* (Sponsor: Abbie Smith-Ryan, FACSM)

(No relevant relationships reported)

Slips, trips, and falls (STF) are one of the primary causes of non-fatal injuries in firefighters, incurring a large economic burden. Laboratory based measures of functional balance may help identify key risk factors for STF injuries.
PURPOSE: The purpose of the current investigation is to examine the impact of age and adiposity [body mass index (BMI) and percent fat (%BF)] on a functional balance assessment in career firefighters.
METHODS: Forty-nine healthy career firefighters (mean ± SD age = 35 ± 8 yrs; stature = 178.72 ± 7.99 cm; mass = 93.76 ± 21.85 kg; BMI = 29.11 ± 5.34 kg/m^2; %BF = 25.22 ± 5.34%) volunteered to participate in this study. Data were collected over two separate visits. The first visit required participants to arrive to the laboratory following a four-hour fast prior to a dual energy x-ray absorptiometry scan to estimate %BF and be familiarized with the functional balance assessment. On the subsequent visit, participants completed the assessment for time while wearing their personal protective equipment and a self-contained breathing apparatus. The task required firefighters to step down from a raised platform, walk across a narrow beam, pass beneath an overhead obstacle (at 75% of their height), and step up to a final raised platform. The task was repeated while walking backwards as fast as possible. Each participant performed five trials that were digitally recorded to account for minor (i.e. foot contact with the ground) and major errors (i.e. overhead obstacle falls) with a minute rest between each to create a performance index (PI). Pearson product-moment correlation coefficients were used to examine the relationship between PI and age, BMI, and %BF with an *a priori* alpha level set a $P \le 0.05$.
RESULTS: There was a significant relationship between PI and age (r = 0.406; P = 0.004) and %BF (r = 0.401; P = 0.004), but not BMI (r = 0.242; P = 0.093).
CONCLUSION: The results from the present study demonstrated that increased age and %BF were associated with poorer functional balance performance. These findings may highlight key risk factors that may contribute to an increased risk of STF injuries. Lastly, %BF may be a more sensitive measure of adiposity than BMI when identifying STF risk factors.

Risk Of Metabolic Syndrome In Adulthood Attributable To Childhood Grip Strength

Brooklyn Fraser[1], Leigh Blizzard[1], Michael Schmidt[2], Terence Dwyer[3], Alison Venn[1], Costan Magnussen[1]. [1]*University of Tasmania, Hobart, Australia.* [2]*University of Georgia, Athens, GA.* [3]*Oxford University, Oxford, United Kingdom.*

(No relevant relationships reported)

PURPOSE: Low levels of grip strength in adults independently predicts cardiovascular disease and type 2 diabetes. However, longitudinal evidence spanning child to adulthood is sparse. This study examined the association between child grip strength and adult metabolic syndrome (MetS). **METHODS**: Longitudinal study examining participants who had grip strength, cardiorespiratory fitness (CRF, physical work capacity at 170 beats per minute), and waist circumference measured in

childhood (9, 12, 15 years) and who had measures of MetS taken 20 years later. Child grip strength was categorised according to age-and sex-specific cut-points proposed by Catley and Tomkinson (2013) based on Australian normative data (very high, high, average, low, very low). Waist circumference, blood pressure, HDL cholesterol, triglycerides, and glucose were measured in adulthood and MetS was defined using the harmonised definition and a continuous MetS risk score. **RESULTS**: Children with very low or low grip strength were at six times increased risk of MetS and had a higher continuous MetS risk score in adulthood independent of CRF (RR=6.00, 95% CI=2.53, 14.19; β=0.38, 95% CI=0.23, 0.52), compared with children without very low or low grip strength. Adjustment for childhood waist circumference reduced the effect estimates for both MetS outcomes by 50-62% (RR=2.26, 95% CI=0.90, 5.64; β=0.19, 95% CI=0.07, 0.31) and statistical significance was lost for the dichotomous MetS outcome (p=0.08). **CONCLUSIONS**: Lower levels of childhood grip strength were associated with adult MetS independent of CRF, with part of this effect potentially being mediated through childhood waist circumference. These results suggest strategies aimed at improving grip strength in childhood might reduce future development of MetS. Supported by NHMRC Grant APP1098369

Muscular Strength And Cardiovascular And All-cause Mortality In Adults With Hypercholesterolemia

Duck-chul Lee, FACSM[1], Carl Lavie[2], Xuemei Sui, FACSM[3], Steven Blair, FACSM[3]. [1]*Iowa State University, Ames, IA.* [2]*Ochsner Health System, New Orleans, LA.* [3]*University of South Carolina, Columbia, SC.*

(No relevant relationships reported)

PURPOSE: To determine the associations of muscular strength (MS) with cardiovascular disease (CVD) and all-cause mortality in adults with hypercholesterolemia.
METHODS: Participants comprised 1,925 adults aged ≥40 years (mean age 50) who had a medical examination during 1980-1990 in the Aerobics Center Longitudinal Study. They were free of CVD, cancer, had ≥85% of their age-predicted maximal heart rate on a treadmill test, and hypercholesterolemia at baseline. MS was measured by 1 repetition maximums of bench and leg presses and a composite MS score was computed by combining the standardized values of both tests. Cardiorespiratory fitness (CRF) was estimated from a maximal treadmill test. We used tertiles of the sex- and age-specific total MS scores. Further, MS and CRF were dichotomized into either weak (lower one-third) or unfit (lower half), or strong (upper two-thirds) or fit (upper half) in a joint analysis of MS and CRF with mortality. Mortality follow-up was through 2003 using the National Death Index. Cox regression models included baseline age, sex, examination year, body mass index, smoking, alcohol intake, physical activity, parental CVD, hypertension, diabetes, abnormal electrocardiogram, total cholesterol, and CRF.
RESULTS: During an average follow-up of 18 years, 67 CVD and 172 all-cause deaths occurred. Compared with lower MS group, the hazard ratios (HRs) and 95% confidence intervals (CIs) for CVD and all-cause mortality were 0.45 (0.24-0.85) and 0.58 (0.40-0.85) in middle MS group ,respectively, and 0.46 (0.25-0.86) and 0.63 (0.43-0.93) in upper MS group, respectively, after adjusting for confounders including CRF. We found similar trends in both men and women, and normal weight and overweight or obese adults. In the joint analysis, compared with unfit and weak group, HRs (95% CIs) for CVD and all-cause mortality were 0.41 (0.22-0.78) and 0.41 (0.27-0.62) in unfit and strong group, respectively; 0.70 (0.30-1.66) and 0.60 (0.34-1.08) in fit and weak group, respectively; and 0.39 (0.19-0.82) and 0.59 (0.39-0.90) in fit and strong group, respectively.
CONCLUSIONS: MS, independent of CRF, should be promoted as a predictor of CVD and all-cause mortality in adults with hypercholesterolemia who are at increased mortality risk. Supported by NIH Grant AG06945, HL62508, DK088195, and HL133069.

2060   Board #3   June 1 9:30 AM - 11:30 AM
The Time-Varying Longitudinal Associations Between Muscle Strength, Functional Limitations, and Mortality in Older Adults

Ryan McGrath[1], Brenda Vincent[2], I-Min Lee, FACSM[3], William Kraemer, FACSM[4], Mark Peterson, FACSM[1]. [1]*University of Michigan, Ann Arbor, MI.* [2]*VA Ann Arbor Healthcare System, Ann Arbor, MI.* [3]*Harvard University, Boston, MA.* [4]*The Ohio State University, Columbus, OH.*

(No relevant relationships reported)

Understanding how factors, such as muscle strength, slow the disabling process may better inform interventions designed to preserve function and delay mortality.
PURPOSE: To determine the time-varying associations between 1) handgrip strength (HGS) and individual activities of daily living (ADL) functions, and 2) disaggregated ADL limitations and time to mortality in older adults. **METHODS**: A United States nationally-representative sample of 18,467 older adults (age: 66.9±11.1 years) from the Health and Retirement Study were followed for 8 years. Maximal HGS was measured

---

with a hand-held dynamometer. Ability to perform ADL functions were self-reported. Date of death was identified by the National Death Index and exit interviews. Separate covariate-adjusted hierarchical logit models were used to examine the association between HGS and each ADL outcome. Discrete covariate-adjusted Cox models were used to analyze the association between disaggregated ADL limitations and time to mortality. **RESULTS**: Every 5-kilogram increase in HGS was associated with decreased odds for the following ADL limitations: 9% (95% confidence interval (CI): 0.89, 0.93) for bathing, 6% (CI: 0.92, 0.96) for transferring, 9% (CI: 0.89, 0.93) for walking, 6% (CI: 0.92, 0.96) for dressing, 12% (CI: 0.84, 0.91) for eating, and 4% (CI: 0.94, 0.98) for toileting. The presence of a bathing, transferring, walking, dressing, eating, or toileting ADL limitation was associated with a 1.20 (CI: 1.19, 1.21), 1.04 (CI: 1.03, 1.05), 1.21 (CI: 1.20, 1.22), 1.02 (CI: 1.01, 1.03), 1.14 (CI: 1.13, 1.15), and 1.14 (CI: 1.13, 1.15) higher hazard for mortality, respectively. **CONCLUSIONS**: HGS was associated with reduced odds for each ADL limitation, which in turn, decreased the hazard for mortality in older adults. These findings provide insights into how preserving strength decelerates the disabling process by identifying which ADL functions are most impacted by muscle strength and the subsequent time to mortality for each ADL limitation.

2061 Board #4 June 1 9:30 AM - 11:30 AM

Defining Gender-specific Cut-off Points Of Lower Extremity Muscle Strength For Predicting All-cause Mortality Among Us Older Adults

Ran Li[1], Xi Zhang[2], Jianjun Guo[1], Yiqing Song[3]. *[1]China Institute of Sport Science, Beijing, China. [2]Xinhua Hospital affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, China. [3]Richard M. Fairbanks School of Public Health, Indiana University, Indianapolis, IN.*
(No relevant relationships reported)

Aging-related loss of muscle strength is an important predictor of mortality; but few studies have defined appropriate cut-off point of muscle strength in relation to mortality in a nationally representative population. **PURPOSE**: We aimed to explore the optimal cutoff values of lower extremity muscle strength (LMS) for predicting all-cause mortality in a nationally representative sample of US older adults from the National Health and Nutrition Examination Survey (NHANES). **METHODS**: Data sources included the NHANES1999-2002 with public-use 2011 linked mortality files, which comprised 2,209 men and 2,240 women aged 50 years and older with complete data of knee extension strength measurements. Weighted multivariable logistic regression models were used to account for multistage stratified and clustered sampling. All models were adjusted for age, race, BMI, muscle mass, cigarette smoking, alcohol use, education, leisure time physical activity, sedentary time, and comorbidities. Receiver operating characteristic curves (ROC) and Youden's J statistic were used to identify the gender-specific cutoff points. The validation of the optimal cutoff points for predicting all-cause mortality was internally assessed using bootstrap sampling method. **RESULTS**: Overall, there were nonlinear "L" shaped associations between LMS and all-cause mortality in men and women, separately. ROC curves showed that LMS appeared to provided additional predictive values beyond traditional risk factors with (c statistics: 0.94 (0.93-0.95) in men and 0.96 (0.94-0.98) in women) and without muscle mass (c statistics: 0.93 (0.92-0.95) in men and 0.96 (0.95-0.97) in women) in predicting all-cause mortality. Ten candidate gender-specific cutoff points of LMS, which had the highest Youden's J Index, were identified. In the multivariable logistic regression models the cutoff points were determined at 266newtons for men and 221newtons for women, which were the lowest cutoff points significantly associated with all-cause mortality. Internal validation using the bootstrap method with 500 sex-stratified replications revealed no apparent overfitting problem. **CONCLUSIONS**: Optimal cutoff points of LMS independent of muscle mass may help us to better assess and promote musculoskeletal fitness in terms of health outcome in older adults.

2062 Board #5 June 1 9:30 AM - 11:30 AM

Strength Training versus Aerobic Exercise in Relation to Cause-Specific Mortality

Alpa V. Patel[1], Erika Rees-Punia[2], James M. Hodge[1], Lauren R. Teras[1], Peter T. Campbell[1], Susan M. Gapstur[1]. *[1]American Cancer Society, Atlanta, GA. [2]University of Georgia, Athens, GA.*
(No relevant relationships reported)

BACKGROUND: Physical activity guidelines recommend that all adults engage in at least 150 minutes of moderate-intensity or 75 minutes of vigorous-intensity physical activity (MVPA) per week, and also state that adults should engage in muscle-strengthening activity (MSA) two or more times per week. While many studies have examined the association between aerobic MVPA and mortality, few have examined the association between MSA independent of or in combination with aerobic MVPA and mortality.
PURPOSE: To examine the role of MSA in relation to mortality independent of, and in combination with, MVPA.

METHODS: Data from 72,440 men and women enrolled in the Cancer Prevention Study-II Nutrition Cohort who completed a lifestyle and medical survey (including information on MVPA and MSA) in 2001 were available for analysis. Multivariable Cox proportional hazards regression modeling was used to compute hazard ratios (HR) and 95% confidence intervals (CI) to examine the association between MSA (none versus any) and total mortality. In addition, effect modification by MVPA (<8.75, 8.75-<17.5, and 17.5+ MET-hours per week) and body mass index (BMI, kg/m^2: normal weight 18.5-24.9, overweight 25.0-29.9, obese 30.0+) was examined.
RESULTS: During 12 years of follow-up (2001-2013), 18,023 deaths occurred. After adjusting for MVPA and other potential confounders, engaging in any MSA was associated with a modest, albeit statistically significant, lower risk of total mortality compared to no MSA (HR=0.93, 95% CI 0.89-0.98). Associations were similar when examining cardiovascular disease and cancer-specific mortality. There was no evidence of effect modification by MVPA (interaction p=0.66). The association between MSA and mortality was limited to normal weight individuals (HR=0.88, 95% CI 0.83-0.94), with no association among overweight (HR=0.97, 95% CI 0.90-1.05) or obese (HR=1.03, 95% CI 0.91-1.17) individuals (p for interaction=0.05).
CONCLUSIONS: Engaging in any MSA as part of a physical activity regimen is associated with a modest mortality benefit, regardless of aerobic MVPA participation. MSA may have a greater reduction in risk of normal weight vs overweight or obese individuals.

Strength Training in Older Cancer Survivors in Pennsylvania: What Role Does Multimorbidity Play?

Shirley M. Bluethmann, Wayne Foo, Joachim Wiskermann, Scherezade K. Mama, William Calo, Kathryn H. Schmitz, FACSM. *Penn State College of Medicine, Hershey, PA.*
(Sponsor: Kathryn Schmitz, FACSM)
(No relevant relationships reported)

Background: Older survivors experience physical deterioration from aging and cancer treatment. Strength training (ST) may mitigate symptoms but is underutilized. The extent to which physical limitations from chronic conditions ("multimorbidity") affect ST participation in older survivors is not well known. The purpose of this paper is to: 1) describe ST participation among older cancer survivors (≥55 years) by cancer site and; 2) assess the relationship of multimorbidity and ST in older cancer survivors.
Methods: We analyzed data from older survivors (n=485), identified from the Pennsylvania Cancer Registry, who were mailed a BRFSS-based questionnaire. Per ACSM guidelines, we operationalized ST participation as ≥2 sessions/week. We created age-groups (e.g., 55-64, 65-74, 75+) and a composite score of 7 common conditions (e.g., COPD, heart disease) to assess multimorbidity. Logistic regression estimated the association of demographic and behavioral risk factors (e.g., multimorbidity) with ST participation.
Results: Most respondents were female (62%), older (mean 69 years; range 55-95 years) and represented diverse cancer sites, including breast (n=106), gynecologic (n=99), prostate (n=119), colorectal (n=90) and lung (n=71) cancer survivors. ST participation was generally low; 75% of survivors reported no ST. Among those reported doing ST, survivors reported a mean ST frequency of 2.8 times/week (SE 2.8; CI 2.5,3.8), varying by cancer site/age. Gynecologic (OR=0.10, p<.05; CI 0.107-1.01) and prostate cancer survivors (OR=0.10, p<.05; CI 0.01, 0.95) were less likely to report doing ST than breast cancer survivors. We observed that older survivors with 3 comorbid conditions were less likely (OR=0.23, p=.10; CI 0.43,1.32) than survivors with fewer conditions to do ST, controlling for covariates.
Conclusion: Uptake of recommended ST is suboptimal in older survivors. Older gynecologic and prostate survivors, and those with greater multimorbidity (i.e. score=3) may have greater difficulty achieving recommended ST than survivors of other sites or with less comorbidity. Designing interventions for survivors with unique barriers, such as gynecologic and prostate cancer survivors and those with greater multimorbidity, may help these older survivors to use ST to improve symptoms and quality of life.

2064   Board #7   June 1 9:30 AM - 11:30 AM

Muscle Strength And Prevalence Of Diabetes, A Cross-sectional Study Among Japanese Men

Rumi Miyamoto[1], Susumu S. Sawada, FACSM[2], Yuko Gando[2], Munehiro Matsushita[3], I-Min Lee, FACSM[4], Steven N. Blair, FACSM[5], Shingo Muranaga[1], Yumiko Osawa[1], Kaori Ishii[6], Kohichiro Oka[6]. *[1]Kameda Medical Center, Kamogawa, Chiba, Japan. [2]National Institutes of Biomedical Innovation, Health and Nutrition, Tokyo, Japan. [3]Dokkyo Medical University, Tochigi, Japan. [4]Harvard Medical School, Boston, MA. [5]University of South Carolina, Columbia, SC. [6]Waseda University, Saitama, Japan.*
(No relevant relationships reported)

Some studies report that there is an inverse relationship between muscle strength and the prevalence of diabetes. However, limited data are available on this relationship among Japanese.
PURPOSE: To investigate the relationship between muscle strength measured by a very simple one-leg-stand-up (from a 40cm high seat) test and the prevalence of diabetes among Japanese men.
METHODS: This cross-sectional analysis was conducted in 1,674 Japanese men [median (inter quartile range) age 61 (55-67) years] who completed health examinations and a one-leg-stand-up test. Smoking and drinking habits were collected via a self-administered questionnaire. The prevalence of diabetes, defined as fasting plasma glucose $\geq$126 mg/dL and/or hemoglobin A1c $\geq$6.5% and/or self-reported physician-diagnosed diabetes, was evaluated. Odds ratios and 95% confidence intervals for the prevalence of diabetes were obtained using logistic regression models to assess the relationship between muscle strength and the prevalence of diabetes.
RESULTS: In total, 187 participants had diabetes, and 467 participants could not stand up from a 40cm high seat. Using men who could stand up as reference, the age-adjusted odds ratio of diabetes for men who could not stand up was 1.44 (1.06-1.94). After adjustment for age, smoking and drinking, the multivariable odds ratio was 1.43 (1.05-1.93). With additional adjustment for body mass index, the multivariable odds ratio was 1.26 (0.92-1.71).
CONCLUSION: Low muscle strength measured by a very simple fitness test was associated with a higher prevalence of diabetes among Japanese men. This association was mediated in part by body mass index.

2065   Board #8   June 1 9:30 AM - 11:30 AM

Muscular Strength and Cardiorespiratory Fitness on Osteopenia in Older Adults

Hyun Soo Kim, Nathan Meier, Duck-chul Lee, FACSM. *Iowa State Univrsity, Ames, IA.* (Sponsor: Duck-chul Lee, FACSM)
(No relevant relationships reported)

Purpose To examine the independent associations of muscular strength (MS) and cardiorespiratory fitness (CRF) with the prevalence of osteopenia in older adults.
Methods This cross-sectional study consisted of 127 men and 177 women aged $\geq$65 years old (mean age 74) from the Physical Activity and Aging Study (PAAS). MS was assessed by 1-repetition maximum (1-RM) leg press (lbs) and CRF was assessed by time (minutes) to complete a 400-meter walk test. Both MS and CRF were categorized into four groups based on the sex-specific quartiles of each MS and CRF. Bone mineral density was assessed by dual-energy X-ray absorptiometry (DXA), and osteopenia (pre-osteoporosis stage) was defined as t-score below -1.0 following the World Health Organization guidelines. Odds ratios (ORs) and 95% confidence intervals (95% CIs) were calculated using logistic regression to determine the independent associations of MS and CRF with the prevalence of osteopenia.
Results The prevalence of osteopenia was 45.4% in this study. Compared to the lower MS quartile 1 (lowest 25%), ORs (95% CIs) of osteopenia in MS quartiles 2, 3, and 4 were 0.75 (0.36-1.58), 0.33 (0.15-0.73), and 0.25 (0.11-0.59), respectively, after adjusting for age, sex, heavy alcohol consumption (>14 drinks per week for male, >7 for female), smoking status, physical activity, and CRF. However, we found that CRF was not significantly associated with the prevalence of osteopenia after adjusting for the confounders including MS in this study (trend P=0.19). In the stratified analysis by CRF, we found that higher MS was significantly associated with lower prevalence of osteopenia in both low CRF (lower 50%) (trend P=0.02) and high CRF (higher 50%) (trend P=0.03) after adjusting for age, sex, heavy alcohol consumption, smoking status, and leisure-time physical activity.
Conclusion Higher MS, independent of CRF, was associated with a lower prevalence of osteopenia in older adults. However, prospective studies are required to make causal inferences between MS, independent of and combined with CRF, and the development of osteopenia and osteoporosis in older adults.

E-07   Thematic Poster - **Nutritional Status of Athletes I**

Effects Of A Ketogenic Diet On Triathlon's Athletes Performance: A Pilot Trial.

Antonio Paoli, Davide Grigoletto, Fabio Zambolin, Giuseppe Marcolin. *University of Padova, Padova, Italy.*
(No relevant relationships reported)

PURPOSE Sport nutrition guidelines support the idea that carbohydrates (CHO) are fundamental for performance, mainly for endurance. However recently published studies on long distance athletes suggested some advantages of a low CHO, high fat approach, i.e. ketogenic diets. We aimed to investigate the effects of ketogenic diet (KD) on triathlon athletes. :
METHODS: Sixteen expert athletes (age 30.67±10.46 yrs) were enrolled in the pilot trial. Eight athletes followed a ketogenic diet (KD) for 5 weeks whilst other eight followed a standard western diet (WD). Subjects were tested for maximal oxygen consumption (VO_2max), peak power output (PPO), respiratory ratio (RR), heart rate, VO_2, and blood lactate during one hour cycloergometer test at 45% of PPO, and body composition through electrical impedance (BIA). A two way ANOVA treatment x time test was performed.
RESULTS: After 5 weeks subjects in the KD group showed a significant increase of VO_2max ($mlO_2xKg^{-1}xmin^{-1}$) 35.68±3.86 to 36.6±5.1; a significant increase of PPO (140±5.29 to 145±9), a significant decrease of fat mass (from 10.28±3.04 to 7.86±2.53 Kg), lactate (from 2.02±0.7 to 1.2±0.6) and of RR (from 0.86±0.03 to 0.79±0.01). No changes of lean body mass and time to exhaustion were detected.
CONCLUSIONS: Our data suggest that a ketogenic diet performed for a sufficient time (> 4 weeks) could improve some parameters related to performance in high level triathlon athletes

Comparative Analysis of the Gut Microbiota and Acute Changes in Exercise Among Collegiate Swimmers

Jarrad T. Hampton-Marcell. *University of Illinois at Chicago, Chicago, IL.*
(No relevant relationships reported)

ABSTRACT
Background: Numerous physiological responses occur due to changing energy demands induced by exercise training, including changes in substrate sensing and utilization in the gastrointestinal tractn and extracellular sensing to optimize substrate availability. The gut microbiota can contribute up to 10% of the host's energy demand via short-chained fatty acid production and modulate intestinal permeability and signaling. The interaction between gut microbiota and exercise is poorly understood.
Purpose: Characterize the gut microbiota in collegiate swimmers whom undergo a sequentially reduced volume of training.
Methods: Fecal samples, body composition (air displacement plethysmography) and training logs were collected from Division I NCAA collegiate swimmers for six consecutive weeks for 2016 (n = 9) and 2017 (n = 7), starting just before the taper and proceeding into the off-season. The fecal microbiota was characterized with shotgun metagenomics sequencing followed by multivariate statistical analysis using Qiime v1.9.1 and R programming language. Permutational ANOVAs, supervised learning and Bayesian modeling was used to determine significance (p < 0.05) of host-microbe interactions.
Results: Systematic reduction in practice volume from Phase 1 (mean = 23.7 km/wk) to Phase 3 (mean = 13.9 km/wk) did not show any significant shifts in body composition (p > 0.05). Yet the microbial community showed a moderate but significant shift in structure (Adonis, p < 0.05, R = 0.154) and predicted function (Adonis, p < 0.05, R = 0.352). During high levels of practice volume, swimmers were dominated by the Clostridiales order of Firmicutes. Despite interpersonal variation in community composition, its temporal shift was largely explained by Clostridium Cluster IV and XIVa, which are known short-chained fatty acid producers.
Conclusion: Acute reduction in exercise among collegiate athletes significantly shifts the sub-phylum of specific Clostridiales in gut microbiota, possibly due to reduced exercise volume or requisite alterations in the diet.

Describing Weight Regain Methodologies of Male Competitive Natural Bodybuilders

Venny Lalu, Diane DellaValle. *Marywood University, Scranton, PA.*

(No relevant relationships reported)

PURPOSE: Research focusing on bodybuilding training and nutrition strategies is limited and no research has attempted to examine weight regain strategies in these athletes. Due to this limited research, contemporary bodybuilding protocols are often based on anecdote and self-trial. This study will provide information for future research that may lead to evidence based strategies for coaches and athletes. The purpose of this cross-sectional study was to describe demographic characteristics and weight regain methodologies of male, competitive, natural bodybuilders.
METHODS: Recruitment was conducted via social media posts. Participants were invited to complete an online survey that included health and demographic information, dietary supplement use, and recreational and performance enhancing drug use. Bodybuilding training and competition information included weight regain methodology, and training phase-related weight loss and gain information. Body Mass Index (BMI) was calculated based on self-reported height and weight.
RESULTS: Participants included 24 male natural bodybuilders (Age 28.3±6.6 years, 100% male, 77.8% white). The average BMI of the sample was 25.9±6.6. Participants reported using an average of 5.9±2.9 supplements during the offseason, 6.2±2.9 during contest preparation, and 5.4±2.8 during the recovery period. The majority of the sample (85.2%) reported being amateur competitors, and 48.1% of participants reported previously competing in 1-2 bodybuilding competitions. Participants reported an average contest preparation length of 152.3±95.3 days, and an average competitive season of 40.4±42.5 days. 62.9% of participants reported losing > 25 lbs during contest preparation while weight gain varied from ≤10lbs to ≥35lbs. Participants reported using the reverse dieting method of weight regain most often in the past (48.1%).
CONCLUSION: This study is the first to describe the weight regain methods of male, natural, bodybuilders and allows for further exploration of this understudied population's nutritional strategies. The current study allows for future research to be conducted which may inform coaches and athletes of the safest and most effective methods for constructing individualized dietary and training protocols.

Physical Performance is not Improved with Vitamin D Repletion

Shane D. Scholten[1], Mikenzie Mikkelson[2], Jesse Springer[3], Cortney Dowling[4], Nathan Lucs[5]. *[1]Augustana University, Sioux Falls, SD. [2]Black Hills State University, Spearfish, SD. [3]University of Sioux Falls, Sioux Falls, SD. [4]Liberty University, Lynchburg, VA. [5]Des Moines University, Des Moines, IA.* (Sponsor: Sherry Barkley, PhD, FACSM)

(No relevant relationships reported)

Vitamin D insufficiency is associated with impaired physical performance in physically active adults. Vitamin D repletion could have a positive effect on neuromuscular function, which could increase physical performance. **PURPOSE:** This study assessed the role of vitamin D repletion on markers of anaerobic performance in physically active adults. **METHODS:** 16 physically active participants (5 insufficient/deficient participants with vitamin D<75 nmol/L, 11 sufficient participants with vitamin D>75 nmol/L) participated in a double blind study to assess anaerobic fitness (vertical jump, hand grip strength, 10 meter sprint, and Wingate bike test). Anaerobic fitness was assessed pre and post 8 weeks supplementation. Vitamin D insufficient/deficient participants were given doses sufficient to reach 120 nmol/L while sufficient participants received a placebo. All liquid supplements were prepared by a local pharmacy. **RESULTS:** The vitamin D group significantly increased vitamin D status (64.2 to 135.6 nmol/L, p<0.01) compared with the placebo (115.4 to 110.2 nmol/L). Vitamin D repletion was not found to significantly improve any of the anaerobic performance tests (p>0.05). **CONCLUSION:** This investigation demonstrated a lack of effectiveness for vitamin D repletion on markers of anaerobic performance in physically active adults. Supported by NIH grant P20GM103443.

Performance data. None of the variables were significant at the p>0.05 level.		
	Pre-supplement	Post-supplement
10 meter sprint (s)		
Vitamin D	2.00 + 0.14	2.01 + 0.15
Placebo	2.04 + 0.09	2.08 + 0.15
Vertical Jump (cm)		
Vitamin D	63.50 ± 11.91	62.03 ± 14.58
Placebo	61.84 ± 11.22	61.97 ± 11.86
30 second Wingate (avg watts)		
Vitamin D	613.72 ± 58.35	608.02 ± 91.59
Placebo	567.47 ± 146.88	555.81 ± 235.88
Hand Grip (kg)		
Vitamin D	54.70 ± 11.12	56.78 ± 9.51
Placebo	50.05 ± 14.553	49.10 ± 11.06

Antioxidant Intake, Adiposity, And Aerobic Capacity In An Athlete Population

Emily N. Werner[1], Sinclair A. Smith[2], Janell Mensinger[3], Brandy-Joe Milliron[3], Heather H. Betz[4], Stella L. Volpe, FACSM[3]. *[1]Michigan State University, East Lansing, MI. [2]Drexel University, Phildelphia, PA. [3]Drexel University, Philadelphia, PA. [4]Albion College, Albion, MI.* (Sponsor: Stella L. Volpe, FACSM)

(No relevant relationships reported)

Dietary intake, body composition, and aerobic capacity contribute to an athlete's performance.
PURPOSE: To evaluate relationships among antioxidant intake, adiposity, and aerobic capacity, and determine what characteristics have the greatest relationship with aerobic capacity in an athlete population. **METHODS:** Athletes defined as ≥18 years of age and exercising ≥ twice weekly were recruited. Measurements included days of self-reported physical activity per week, height, body weight, body mass index, and waist circumference. Percent body fat (PBF), lean body mass, and fat-free mass were measured via dual-energy X-ray absorptiometry. Maximal oxygen consumption (VO_2max) was analyzed using indirect calorimetry. Kilocalorie, macronutrient (carbohydrate, protein, fat), and antioxidant (β-carotene, vitamins A, C and E, iron, zinc, copper, and selenium) intakes were self-reported via Block 2005 Food Frequency Questionnaires. Antioxidants were analyzed as percentages of the Recommended Dietary Allowance. Bivariate Pearson Product Moment correlations were conducted to explore relationships among antioxidant intake, adiposity and aerobic capacity. A backwards multiple regression was used to determine which characteristic(s) had the strongest relationship with VO_2max. **RESULTS:** Thirty-two athletes (n=17 women, n=15 men; 35.7 ± 11.3 years of age) were measured. There were no differences between antioxidant intake and adiposity or aerobic capacity. There were significant negative relationships between PBF and VO_2max for women and men combined (p<0.001), as well as women (p = 0.013), and men (p=0.013), respectively. The backwards regression showed PBF (B = -0.504, p<0.001), vitamin C intake (B = -0.492, p=0.063), and vitamin E intake (B = 2.055, p=0.154) combined explained approximately 51% of the variance in VO_2max [R^2= 0.514, F(3,28) = 0.9.853, p<0.001]. After excluding vitamin C and vitamin E from the model, PBF alone explained 41% of the variance in VO_2max [B = -0.493, p<0.001; R^2= 0.442, F(1, 30) = 23.799, p<0.001]. **CONCLUSION:** Percent body fat alone, or combined with vitamins C and E, may have a substantial relationship with VO_2max. Further research should consider antioxidant intake and body composition in the investigation of the nutrition-related exercise benefits.
This research was unfunded.

Relationship between In-Race Nutrition and Experience Level on Overall Finish Time for Ironman Triathletes

Stephanie Harpenau, Elaina Biechler. *Loras College, Dubuque, IA.* (Sponsor: Vincent Paolone, FACSM)

(No relevant relationships reported)

Nutrition and experience level of triathletes are two factors that can affect overall finish time in an Ironman triathlon. While there appears to be a dose-response relationship between in race calories consumed and Ironman performance, there is little to no current research linking this with the experience level of the triathletes. **PURPOSE:** The purpose of the present investigation is to determine the relationship between years participating in triathlon, calories per hour on the bike, and overall ironman finish time.

METHODS: Ironman triathletes (n=152) were surveyed at Ironman Wisconsin and Ironman World Championships to determine their in-race nutrition strategy and years of experience in triathlon. A multivariate regression was used to determine if there was a relationship between years participating in triathlon, calories per hour consumed on the bike, and overall ironman finish time. **RESULTS**: The overall regression model was statistically significant $F(8, 284)= 2.27$, $p < .05$. Tukey's HSD post-hoc test revealed that the number of years in triathlon was not a significant predictor of finish time (p= .836), however the number of years in triathlon was uniquely significant in the prediction of calories consumed per hour on the bike (p < .05). **CONCLUSIONS**: Although there was no relationship between number of years in triathlon and overall finish time, there was a significant relationship between number of years in triathlon and prediction of calories consumed per hour on the bike. This suggests that the more experienced Ironman triathletes consumed more calories per hour on the bike.

Longitudinal Changes in Vitamin D and Body Composition in NCAA D1 Male Basketball Players

Carolyn Aprik[1], Terry Sauerbry[1], Lorenzo DiPace[1], Brigid Byrd[2], Lisa DeCeuninck[1], Barb Ledin[3], Tamara Hew-Butler, FACSM[1]. [1]Oakland University, Rochester, MI. [2]Wayne State University, Detroit, MI. [3]Crittenton Hospital, Rochester, MI. (Sponsor: Dr. Tamara Hew-Butler, FACSM)

(No relevant relationships reported)

Quantification of body composition changes with seasonal Vitamin D changes is not well-described. **PURPOSE**: To: 1) assess longitudinal changes in total body fat, lean, and bone tissue mass over 10-months and 2) explore relationships between Vitamin D, body composition, diet and sun exposure. **METHODS**: Male collegiate basketball players underwent dual energy x-ray absorptiometry (DXA) scans on four occasions: December 2016 (Start); April 2017 (End); July 2017 (Start Weights); October 2017 (End Weights) to quantify total body fat, lean, and bone mass. Blood was collected on 3 occasions (End; Start Weights; End Weights) and analyzed for serum 25-hydroxy vitamin D (25-OH-D). Food frequency questionnaires completed twice (Start and End Weights) with subjective reporting of sun exposure throughout weight-training. **RESULTS**: 11 (7 African-American) completed testing (age 20±1years; BMI 24.0±1.7kg/m²). Non-significant (NS) changes noted in total body fat percentage, which was lowest at End (16.1±2.1; 15.5±1.8; 16.6±2.2; 15.8±2.0%) and lean mass which was highest at End Weights (70.4±9.5; 71.4±9.1; 70.8±9.1; 74.3±9.3kg) while bone mineral density (BMD) increased steadily over time (1.33±0.10; 1.34±0.13; 1.35±0.12; 1.36±0.12g/cm²); (Start; End; Start Weights; End Weights, respectively). Serum 25-OH-D levels were deficient (<20ng/mL) at End (18.9±7.3ng/mL) but replete at Start Weights (32.2±12.8ng/mL) and End Weights (32.2±7.7ng/mL). African-American players spent less hours per week in the sun vs Caucasian players (6.5±2.3 vs. 11.2±3.7 hours/week; p=0.02) and ingested less Vitamin D in their diet (135.9±58.6 vs. 207.0±70.4; p=0.10)(African-American vs. Caucasian, respectively). Start Weight serum 25-OH-D levels significantly associated with: End Weight minus Start Weight (Δ) total fat mass (r=0.69;p=0.02), dietary sodium intake (r=0.65;p=0.04), and dietary iron intake (r=0.89;p=0.001). **CONCLUSION**: Collegiate male basketball players living in the Midwest (latitude 42°) demonstrate serum 25-OH-D deficiency at the end of the competitive season, but are replete (>30ng/mL) during summer training. Mild (NS) fluctuations in body composition occurred, with increased fat while detraining and increased lean mass with strength training. BMD increased despite seasonal variation in serum 25-OH-D.

Exploration of the Influences on Food Choices by a Culturally Diverse Cohort of International Athletes

Rachael Thurecht, Fiona Pelly. *University of the Sunshine Coast, Sippy Downs, Australia.*

(No relevant relationships reported)

Optimised nutrition and hydration can have a substantial effect on athletic performance, recovery and weight goals. However, an athlete's food selection may not be ideally matched to performance goals due to the various influences that drive food choice. **PURPOSE:** The aim of this study was to administer a preliminary Athlete Food Choice Questionnaire (AFCQ) with a diverse international athlete population. Objectives 1) to identify the factors that are frequently influencing athletes' food choices; 2) to investigate if frequently reported influences vary between athlete cohorts based on gender, sport and nationality. **METHODS:** The AFCQ was developed for the purpose of this study based on existing literature and input from sports nutrition experts. This consisted of demographic questions, and a 5-point Likert scale question comprising 84 factors possible of influencing food choice, organized into 10 groupings. Athletes living in the athlete's village at the 2017 Universiade were invited to complete an AFCQ. Kruskal-Wallis ANOVA and the Bonferroni adjusted Mann-Whitney U test were used to examine associations between variables. Only Performance group factors are presented here. **RESULTS:** A total of 156 AFCQ were received (41.6% male, 58.4% female, age *M*=21.5 ± 2.3 years). Athletes were from 31

(24.4%) attending countries and 17 (77.3%) competing sports. The top three influential factors were from the Performance group, the number one was "*My need to fuel my body for competition*" (*M*= 4.25 ± 0.8). Across all sporting types, country regions and gender either the Sensory Attributes or Performance groups ranked as the top factors frequently influencing athletes' food choices. Athletes in athletics or swimming were more frequently (*Mdn*= 5) influenced by their need to fuel their body for training than those in team sports (*Mdn*= 4), *U*= 952.5, *p*<0.003, *r*= 0.3, or skill-based and racquet sports (*Mdn*= 4), *U*= 117.5, *p*<0.001, *r*= 0.4. **CONCLUSION:** The results of this study will help inform the development of a validated food choice questionnaire for athletes and provide information to assist those working with athletes from a variety of sports and countries to deliver suitable advice for fuelling performance and recovery. Supported with funding from the event organisers and caterers of the 2017 Universiade athletes' village dining hall.

A Nonlinear Dynamics Approach To Oxygen, Ventilation, and Heart Rate Dynamics During Exercise In Young Adults

Nathaniel T. Berry[1], Jessica Dollar[1], Lily Shanahan[2], Susan D. Calkins[1], Susan P. Keane[1], Laurie Wideman, FACSM[1]. [1]University of North Carolina at Greensboro, Greensboro, NC. [2]University of Zurich, Zurich, Switzerland. (Sponsor: Laurie Wideman, FACSM)

(No relevant relationships reported)

Fitness induced adaptations, such as changes in oxygen uptake (VO_2), respiration, and cardiac autonomic regulation are known to occur at rest and during exercise following endurance training. For example, submaximal intensities are associated with reductions in VO_2 per workload, reductions in heart rate (HR), and reductions in ventilation (V_E) while maximal intensities are associated with increases in VO_2 and V_E. However, less is known about the breath-by-breath dynamics of VO_2 and V_E during exercise with changes in cardiac autonomic regulation in relation to fitness. **PURPOSE** To investigate the influence of gender, body fat (BF) and maximal VO_2 (VO_{2max}) on the breath-by-breath dynamics of VO_2 and V_E, as well as HR variability (HRV), during an incremental treadmill test to exhaustion. **METHODS** Breath-by-breath VO_2 and V_E, as well as continuous R-R intervals were collected throughout an incremental treadmill test for N=39 individuals (Males: n=20; height=177±8 cm, weight=79±18 kg; BF=18±9%; VO_{2max}=54±9 ml/kg/min – Females: n=19; height=164±6 cm, weight=74±21 kg; BF=33±12%; VO_{2max}=36±10 ml/kg/min). Individual time-series were fit using polynomial regression models. The residuals from these models were used to detrend the data. The standard deviation of normal intervals (SDNI), root mean square of successive differences (rMSSD), and sample entropy (SampEn) of the residuals were calculated and relations among these variables with gender, BF, and VO_{2max} were analyzed using multivariate analysis of variance. **RESULTS** There were statistically significant differences in the variability around the increase in physiological demands of incremental exercise (SDNI; rMSSD) based on Gender (p<0.001; p=0.004), BF (p<0.001; p=0.002), and VO_{2max} (p=0.05; p=0.04). However, the complexity (SampEn) surrounding the increase in VO_2, V_E, and HRV dynamics during incremental exercise were not different based on gender, BF, or VO_{2max}. **CONCLUSIONS** The variability surrounding the increasing physiological demands (specifically, VO_2 and V_E) of incremental exercise appear to be differentially affected by gender, BF, and fitness. Better understanding these relationships may provide important information about how chronic stimuli, such as training or disease, impact the dynamics of the system.

2077 Board #2 June 1 9:30 AM - 11:30 AM

Dynamics of Skeletal Muscle Interstitial PO_2 During Recovery from Contractions

Daniel M. Hirai, Trenton D. Colburn, Jesse C. Craig, Ayaka Tabuchi, Timothy I. Musch, FACSM, David C. Poole, FACSM. *Kansas State University, Manhattan, KS.* (Sponsor: David C. Poole, FACSM)

(No relevant relationships reported)

The oxygen partial pressure in the interstitial space ($PO_2$is) drives O_2 diffusion into the myocyte thus supporting oxidative phosphorylation. Although crucial for metabolic recovery and the capacity to perform repetitive tasks, the time course of skeletal muscle $PO_2$is during recovery from contractions remains unknown. **PURPOSE:** To resolve the temporal profile and determine model parameters of $PO_2$is off-kinetics after cessation of contractions in healthy skeletal muscle. We tested the hypothesis that $PO_2$is would recover to resting values and display considerable on-off asymmetry (fast on- and slow off-kinetics) reflective of slower microcirculatory O_2 delivery relative to muscle O_2 utilization dynamics in recovery. Microvascular PO_2 (PO_2mv) was also evaluated to test the hypothesis that a significant transmural gradient ($\Delta PO_2 = PO_2$mv-$PO_2$is) would be sustained during recovery. **METHODS:** PO_2mv and $PO_2$is were determined via phosphorescence quenching (Oxyphor probes G2 and G4, respectively) in the exposed rat spinotrapezius muscle during and after contractions (1 Hz, 6 V, 3 min per transition; n=12). **RESULTS:** Muscle $PO_2$is rose progressively (p<0.05) from an end-contraction value of 11.2±1.5 to 17.6±2.2 mmHg at the end of the recovery period, which was not different from resting $PO_2$is (17.8±1.9 mmHg; p>0.05). $PO_2$is off-kinetics were slower than on-kinetics (mean response time: 49.3±12.4 vs. 19.2±2.5 s, respectively; p<0.05). A significant transmural ΔPO_2 observed at the end of contractions (17.7±2.7 mmHg) was maintained throughout the recovery period (end-recovery: 19.3±4.5 mmHg; p>0.05). **DISCUSSION:** Consistent with our hypotheses, skeletal muscle $PO_2$is recovered back to resting values with slower off-kinetics compared to the on-transient in line with the on-off asymmetry for capillary hemodynamics. Maintenance of a substantial transmural ΔPO_2 during recovery supports that the microvascular-interstitium interface provides considerable resistance to O_2 transport. As dictated by Fick's law ($VO_2 = DO_2 * \Delta PO_2$), modulation of O_2 flux during and following contractions (VO_2) must be achieved via corresponding changes in effective diffusing capacity (DO_2; mainly capillary red blood cell hemodynamics and distribution) in the face of unaltered ΔPO_2. Funding: NIH HL-2-108328

Different Central Hemodynamic Response Among Patients with Incomplete Spinal Cord Injury

Monira I. Aldhahi, Lisa MK Chin, Randall E. Keyser, FACSM, Andrew A. Guccione. *George Mason University, Fairfax, VA.*

(No relevant relationships reported)

The cardiovascular response to physical activity is largely regulated by the autonomic nervous system. Sympathetic innervation of the heart originates between segments T1-5, while innervation originating between segments T6-L2 affects vascular response. Injury to the spinal cord induces loss of supraspinal sympathetic control over the cardiovascular system, which may culminate in blunted speed and magnitude of central hemodynamic responses during transitions in metabolic demand. **Purpose:** To investigate the cardiac output (Qt) response in relation to oxygen consumption (VO_2) in patients with incomplete spinal cord injury (iSCI). **Methods**: We tested 11 subjects in 3 groups: Tetraplegic group (TG, n=4, 41 ± 21 years); Paraplegic group (PG, n=4, 47 ± 19 years) and healthy controls (HC; n=3, 27 ± 8 years). Each group performed a constant-workload test on the treadmill at a self-selected walking speed. Qt and VO_2 were measured simultaneously by impedance cardiography and pulmonary gas exchange analysis. **Results**: Despite HC walking at a greater speed (1.5 mph vs. TG at 0.6 mph and PG at 1.0 mph), there was no difference in Qt or VO_2 amplitude amongst the groups. Qt kinetics (reported as the time constant, τ) was longer (p<0.05) in TG (45 ± 21s) compared to either PG or HC (17±4s; 6±5s, respectively). Phase 2 VO_2 on-kinetics were not different among the groups (TG, 33±30s; PG, 25±20s; HC, 20±6s). The ratio of τQt/τVO_2 was poor (>1.0) in only TG, however was correlated (r = 0.96, p =0.002) with the responsiveness of the oxidative metabolic system (ΔVO_2/τVO_2) across all groups. **Conclusion:** Sympathetic innervation appears to influence the temporal profile of Qt depending on the level of lesion. Tetraplegics demonstrated slower Qt adjustment to increased metabolic demand compared to paraplegics. The slow increase in Qt relative to VO_2 observed in tetraplegics suggests poor matching between central hemodynamics and metabolic demand in those with a higher level of injury. SCI elicits a lesion-dependent impairment in Qt kinetic profiles that may contribute to oxygen delivery to utilization mismatch occurring during walking in people who have incomplete cervical injury.

Predicting Oxygen Uptake Responses During Cycling Using an Artificial Neural Network

Andrew Borror[1], Michael Mazzoleni[2], James Coppock[3], Brian Mann[4], Claudio Battaglini, FACSM[1]. *[1]The University of North Carolina at Chapel Hill, Chapel Hill, NC. [2]Under Armour Inc., Baltimore, MD. [3]The University of North Carolina at Greensboro, Greensboro, NC. [4]Duke University, Durham, NC.* (Sponsor: Dr. Claudio Battaglini, FACSM)

(No relevant relationships reported)

PURPOSE: Oxygen Uptake (VO_2) is a valuable metric for the prescription of exercise intensity and the monitoring of training progress. However, VO_2 is difficult to measure in a non-laboratory setting. Conversely, heart rate (HR), which is intrinsically linked to VO_2, is an easily obtained measure. Recently, VO_2 predictions have been made during steady-state exercise using an artificial neural network (ANN). However, these previous models incorporated protocol-specific variables, making them unable to accurately estimate VO_2 during arbitrary exercise intensities. Therefore, the purpose of this study was to predict VO_2 during different exercise intensities with an ANN using HR and exercise intensity data. METHODS: 12 moderately-active adult males (age: 21.1 ± 2.5 years) performed a 50-minute bout of cycling at a variety of exercise intensities. VO_2, HR, power output, and cadence were recorded throughout the test. An ANN was trained, validated and tested using the following inputs: HR, time derivative of HR, power output, cadence, and body mass. RESULTS: The ANN accurately predicted the experimental VO_2 time series values throughout the test (R^2 = 0.95, SEE = 1.7 mL/kg/min). CONCLUSIONS: The predictive accuracy of this ANN is promising considering the large range of intensities and long duration of exercise. Future applications of this method could allow athletes to have accurate real-time VO_2 predictions during exercise, improving the accuracy of training intensity.

Recovery Interstitial PO_2 Dynamics Following Contractions in Healthy Skeletal Muscle of Different Oxidative Capacity

Trenton D. Colburn, Jesse C. Craig, Daniel M. Hirai, Timothy I. Musch, FACSM, David C. Poole, FACSM. *Kansas State University, Manhattan, KS.* (Sponsor: Timothy I. Musch, FACSM)

(No relevant relationships reported)

The recovery of skeletal muscle from repetitive tasks is dependent, in part, on adequate O_2 delivery and blood-mitochondrial O_2 diffusion. Key steps in this pathway include the microvascular and interstitial space (is) and novel use of specific phosphorescence probes allow measurements of O_2 partial pressures (PO_2) at those sites near the myocytes. Given the disparate contribution of nitric oxide (NO) between fiber types we sought to resolve how NO impacts $PO_2$is in recovery following rhythmic muscle contractions. **PURPOSE**: To determine the contribution of NO bioavailability to the temporal profiles of $PO_2$is off-kinetics in two fast-twitch muscles with different oxidative capacities (citrate synthase: peroneal (PER) ~20 vs white gastrocnemius (WG) ~8-11 μmol/min/g). We tested the hypothesis that the more oxidative PER would display faster kinetics while recovering to baseline $PO_2$is levels compared to the WG. In addition, NO synthase inhibition via L-nitroarginine methyl ester (L-NAME) would slow recovery off-kinetics whereas this process would be speeded by increased NO. **METHODS**: $PO_2$is was determined via phosphorescence quenching (Oxyphor G4) in the exposed rat PER and WG (n=5) during and following electrically stimulated muscle contractions (1 Hz, 8 V, both 3 min) under control (CON), sodium nitroprusside (SNP, NO donor) and L-NAME (n= 3 PER, 5 WG) conditions. **RESULTS**: PER $PO_2$is was higher than WG for CON at baseline (18.1 ± 1.8 vs 11.3 ± 1.2 mmHg), end contractions (11.5 ± 1.2 vs 5.2 ± 0.9 mmHg), and following recovery (19.6 ± 2.1 vs 10.1 ± 0.9 mmHg; p<0.05 for all). SNP elevated $PO_2$is at all time points in both muscles compared to CON and L-NAME (p<0.05). $PO_2$is recovered to baseline levels in both muscles in CON and L-NAME (p>0.05) but not SNP (p<0.05). Off-kinetics were faster in the PER compared to WG in CON (35 ± 6 vs 76 ± 6 s; p<0.05). L-NAME did not alter PER off-kinetics but prolonged recovery in WG (101 ± 8 s; p<0.05). **CONCLUSIONS**: Consistent with our hypothesis, $PO_2$is returned to baseline levels faster in the CON PER than WG. This likely reflects greater O_2 delivery in PER. However, NO synthase inhibition via L-NAME did not diminish the magnitude nor rate of recovery in PER indicating that the interstitial-mitochondrial pressure head for O_2 delivery may be preserved via other pathways in more oxidative muscles in health.

2081   Board #6   June 1 9:30 AM - 11:30 AM

Estimating the Aerobic Load of Short Non Steady State Cyclic Tasks

Ilse J. Blokland, Thomas van Kan, Jos J. de Koning, FACSM, Han Houdijk. *Vrije Universiteit Amsterdam, Amsterdam, Netherlands.*

(No relevant relationships reported)

Current analysis of aerobic load requires steady state oxygen uptake (VO_2), limiting analyses to relatively long lasting, cyclic activities. This is problematic when assessing the aerobic load experienced by patients who are unable to perform cyclic tasks for a longer duration. **PURPOSE**: To assess validity and reliability of a method estimating the aerobic load of short non steady state cyclic tasks. **METHODS**: Thirteen healthy adults walked on a treadmill while VO_2 was measured using breath by breath respirometry. Six trials of varying length and intensity (1, 2 and 6 minutes at both 4 and 5 km/h) were performed and repeated on a second day. Aerobic load of the short walking tasks (VO_{2short}) was estimated by adding the recovery VO_2 to the VO_2 over the exercise period. The 6 minute trials were used to calculate steady state VO_2. Concurrent validity of VO_{2short} with steady state VO_2 was assessed using a no-intercept linear regression analysis. Test-retest reliability of all trials was assessed using intraclass correlation coefficients (ICC). **RESULTS**: VO_{2short} was correlated with steady state VO_2 (r = 0.60-0.84) with highest correlations for the lower intensity trials. Steady state VO_2 was consistently lower than VO_{2short}. Regression coefficients between steady state VO_2 and VO_{2short} ranged between 0.72-0.81 (p<0.001). Test-retest reliability of VO_{2short} (ICC = 0.60-0.87) was comparable to that of steady state VO_2 (ICC = 0.63-0.78). **CONCLUSIONS**: The estimated aerobic load of short walking bouts is highly correlated with steady state VO_2 at similar intensity but systematically larger, potentially due to overestimation of recovery VO_2. Test-retest reliability of the presented method is similar to that of steady state VO_2. Therefore, based on this study, using short bouts of activity seems feasible to assess aerobic load in patients unable to perform cyclic tasks for a longer time, but the overestimation of recovery VO_2 needs to be better understood.

2082   Board #7   June 1 9:30 AM - 11:30 AM

Do Contrasting Recruitment Patterns Underlie The Different Patterns Of Muscle Deoxygenation And Hemoglobin Response In Quadriceps Muscles?

Dai Okushima[1], David C. Poole, FACSM[2], Thormas J. Barstow, FACSM[2], Narihiko Kondo[3], Shunsaku Koga[1]. *[1]Kobe Design University, Kobe, Japan. [2]Kansas State University, Manhattan, KS. [3]Kobe University, Kobe, Japan.*

(No relevant relationships reported)

Previous investigations reported greater convective and diffusive O_2 conductance in whole-leg muscles during knee extension exercise (KE) compare to conventional cycling (CE). One reason for this is thought to derive from different muscle recruitment pattern in CE and KE. However, it is unknown whether the different muscle recruitment patterns might account for the disparate O_2 conductances during KE and CE or not. **PURPOSE:** Using time-resolved near-infrared spectroscopy (NIRS) during ramp incremental KE and CE, we tested the hypotheses that compared to CE, KE would have (1) lower amplitude (from baseline to exhaustion) of deoxy[Hb+Mb] (reflecting a greater O_2 delivery-to-utilization), (2) greater amplitude and value at task failure (i.e. reaching $\dot{V}O_{2max}$) of total[Hb+Mb] (diffusive O_2 potential) in quadriceps (*vastus lateralis* [VL] and *rectus femoris* [RF]). We also hypothesized that muscle recruitment pattern will determine muscle oxy- and deoxygenation characteristics. **METHODS:** Eight subjects completed ramp incremental CE (20 W/min) and KE (10 W/min) to the limit of tolerance. Pulmonary VO_2 was measured breath-by-breath. Deoxy- and total[Hb+Mb] were quantified in the VL and RF muscle by time-resolved NIRS. VL and RF muscle activation levels were estimated by electromyography. **RESULTS:** In VL muscle, despite greater activation for CE than KE, the amplitude of deoxy- and total[Hb+Mb] from baseline to task failure were not different between exercise modes. However, in RF muscle, deoxy- (17.0±11.3 vs. 39.5±13.8 μM, *P*<0.05) and total[Hb+Mb] amplitude (5.3±4.0 vs. 23.8±8.5 μM, *P*<0.05) were lower for KE compared with CE despite greater activation for KE than CE. In addition, total[Hb+Mb] values at task failure were not a function of exercise mode in either VL or RF muscle. **CONCLUSION:** These results do not support the notion that different recruitment patterns for CE versus KE underlie the different patterns of muscle deoxygenation and hemoglobin response across quadriceps muscles. Indeed, the total[Hb+Mb] responses suggest that perfusive and diffusive O_2 delivery in VL and RF muscles are determined more by structural and functional factors (e.g. arteriolar vasodilation regulation and capillary hematocrit control) as opposed to muscle recruitment patterns *per se*. Supported by JSPS-15K16476, 16K13011.

Validation of A Pacer Prediction Equation For Assessing Aerobic Capacity Of Visually Impairedchildren

Mónika Kaj, Katalin Kälbli, Anita Király, Tamás Csányi. *Hungarian School Sport Federation, Budapest, Hungary.*

(No relevant relationships reported)

The Hungarian National Student Fitness Test (NETFIT®) is a health-related, criterion-referenced test system developed by the Hungarian School Sport Federation (HSSF) and The Cooper Institute (TCI) that was implemented in 2014/15 in schools throughout the country. The test battery was developed for typically developing children (TDC), so the interpretation of the test results was difficult for students with special educational needs (SEN).
PURPOSE: to evaluate the validity of the Progressive Aerobic Cardiovascular and Endurance Run (PACER) test for children with visual impairment.
METHODS: 20 partially sighted and 20 legally blind children (aged 10–19 years old) were selected randomly from 3 special schools to complete both laboratory (maximal treadmill protocol) and field assessments (PACER) of aerobic capacity. Agreement between lab- and PACER-derived peak oxygen consumption (VO_2) was examined using linear regression analyzis and two-sided equivalence testing techniques, respectively.
RESULTS: The final sample resulted in a total of 22 visually impaired children. The regression modell used in NETFIT® fit well for the partially sighted children (R^2=0.827), but not for blind children. There was a significant difference between the predicted and the measured peak VO_2 values by blind children (34.88 vs. 39.14 mL/kg/min, t=-2.287, p=0.038). Multiple regression analyzis of PACER performance variables and peak VO_2 measures indicated the best model for estimating relative peak VO_2 for blind children: peak VO2 =43.608 + (0.636*shuttles) – (0.829 * BMI). The lab and PACER VO_2 using the new regression model shared 84% of the variance by blind children (R^2=0.835) and that limits of agreement ranged from -9.86 mL/kg/min to +18.9 mL/kg/min. The absolute error values were 1% for girl and 11% for boys, and the average peak VO_2 estimates from PACER were within the 10% equivalence region for both sexes (girls: 35.22 to 28.18 mL/kg/min, boys: 37.82 to 46.22 mL/kg/min).
CONCLUSION: The PACER test using the new regression model for blind children is a reliable field test to assess aerobic capcity for children with visual impairment. From the schoolyear 2017/2018 the adapted NETFIT® will use this method in the mandatory assessments.
Financed by priority project EFOP 3.2.8.-16. granted by European Union.

Development And Validation Of Sports Orientation Questionnaire For Chinese Adolescent Students

Jindong Chang[1], Xiaolei Liu[2], Ming Yang[1], Yi Liu[1], Mingxi Guan[3], Yang Li[1], Yunsai Chen[1], Xin Liu[1], Yan Peng[4], Hao Guo[5], Naiqing Song[1]. *[1]Southwest University, Chongqing, China. [2]High School Affiliated to Southwest University, Chongqing, China. [3]Chongqing Business Vocational College, Chongqing, China. [4]Sichuan Aerospace Vocatinal College, Chengdu, China. [5]Chongqing College of Humanities,Science & Technology, Chongqing, China.*

(No relevant relationships reported)

PURPOSE: Sports orientation is critical for the adolescent. Gill & Deeter (1988) had developed and validated a sports orientation questionnaire for elite athletes. However, it was a lack of assessment for general students of sports orientation. The purpose of this study was to develop and validate a "Sports Orientation Questionnaire" for Chinese Adolescent Students (SOQ-CAS).
METHODS: Based on literature review and focus group interviews, a 30-item instrument was developed for the initial tests. Using a 5-point Likert scale, formed the SOQ-CAS and was investigated to 486 junior middle school students in Chongqing of China. Finally, 36 missing individuals data were excluded, and 450 valid data were analyzed as study samples (male=236, female=214). Exploratory factor analyses (EFA) and confirmatory factor analysis (CFA) were used to analyze samples data by SPSS 24.0 and AMOS24.0 software.

Abstracts were prepared by the authors and printed as submitted.

RESULTS: The sample was randomly split (a computer-generated randomization sequence into two groups with the ratio 1:2). The first subset of the 30 items (N=150) was performed EFA (KMO=0.877, p=0.000). EFA resulted in a 12-item, 3-subscale that each included a 4-factor scale. EFA item loadings ranged from 0.68 to 0.85, and Cronbach's alpha ranged from 0.81 to 0.87. Based on the EFA results, CFA was performed to cross-validate and confirm the 4-factor structure model (N=300). Results showed that the model index were x2=0.000, RMSEA=0.06, GFI=0.94, NFI=0.91, TLI= 0.93, CFI=0.95. The final three subscales of the SOQ-CAS was named competitiveness, win orientation, and goal orientation.

CONCLUSIONS: The SOQ-CAS was a reliable and valid measure of sports orientation of Chinese adolescent students. It can be used for the assessment of daily exercise or physical education. The future research will focus on exploring the Motor Quotient (MQ) assessment by SOQ-CAS.

In-situ Testing Of Cardiorespiratory Fitness And Body Mass Index Of School Children In The UK

Samuel Tuvey[1], Elizabeth Horton[1], Alfonso Jimenez[1], Steven Mann[2]. [1]Coventry University, Coventry, United Kingdom. [2]ukactive Research Institute, London, United Kingdom. (Sponsor: Gary Liguori, FACSM)
(No relevant relationships reported)

PURPOSE: Decreasing physical activity (PA) levels of children in the UK is a public health issue. Systematic measurement of objective PA is difficult, however cardiorespiratory fitness (CRF) has been shown to be a valid marker of PA and is a more scalable metric. In the UK there is no national measure of CRF that could be used to identify children at risk for cardiometabolic disease (CMD). The aim is to investigate the relationship between CRF and body mass index (BMI) to identify children at risk for CMD. **METHODS:** This study recruited 665 children (52% male; age 9±0.87years) from 11 primary schools in London. Testing was performed by in-place delivery staff from an external organisation. Data collection took place with the same participants in Autumn 2016 and Summer 2017. CRF was measured using the 20m Multistage Shuttle Run (20mMSR) and BMI was calculated from height and mass. Boys not reaching 33 and girls 25 shuttles are at an increased risk of CMD and were classified as "unfit". CRF and BMI z-scores were calculated adjusting for age and gender. BMI and CRF z-scores were correlated, the change in variables were assessed by paired t-tests, and differences in groups were analysed by chi square. **RESULTS:** Moderate negative correlations were found between CRF and BMI in the Autumn Term (r=-0.310, p<0.001) and Summer Term (r=-0.359, p<0.001). There was a significant increase in CRF (p<0.05) and a significant decrease in BMI (p<0.001) between the Autumn and Summer Term. Percentage of children that failed to reach the 20mMSR cut-point decreased from 47% to 38% (p<0.01). Percentage of children that were categorised as overweight or obese decreased from 30% to 22% (p<0.01). Percentage of children categorised as healthy weight but did not meet the cut-point for reduced risk to CMD decreased, from 27% to 23% (p=0.069). **CONCLUSION:** This study indicates that there is a strong association between CRF and BMI and that the health of children improves throughout the academic year. This study also found that a quarter of children categorised as being a healthy weight failed to reach the cut-point in the 20mMSR. Currently, only BMI is measured on a national scale in the UK, and these results demonstrate that a large proportion of children are not recognised as being at risk for CMD, therefore, the inclusion of the 20mMSR may be beneficial.

2087   Board #4   June 1 9:30 AM - 11:30 AM

Effects Of Chronic Hypobaric Hypoxia, Biological Maturation And Training On The Hemoglobin Mass In Children And Adolescents

Erica Mabel Mancera-Soto[1], Diana Marcela Ramos-Caballero[1], Edgar Cristancho[1], Walter Schmidt[2]. [1]Universidad Nacional de Colombia, Bogotá, Colombia. [2]Bayreuth University, Bayreuth, Germany. (Sponsor: William Byrnes, FACSM)
(No relevant relationships reported)

Hemoglobin mass (Hbmass) is an important factor for endurance performance and athletes born and living at altitude are described to possess elevated Hbmass values due to lifelong hypoxic exposure. It may be hypothesized that this adaptation already occurs in early life. To date, however, there exists only few data on the training influences on Hbmass during childhood and no data exists describing chronic hypoxic effects in children and adolescents. **PURPOSE:** To investigate the effects of age, sex, training status and altitude on Hbmass in children and adolescents in a cross-sectional study. **METHODS:** 436 children, 197 females and 237 males, homogenously distributed over the age from 9 to 18 years participated in the study. 189 of them were born and lived permanently at 960m, 247 at 2600m. 168 did not practice any training and 268 were endurance trained with a mean endurance training volume of 14.0h ±5.8/week. Hbmass was determined using the optimized CO-rebreathing technique and VO2max by an incremental step-test on a treadmill. Analyses of variance and multiple regression analyses were performed to estimate the effects of sex, body mass, age, sexual development (scale according to Tanner), training status, and altitude on Hbmass. **RESULTS:** Overall, ANOVA yielded highly significant effects for sex, age, body mass, altitude and training state (all p< 0.001); and regression analysis (r=0.91) showed highest effects of sex (+121.5g, ß=0.31 in males) and body mass (9.5g/kg, ß=0.57). Because Hbmass of girls reached a plateau at approx. 14 years and boys increased Hbmass until the age of 17 regression analyses were performed separately for females and males and the following effects were found: Males: r=0.93; Hbmass = 11.8*kg + 15.4*years + 60.9 (for trained status) + 35.1 (for altitude residents) + 13.7*(stage of Tanner) - 254.2; females: r=0.84; Hbmass = 6.8*kg + 9.8*years + 54.6 (trained) + 36.9 (altitude) -24.8. Absolute and relative VO2max was closely related to Hbmass (absolute values: r=0.85, y=3.57x + 308; relative values: r=0.70, y=3.56x+6.1). **CONCLUSION:** Beside the well-known effects of body mass, age and sex also growing-up at altitude and endurance training have remarkable effects on Hbmass in children and adolescents. VO2max is closely related to Hbmass. Like in adults, a change by 1 gram changes VO2max by 3.5ml/min.

Effect Of Cardiorespiratory Fitness, Fatigue And Muscular Strength On Gait Biomechanics In Obese Children

Bhupinder Singh, Melanie F. Niino, Jennifer D. Goulart, Amber Hammons. *California State University, Fresno, CA.*
(No relevant relationships reported)

PURPOSE: The purpose is to explore the effects of cardiorespiratory fitness, fatigue, adiposity, and muscular strength in predicting altered gait biomechanics in 8-11 year old obese children.

METHODS: Thirty children, 15 girls and 15 boys, mean age 9.8±0.9 years, and mean BMI percentile 96.1±4.1, were recruited from University of Iowa Obesity Clinic. The 15 m Progressive Aerobic Cardiovascular Endurance Run (PACER) protocol was used to estimate aerobic fitness (VO_2max) and to fatigue the subjects. Adiposity, measured as percent body fat, was estimated by air displacement plethysmography (Bod Pod). Right leg isometric strength was assessed on a leg press device. Three-dimensional gait analysis (Optotrak, Kistler) using a link-based model was performed pre- and post-fatigue to calculate joint moments. Paired t-tests were used to compare pre- and post-fatigue moments, and a stepwise regression model including moments as dependent variable and fitness, adiposity and strength, as the three independent variables was used for pre- and post-fatigue. P-value < 0.05 was considered significant.

RESULTS: Subjects completed an average of 17.5±8.5 PACER laps (range: 4-45). Mean aerobic fitness as estimated by PACER was low (34.1±6.0 mL·min-1·kg-1). Mean adiposity was 32.2±7.6 % body fat and mean right lower limb strength, was 7.54±2.29 N/kg. Following fatigue, knee adduction moments (0.35±0.2 to 0.43±0.2 Nm/kg, p= 0.01), knee extensor moments (0.57±0.3 to 0.67±0.2 Nm/kg, p= 0.02) and hip extensor moments increased (0.77±0.4 to 0.97±0.4 Nm/kg, p=0.01). The step-wise regression model for knee extensor moments pre-fatigue selected strength and adiposity as predictor variables (R2=0.35) and post-fatigue selected strength (R2=0.29). Knee and hip adductor moments selected adiposity as a predictor variable for pre-fatigue (R2=0.3 and 0.22 respectively). None of the models included cardiorespiratory fitness.

CONCLUSIONS: Increase in hip and knee moments after fatigue suggests biomechanical deficiencies, which may lead to increased joint stress or to injury.

The result suggests that level of adiposity and strength might be important factors in predicting gait biomechanics and could make a significant impact for healthcare professionals as they encourage wellness and fitness among their obese clientele.

2089   Board #6   June 1 9:30 AM - 11:30 AM

Effects Of A 5-day Sports/Fitness Camp On Walking Efficiency In Children With Cerebral Palsy

Adam R. Blanchard[1], Katherine Dimitropoulou[1], Paul Weiland[2], Kelly Boscarino[2], Amber Newell[1], Heakyung Kim[1]. [1]*Columbia University Medical Center, New York, NY.* [2]*Chapter 126 Sports & Fitness, Bristol, CT.*
(No relevant relationships reported)

Physical activity (PA) participation and fitness in children with cerebral palsy (CP) are decreased compared to typically developing peers. Exercise improves fitness and walking ability but little is known for its impact on walking efficiency. **PURPOSE:** The purpose of this pilot/feasibility study was to examine the influence of a five day community sports and fitness camp at an adaptive fitness facility on walking energy consumption (walking efficiency) in children with CP. **METHODS:** Six boys with CP (mean±SD; age, 11.3±4.7 yr; height, 136.9±27.5 cm; weight, 44.9±26.8 kg) participated in supervised sports and PA for 3 hr/d on 5 consecutive days. Activity energy expenditure (AEE; J·kg·s[-1]) and oxygen consumption (VO$_2$; ml·kg·min[-1]) were assessed by Actiheart monitor during five, 10meter walks on day 1 and 5. The PA Questionnaire for Adolescents assessed baseline PA levels. Paired samples t-tests evaluated differences in AEE and VO$_2$ pre- to post- camp; and independent-samples t-test evaluated between-group differences between high and low baseline PA with changes in AEE and VO$_2$. **RESULTS:** Although non-significant (low N), medium effect size was seen in the reduction of AEE during walking on day 5 (2.5±0.5 J·kg·s[-1]) compared to baseline (2.9±0.5 J·kg·s[-1]; p=0.28, Cohen's d=-0.66). Similarly, submaximal VO$_2$ was lower on day 5 (8.4±2.0 ml·kg·min[-1]) compared to baseline (9.3±3.1 ml·kg·min[-1]; p=0.28, Cohen's d=-0.35). A strong effect size was seen in that children with low PA (n=3) reduced their VO$_2$ greater (Δ-1.6±2.3 ml·kg·min[-1]) than children with high PA (n=3) (Δ0.0±0.9 ml·kg·min[-1]; p=0.31; Cohen's d=0.92) on day 5 compared to day 1. **CONCLUSIONS:** This study was a feasibility study to test the measures and intervention procedures for the development of an evidence-based camp. Findings show that children with CP may improve walking efficiency after participating in a five day community sports/fitness camp held at an adaptive fitness facility. Our next step is to design an appropriately powered intervention to confirm these results and to determine the best frequency, intensity, time, and type of sports/PA performed in the camp.

Differences In Lean Mass And Strength In Adolescent ACLR Female Athletes: A Case-Control Study

Christiana J. Raymond-Pope[1], Donald R. Dengel, FACSM[1], John S. Fitzgerald[2], Bradley J. Nelson[1], Tyler A. Bosch[1]. [1]*University of Minnesota, Minneapolis, MN.* [2]*University of North Dakota, Grand Forks, ND.* (Sponsor: Donald R. Dengel, FACSM)
(No relevant relationships reported)

PURPOSE: To compare differences in total and segmental lean mass (LM), muscle strength and lower leg force production between adolescent female athletes with and without anterior cruciate ligament repair (ACLR). **METHODS:** Twenty-four females, 12 ACLR and 12 healthy controls (CON), were matched by age (16.4±0.9 vs 16.4±1.0 yrs), body mass index (23.2±2.1 vs 23.2±2.7 kg/m^2), and sport. Total, segmental, and regional body composition were measured by 3 DXA scans (1 total body, 2 lateral leg). Muscle peak torque for knee extension/flexion (60, 120°/sec) was measured using isokinetic dynamometry. Lower limb force, power and jump height were measured using a squat jump on dual force plates. Paired t-tests assessed total, regional and segmental lean mass, peak torque and lower limb force production differences within (Involved/Non-involved) and between groups (ACLR/CON). Linear regression assessed the total-leg LM vs peak force relation of each leg and of ACLR vs CON. **RESULTS:** No body composition differences were observed between ACLR and CON groups (p=0.07-0.90). However, ACLR INV legs had significantly lower total LM (7.1±0.8 vs 7.4±1.0 kg, p=0.004), anterior upper leg LM (1.5±0.3 vs 1.62±0.2 kg, p=0.007), and posterior upper leg LM (1.9±0.2 vs 2.0±0.2 kg, p=0.036). Peak torque was significantly lower in ACLR INV vs NINV legs (p<0.003) and vs CON (p=0.010-0.019) for extension and 60 and 120°/sec and flexion at 60°/sec (p=0.011), with no differences between ACLR NINV vs CON (p=0.23-0.90). Peak force was significantly lower in ACLR INV vs NINV legs (296±45 vs 375±55 N, p<0.001) and between ACLR INV legs vs CON (296±45 vs 372±88 N, p<0.015), but no significant (p=0.736) difference between ACLR NINV leg vs CON. The slope between total LM and peak force was smaller for ACLR participants (INV: m=0.02 r=0.36, p=0.25; NINV: m=0.03, r=0.50, p=0.10) compared to CON (INV: m=0.06, r=0.63, p=0.03; NINV: m=0.06, r=0.62, p=0.03). **CONCLUSION:** One year post-ACLR female athletes have significant differences in the quantity and quality of leg muscle, compared to matched CON athletes, for both involved and non-involved legs. Importantly, muscle function (strength and force production) is limited in both ACLR legs relative to the amount of lean mass, which may provide evidence for increased risk of ACL tear in the involved and non-involved legs.

2091   Board #8   June 1 9:30 AM - 11:30 AM

Predictors of Initial Acceleration and Maximum Speed Phases of Sprint Running in Children and Adolescents

Lorena Correas-Gómez[1], José Ramón Alvero-Cruz[1], Jesús Barrera-Expósito[2], Elvis A. Carnero[3]. [1]*University of Málaga, Málaga, Spain.* [2]*Nuestra Señora de la Victoria "Martiricos" High School, Málaga, Spain.* [3]*Translational Research Institute for Metabolism and Diabetes, Florida Hospital, Orlando, FL.*
(No relevant relationships reported)

Sprint capacity is a key factor to succeed in many sports modalities and to identify successful predictors must be relevant to optimize speed training and talent detection. Jump tests, muscle strength, and anthropometric variables have been widely associated with sprint performance in adults. However, seeking the best sprinters among young individuals must be influenced by other variables such as sports training, body size, and maturation. Thus, the potential of jump and strength tests to explain sprinting phases (acceleration and maximum speed) might be affected during developmental ages. **PURPOSE**: To examine relations between the phases of sprinting performance (30m) and body composition (BC), maturation, strength, and jump tests in children and adolescents. **METHODS**: A database of 456 measures of participants aged 8-18y was analyzed (244 boys, age=14.8±2.3y, BMI=21.6±3.9kg/m^2). Photoelectrical cells were used to measure sprint times (S30m, S0-15m, and S15-30m). An electronic mat read flight time to calculate vertical height after squat jump (SJ), counter-movement jump (CMJ), and CMJ with arms (CMJA); the difference between SJ and CMJ was also calculated (VJ-d). Lower limbs strength was tested with a portable dynamometer (LLS). Fat-free mass (FFM) was assessed by anthropometry and bioelectrical impedance analysis. Sports participation (SP) was recorded by questionnaire. A stepwise regression analysis was used to explore the relationship between sprint phases and BC, SP, jump and strength. **RESULTS**: CMJA was the best predictor of S30m speed (R^2=0.724, P<0.001) and acceleration phase (S0-15m, R^2=0.566, P<0.001). Maximum speed phase was best explained by SJ (S15-30m, R^2=0.530, P<0.001). The model including FFM, gender, VJ-d, and maturity predicted S30m (R^2=0.780, SEE=0.28m/s) and S15-30m (R^2=0.698, SEE=0.51m/s). For S0-15m, the predictors were CMJA, impedance index, and SP (R^2=0.610, SEE=0.36m/s). **CONCLUSION**: In accordance with other studies, sprinting performance was partially dependent on FFM and maturity. As expected, participation in organized sports seems to affect positively S30m and acceleration performance but did not explain maximal speed phase. Overall, the results highlight the relevance of BC and jump tests as a plausible model to track sprint performance in children and adolescents.

E-10   Free Communication/Slide - Athlete Assessment

Anthropometric Measures And Performance Tests In The Evaluation Of Performance And Injury Risk In Division 1 Collegiate Athletes

Alexander M. Carnall[1], Jennifer Bunn[2], John Manor[2]. [1]*University of Memphis, Memphis, TN.* [2]*Campbell University, Buies Creek, NC.* (Sponsor: Dr. Mike Webster, FACSM)
(No relevant relationships reported)

PURPOSE: Simple tools of measurement like mean and peak power output, eccentric utilization ratio (EUR), and simple anthropometrics could potentially have predictive value in determining the accelerative and decelerative strategies of athletes. The objective of the present study is to determine the efficacy of these measurements in the identification of pathological preferential movement strategies which may limit performance or heighten injury risk. METHODS: 31 NCAA Division 1 athletes were recruited and asked to perform five trials of a simple drop-jump task. Subjects met inclusive criteria if they were cleared for full participation, and were assessed based on body composition, mean and peak power output, EUR, bodily segment lengths, and handheld dynamometer muscle forces. A motion capture system was used to measure peak joint flexion ranges of motion. RESULTS: A stepwise linear regression was

Abstracts were prepared by the authors and printed as submitted.

FRIDAY, JUNE 1, 2018

applied to identify potentially influential factors in the accelerative and decelerative preferential strategies between male and female athletes. Preliminary findings suggest that torso length (r=.530, p=.042) and torso to femur length ratio (r=.782, p=.005) are potentially related to peak trunk, and peak knee flexion values respectively in males. In females, it appears that EUR may hold value in identifying peak trunk flexion (r=.675, p=.004), hip flexion (r=.604, p=.013), and combined lower extremity flexion (r=.552, p=.027) strategies in females. CONCLUSIONS: Preliminary findings of the present study suggest that while males have highly variable movement strategies, females may tend to rely more heavily on storage and return of eccentric energy via the contractile component of the posterior chain in order to increase athleticism and create greater joint integrity in decelerative tasks.

2094   June 1 9:45 AM - 10:00 AM

Pre-Season Measures of Neurologic Function and Subsequent Head Impact Exposure in Youth Football

Thayne A. Munce, FACSM[1], Jason C. Dorman[1], Paul A. Thompson[2], Verle D. Valentine, FACSM[1]. [1]Sanford Sports Science Institute, Sioux Falls, SD. [2]Sanford Research, Sioux Falls, SD.
(No relevant relationships reported)

Repetitive head impacts in football create a risk for concussion, as well as sub-concussive brain injury. Nearly 70% of US football players are younger than high school age, yet little is known about intrinsic characteristics of youth players that may make them more likely to experience repetitive head impacts, resulting in an increased injury risk. **PURPOSE:** To examine the association between select measures of neurologic function and head impact exposure of youth football players. **METHODS:** During a 5-year period (2012-2016), 66 middle school football players (12.9 ± 0.6 yr) were evaluated before their respective seasons (97 player-seasons) using objective, clinical assessments of neurologic function. Participants were assessed for rapid number naming speed (King-Device Test; KD; sec), simple reaction time (RT; sec), and standing balance (BA) performed during an eyes-open, dual-task condition. Head impact frequency, severity (linear acceleration; rotational acceleration) and location during each practice and game were measured using the Head Impact Telemetry (HIT) system. Predictive modeling was performed to examine the relation of KD, RT and BA values with several head impact exposure outcome variables. **RESULTS:** The overall predictive model was significantly related to individual head impact frequency in practices (P = 0.002). Among the discrete variables, faster RT and KD times were both found to be significantly related to increased individual head impact frequency in practices (P < 0.001; P = 0.032, respectively). Faster KD times were also significantly associated with higher 95th percentile linear acceleration values (P = 0.014). There were no significant relations (P = 0.145-0.840) between any measure of neurologic function and the other head impact exposure measures examined. **CONCLUSION:** Faster reaction time and rapid number naming speed assessed during the pre-season were related to increased head impact frequency and/or severity of youth football players. While these associations are likely complex, it is possible that these specific measures of neurologic function are surrogate indicators of players' intrinsic ability and/or desire to initiate contact. Identifying players who are more likely to experience repetitive head impacts may be useful for efforts aimed at modifying injury risk.

2095   June 1 10:00 AM - 10:15 AM

Kinematic Differences of the Single Leg Cross Over Triple Hop and Modified T-Test

David Mangone, Brandon Henley, Joshua Flores-Vitti, Kathryn Young, Richard Feinn, Karen Myrick, Juan C. Garbalosa. Quinnipiac University, Hamden, CT.
(No relevant relationships reported)

Return to sport (RTS) testing has been advocated as a means of reducing the high re-injury rates of the anterior cruciate ligament (ACL). The effectiveness of RTS testing has recently come into question. Potentially, the use of RTS tests that mimic game-like scenarios more closely may help resolve this issue.**PURPOSE**: To determine how a currently used RTS test, the cross over triple jump (COH), compares to a game-like agility test, the modified T-test (MTT) with respect to lower extremity biomechanics. **METHODS**: Nineteen Division I female athletes who were free of injury at the time of enrollment completed the testing protocol. The protocol consisted of having the athlete's complete a 5 minute warm-up followed the completion of COH and MTT test, the order of which was randomized. The COH test consisted of having the subject jump forward on one limb while crossing two parallel lines, 15.25 cm apart three times on each limb. The MTT consisted of having the subject run through a T shaped obstacle course 4 times, alternating sides. Adequate rest was afforded between trials to ensure non-fatigue. The location of retroreflective markers located over specific bony landmarks located on the subjects lower extremity was recorded while the athletes completed the tests using a 16 camera motion analysis system recording at 240 Hz. Using a multilevel multivariate analysis the three dimensional joint angles of the hip and knee at the time of maximum knee valgus were compared for angular differences (Δ) between the jump and cut performances using the marker data.

RESULTS: Compared to MTT, athletes during COH were significantly more flexed at (Δ = 9.0 degrees ± 2.6, p=.001) and tended to be more internally rotated (Δ = 2.2 degrees ± 1.2, p=.088) at the hip and more flexed (Δ = 3.5 degrees ± 2.1, p=.093) at the knee. No differences were noted in the frontal plane position of the hip and knee or the transverse plane position of the knee.
CONCLUSIONS: The COH and MTT do not appear to produce similar lower extremity kinematics. The MTT appears to place more stress on the lower extremity and may be a better test to determine RTS.

2096   June 1 10:15 AM - 10:30 AM

Correlation of Hop Distance and Loading Symmetry during Return to Sport Testing in Healthy Subjects

Kristen Renner[1], Alex Peebles[1], Thomas K. Miller[2], Robin Queen, FACSM[1]. [1]Virginia Tech, Blacksburg, VA. [2]Virginia Tech Carilion School of Medicine, Roanoke, VA. (Sponsor: Robin Queen, FACSM)
(No relevant relationships reported)

The hop distance symmetry is used frequently to determine readiness to return to sport (RTS) following anterior cruciate ligament reconstruction (ACLR). It is unknown if loading symmetry is able to provide novel insights in determining readiness to RTS. **PURPOSE:** To determine if hop distance limb symmetry index (LSI) is correlated with loading LSI when completing RTS hop testing. **METHODS:** 33 healthy participants (16 male, 17 female - age 21.8 ± 3.0, height: 1.74 ± 5.79m , weight: 68.6 ± 7.8 kg) were fit with a pair of loadsol (Novel Electronics, St. Paul, MN), single sensor insoles (100 Hz). Each participant completed the Marx Activity Scale and 7 single hops (SH), 3 triple hops (TH) and 3 crossover hops (CH) per limb. The LSI (Sx/NSx*100) was calculated for hop distance as well as peak load (GRF), loading rate (LR) and impulse (I) for the final hop of each trial and condition. The LSI was calculated for each trial pair and then averaged across trials for each task. Pearson's correlation coefficients (R) were calculated between all symmetry metrics (distance and loading) and Marx score. A linear regression was completed to determine if the loading symmetry metrics predicted the hop distance symmetry. All tests were run in SPSS with a p-value<0.05 indicating significance. **RESULTS:** The hop distance and loading LSI measures either had no or weak correlations (Table 1). The Marx score was weakly correlated with the CH hop distance (R=0.36, p=0.04) and the SH LR (R=0.36, p=0.05). The regression analysis yielded no significant models for the SH, TH, or CH to predict the hop distance LSI. **CONCLUSIONS:** The load symmetry metrics and hop distance symmetry were weakly correlated and the load symmetry metrics were not able to predict hop distance symmetry. These results indicate that the loading symmetry and hop distance symmetry provide different information. Therefore, future work should determine which of these measures could be used as predictors of secondary ACL injury risk.

Wobble Board Dynamic Assessment in Subjects with Chronic Ankle Instability

Andrea Fusco[1], Philip X. Fuchs[2], Giuseppe F. Giancotti[1], Marianna De Maio[1], Carlo Varalda[3], Herbert Wagner[2], Laura Capranica[4], Cristina Cortis[1]. [1]University of Cassino e Lazio Meridionale, Cassino, Italy. [2]University of Salzburg, Salzburg, Austria. [3]Italian Weightlifting Federation FIPE, Roma, Italy. [4]University of Rome Foro Italico, Roma, Italy. (Sponsor: Carl Foster, FACSM)
(No relevant relationships reported)

Chronic ankle instability (CAI) has been shown to cause balance impairments during still standing and dynamic postural-control tasks. Although computerized wobble boards (WBs) are used to train postural stability and to assess dynamic balance performances, little is known about their ability to detect balance deficits in subjects with unilateral CAI. **PURPOSE:** To determine the WB ability in detecting impairments in subjects with unilateral CAI. **METHODS:** After a familiarization phase, 16 (8 female, 8 male) subjects (age=23.5±1.7years; weight=66.6±14.5kg; height=167.7±11.3cm) performed a single limb task on a WB and Y balance test (YBT). WB performance (Balance Board WSP, Italy; diameter=40cm) was assessed as the time spent in the target zone (diameter=6.5cm) displayed on a screen during a

single leg 30seconds trial with a 1-minute sitting rest in between. For YBT, normalized reach distances for anterior (A), posteromedial (PM), posterolateral (PL) directions and composite (COMP) values were recorded according to the protocol. ANOVA ($p<.05$) was used to evaluate limb differences (injured; uninjured) in relation to gender. **RESULTS:** For WB, females showed better ($p<.05$) performances than males, regardless of limb. Significantly ($p<.0001$) better performaces were found in the uninjured (WB=20±4.3s; A=89.4±9.9%; PM=101.8±13.1%; PL=107.7±13.4%; COMP=104±10.9%) limb compared to the injured (WB=16.6±4.3s; A=86.1±11.6%; PM=96.1±10.7%; PL=101.3±14.9%; COMP=100.2±11.9%) one, regardless of gender. **CONCLUSIONS:** WB test showed to be an effective tool for detecting balance deficits between injured and uninjured limb in subjects with unilateral CAI. The single outcome from the WB provided an accurate, precise and fast method for quantifying balance deficits in individuals with CAI. Hence, WBs have the capability to fill the gap caused by limitations between subjective-based clinical assessment and laboratory-based testing. Their affordable, portable and user-friendly nature make WBs suitable to be used outside of laboratory settings and helpful in clinical-decision making. Gender differences during the WB test could be due to anthropometric, neuromuscular and neurophysiologic factors. Therefore, future studies should investigate the influence of anthropometric factors on WB performances.

2098   June 1 10:45 AM - 11:00 AM

Reliability and Performance Changes with the Addition of a Cognitive Task to Static and Dynamic Postural Stability Testing

Caroline Westwood, Carolyn Killelea, Mallory Faherty, Timothy Sell, FACSM. *Duke University, Durham, NC.* (Sponsor: Timothy Sell, FACSM)

(No relevant relationships reported)

Concussions are an unfortunate consequence of sports participation. They affect motor control, neurocognitive performance, and recent reports indicate they increase the risk of lower extremity musculoskeletal injury (LEMI) upon return to sport. The increased risk of secondary LEMI may indicate the need to establish a test that is predictive of LEMI risk following return to sport. **PURPOSE:** Assess the between-session reliability and the effects of adding a cognitive task to static and dynamic postural stability testing. **METHODS:** Twelve healthy, physically active subjects (Age: 22.3 ± 2.9 years, Height: 174.4 ± 7.5 cm, Weight: 154.5 ± 28.0 lbs) participated. Subjects underwent static and dynamic postural stability testing with and without the addition of a cognitive task (Stroop task) on two separate days. Static postural stability was assessed with a single-leg balance task under eyes open (with and without the addition of the Stroop task) and eyes closed conditions. Variability of each ground reaction force component was averaged across three trials for each of the static postural stability conditions. Dynamic postural stability testing consisted of forward jump over a hurdle with a one-legged landing performed with and without the addition of the Stroop task. A stability index was calculated based on the resultant ground reaction force and each of its components. Interclass correlation coefficients (ICC, 2,1) were calculated to determine the between-session reliability of each testing condition. Comparisons were made across the static conditions and between the dynamic postural stability tasks. **RESULTS:** The addition of a cognitive load proved to have moderate to excellent between-session reliability for the majority of variables calculated during static (ICC values 0.74 – 0.81) and dynamic postural stability testing (ICC values 0.77 – 0.80; ML=0.800, V=0.774, DPSI=0.781). No significant differences were observed between the postural stability tasks (with or without the Stroop task). **CONCLUSION:** Postural stability tasks with the addition of a cognitive load prove to have moderate to excellent reliability in a healthy population. These results provide new evidence on the feasibility of dual-task postural stability testing when examining risk of LEMI following return to sport.

2099   June 1 11:00 AM - 11:15 AM

Effect of Training Level on a Visuomotor Balance Task in Youth with Previous Sport-Related Concussion.

Katelyn Mitchell, Michael E. Cinelli. *Wilfrid Laurier University, Waterloo, ON, Canada.*

(No relevant relationships reported)

INTRODUCTION: The demands of sport require the integration of cognition and sensory inputs to produce more complex, goal-directed movement. Howell and colleagues (1) revealed that the differences in balance control between athletes with or without previous concussion were greater in youth compared to young adults during dual-task gait. **PURPOSE:** 1) To determine if a novel visuomotor dynamic balance task can objectively identify differences between youth hockey players with/without sport-related concussion (SRC); and 2) If there are balance control differences between players who participate in minor hockey and private hockey academy training. **METHODS:** Youth hockey players (N=47; age=12-17 years), who reported previous SRC (n=17) and CONTROL (n=30). Group 1 was from a minor hockey team (SRC1=4; CONTROL1=12) and group 2 a private hockey academy (SRC2=13, CONTROL2=18). Participants stood in single support on a Nintendo Wii Balance

board sampled at 100Hz and performed a lower limb reaching task with their non-stance foot. Five FitLights were arranged on the floor anteriorly at ±60°, ±30°, and 0° and were used as Go(GREEN)/No-Go(RED) stimuli. Balance control was assessed using RMS velocity of COP (vCOP) in anterior-posterior (A/P) and medial-lateral (M/L) planes. **RESULTS:** There were significant differences for both A/P vCOP (SRC= 8.04cm/s; CONTROL= 11.04cm/s, p <.05) and M/L vCOP (SRC= 6.27cm/s; CONTROL= 7.72cm/s, p <.05), as the SRC group performed the task slower than CONTROL There were no significant differences between SRC1 and SRC2 in vCOP A/P (p=0.50) or M/L (p=0.26) likewise for CONTROL1 and CONTROL2 vCOP A/P (p=0.88) and M/L (p=0.97). **CONCLUSION:** The assessment of a visuomotor dynamic balance task can objectively identify youth athletes with previous history of SRC regardless of training levels. Incorporating cognitive-motor tasks may help to improve balance control deficits in youth post-SRC and ensure true readiness for return-to-sport.

Reliability of Evaluating the Single Leg Squat Using Multiple Assessment Methods

Carolyn Dartt, Sarah De La Motte, Patricia Deuster, Timothy Gribbin. *Uniformed Services University, Bethesda, MD.*

(No relevant relationships reported)

Purpose: The Single Leg Squat (SLS) test is a physical assessment to identify movement deficits that may predispose individuals to musculoskeletal injury (MSKI). The SLS is used clinically and in research to develop corrective exercise strategies for improving movement efficiency and modify potential MSKI risk factors. Our purpose was to compare the reliability of individual criteria and overall performance of the SLS test between three assessment methods: real-time scoring (RT); post-testing video analysis (PTVA); and post-testing analysis by using PhysiMax (PM) software. **Methods:** Male U.S. Marines (N=81; PTVA n=35, PM n=22, RT n=8) entering the School of Infantry-West performed the SLS prior to beginning training. Squats were scored using RT, PTVA, and PM software. Nine individual SLS criteria were evaluated dichotomously: 0 indicated no deficiency and 1 indicated a deficiency was present. Overall SLS performance was scored as excellent, average or poor. Interrater (IRR) and intrarater (IAR) reliability were measured using % agreement (%), Cohen's Kappa (κ), and intraclass correlation coefficients (ICC). **Results:** Individual SLS criteria reliability was poor for several items, namely Hip Drop (IRR-RT: 44.4%; κ=-0.15; PTVA: 22.5%, κ=-0.02; and IAR-PTVA: 83.4%, κ=0.31; PM: 77.2%, κ=0.15,) and Trunk Inward Rotation (IRR-RT: 55.5%, κ =0.05; PTVA: 63.4%, κ=0.26; and IAR-PTVA: 57.9%, κ=0. 16; PM 81.8%, κ=0.07). For SLS overall performance, IRR % agreement was weaker for PTVA (47.9%) compared to RT (62.5%); however ICC's were both poor (PTVA: 0.20 ICC, 95% CI: -0.03-0.41; RT: 0.35 ICC, 95% CI: -0.42-0.82). SLS overall performance IAR % agreement for PTVA and PM was similar (57.9% vs. 59.1%) but ICC's were good for PM (0.63 ICC, 95%CI: 0.30-0.83) and poor for PTVA (0.34 ICC, 95%CI: -0.12-0.68). **Conclusion:** Although the SLS has been clinically validated to identify movement deficits, individual item IRR and IAR appear to be generally poor regardless of the assessment method. Overall performance evaluations also had low agreement, but PM software showed the best IAR-ICC, demonstrating good reliability which should be investigated further. However, our results may be limited by small sample sizes. Further research is needed with a larger sample to better compare SLS assessment reliability between RT, PTVA and PM.

Abstracts were prepared by the authors and printed as submitted.

E-11 Free Communication/Slide - **Exercise Psychology- Pain**

Friday, June 1, 2018, 9:30 AM - 11:30 AM

Physical Activity is Indirectly Associated with Pain in College-Aged Women: Somatization and Panic Symptom Pathways

Patrick J. O'Connor, FACSM[1], Matthew P. Herring[2], Cillian P. McDowell[2], Rodney K. Dishman, FACSM[1]. *[1]University of Georgia, Athens, GA. [2]University of Limerick, Limerick, Ireland.*

(No relevant relationships reported)

Pain can be improved by the adoption and maintenance of physical activity (PA) but whether PA *per se* causes reductions in pain is uncertain. Pain is often greater in those with elevated symptoms of psychiatric disorders, including anxiety, mood and somatoform disorders. It is plausible that the severity of psychiatric symptoms mediates relationships between PA and pain as PA often reduces these symptoms. **PURPOSE:** To assess relationships among PA, pain and psychiatric symptoms known to increase the risk of pain. **METHODS:** College-aged women (N=1033; 19.7 ± 2.9 years) completed the 7-Day PA Recall and indicated if they had (11.4%), or had not, been experiencing pain for more than a month. The Psychiatric Diagnostic Screening Questionnaire assessed symptoms of somatization, panic, generalized anxiety (GAD) and major depressive (MDD) disorders, which were hypothesized as possible mediators of the relationship between PA and pain. Structural equation models were tested using robust maximum likelihood and Bayes estimation in M*plus* 8.0. **RESULTS:** The hypothesized causal model had good fit (X^2 (10) = 14.75, P = 0.141, CFI=0.996, SRMR=0.018, RMSEA= 0.021) and accounted for a significant (P=0.004) amount of variance (R^2, SE) in pain (5.3%, 1.9%). Direct paths (β, SE) from PA to: MDD (-0.163, 0.045), GAD (-0.175, 0.049), panic (-0.100, 0.046), and somatization (-0.175, 0.049) were significant (P-values ≤ 0.028). The path from PA to pain was not direct (P=0.770), but indirect (P-values ≤ 0.016) and through significant paths (P-values ≤ 0.005) to pain from panic (0.130, 0.046) and somatization (0.156, 0.044). There were no direct or indirect effects from pain to PA in a reciprocal causal model. **CONCLUSION:** The findings support that, among college-aged women, PA is associated with pain indirectly through its associations with symptoms of somatization and panic disorder.

Resistance Training Does Not Alter Pain Sensitivity In Gulf War Veterans With Chronic Musculoskeletal Pain

Jacob B. Lindheimer[1], Aaron J. Stegner[2], Stephanie M. VanRiper[2], Ryan J. Dougherty[3], Neda E. Almassi[2], Jacob V. Ninneman[3], Laura D. Ellingson[4], Patrick J. O'Connor, FACSM[5], Dane B. Cook, FACSM[2]. *[1]US Department of Veterans Affairs, East Orange, NJ. [2]US Department of Veterans Affairs, Madison, WI. [3]University of Wisconsin-Madison, Madison, WI. [4]Iowa State University, Ames, IA. [5]University of Georgia, Athens, GA.* (Sponsor: Dane B. Cook, FACSM)

(No relevant relationships reported)

Chronic musculoskeletal pain (CMP) is a prevalent condition among Veterans of the Persian Gulf War (GV). We have previously demonstrated augmented sensitivity to painful stimuli in GV with CMP. Exercise training is an effective method for reducing pain symptoms in patients with CMP; however, the influence of exercise training on pain sensitivity to experimental stimuli is unknown. **PURPOSE:** To examine the effect of whole-body resistance exercise training (RET) on pain sensitivity among GV with CMP. It was hypothesized that, compared to a wait-list control (WLC) condition, sensitivity to painful stimuli would significantly decrease over time in participants assigned to RET. METHODS: GV who met criteria for widespread CMP were randomly assigned to a 16-week, whole-body resistance exercise training program (*n*=21; 49±5 years) or a wait-list control group (*n*=19; 50±7 years). Pain sensitivity was measured by recording perceptual ratings (0-20) of pain intensity and unpleasantness in response to a series of noxious thermal stimuli (45ºC, 47ºC, 48.9ºC) at baseline, 6, 11, and 17 weeks. Separate three-way repeated measures MANOVA models with time (baseline, 6, 11, and 17 weeks) and temperature (45ºC, 47ºC, 48.9ºC) as the within-subjects factors, and group (RET, WLC) as the between-subjects factor were used to examine the effect of RET on pain intensity and unpleasantness ratings. **RESULTS:** Whole body strength improved across the 16-week training period (average 1-RM%

change from baseline across 10 upper & lower body exercises = 28.95%). Mean pain ratings across measurement time-points for 45ºC, 47ºC, and 48.9ºC stimuli corresponded to 3, 7, and 13, for intensity and 2, 5, and 10 for unpleasantness, respectively. Aside from a significant main effect of temperature in the intensity, $Λ = 0.14$, $F (2,29) = 90.79$, $p < .001$, and unpleasantness, $Λ = 0.17$, $F (2,29) = 72.14$, $p < .001$, MANOVA models, there were no significant main or interaction effects. **CONCLUSIONS:** Resistance exercise training does not affect pain sensitivity in GV with CMP. Importantly, this finding suggests that resistance exercise has a low risk of exacerbating pain sensitivity and is a safe strategy for increasing upper and lower body strength in this population.

2104 June 1 10:00 AM - 10:15 AM

Energy, Health, and Productivity Following a Sedentary Behavior Intervention in Workers with Low Back Pain

Tyler D. Quinn[1], Andrea L. Hergenroeder[1], Sophy J. Perdomo[2], John M. Jakicic, FACSM[1], Anthony Delitto[1], Bethany Barone Gibbs[1]. *[1]University of Pittsburgh, Pittsburgh, PA. [2]University of Kansas, Kansas City, KS.* (Sponsor: John Jakicic, FACSM)

(No relevant relationships reported)

Decreased sedentary behavior is related to several positive health outcomes, however, further investigation of potential effects on presenteeism, health, and productivity in desk workers with chronic low back pain is warranted. **PURPOSE:** The Stand Back randomized trial evaluated subjective measures of health and psychosocial well-being before and after a six month intervention to reduce sedentary behavior. **METHODS:** 24 individuals with chronic low back pain and desk jobs (sitting ≥ 20 hours/week) completed either the control or intervention group. The intervention included monthly behavior counseling, a sit-stand desk attachment, a wrist-worn activity prompter, and cognitive behavioral therapy for pain self-management. The Stanford Presenteeism Scale (SPS), Health Work Questionnaire (HWQ), the SF-36 Health Survey (SF-36), and self-reported work sitting questionnaire were administered at baseline and six months. All questionnaires and subscales were analyzed across intervention groups using ANCOVA regression, adjusting for baseline values. Cohen's d was used to estimate effect size. **RESULTS:** At six month follow-up, the intervention group reported 1.5 hours/day less sitting time (p<0.001) and decreased low back pain Oswestry Disability Index (-7.8%, p=0.027) compared to control. Compared to controls, the subscales of energy/fatigue, social functioning, and pain (SF-36) were significantly improved across groups at six months. Productivity (HWQ), concentration (HWQ), and SPS-score remained unchanged (Table 1). **CONCLUSION:** Interventions to reduce sedentary time may be effective in improving energy, social functioning, and pain with no negative impact on productivity and concentration in desk workers with chronic low back pain.

2105   June 1 10:15 AM - 10:30 AM

Pain Coping Skills of Female Ultrarunners

Mitchell W. Cushman, Ashley M. Bullers, Michael C. Meyers, FACSM. *Idaho State University, Pocatello, ID.*
(No relevant relationships reported)

A female ultrarunner's ability to cope with stressful situations during competition is crucial for optimal development. Therefore, the ability to cope under these circumstances is essential for creating a strong mental capacity that leads to competitive success. **PURPOSE:** To quantify the pain coping skills of female ultra runners. **METHODS:** Following written informed consent, 76 female ultra runners (mean age 38.9 ± 9.4) completed the Sports Inventory for Pain (SIP; Meyers et al., 1992): direct coping (COP), cognitive (COG), catastrophizing (CAT), avoidance (AVD), body awareness (BOD), and total coping resources (TCR). Data were grouped by distance (<50 miles, 50-99 miles, 100+ miles), experience in years (novice-3, 4-9, 10+), age (20-39 years, 40+ years), number of ultra competitions completed (1-2, 3-4, 5+), ethnicity (Caucasian, other), present injury status (yes, no), and competitive injuries (0, 1-2, 3+). To make the data more meaningful, raw SIP scores were converted to normalized standard scores (T-scores) with a mean of 50 and a standard deviation of 10. **RESULTS:** MANOVAs (Wilks' λ criterion) indicated no significant effects across distance ($F_{12,136} = 1.256$, P = 0.252), experience ($F_{12,136} = 0.840$, P = 0.609), age ($F_{6,69} = 0.511$, P = 0.798), ultra competitions completed ($F_{12,136} = 1.004$, P = 0.449), ethnicity ($F_{6,69} = 0.395$, P = 0.880), current injury status ($F_{6,69} = 1.625$, P = 0.153), and competitive injuries ($F_{12,136} = 0.856$, P = 0.59). Coping skills among this group reflected above-average response, with T-scores ranging from 43 to 57. There is a trend for ultrarunners to respond more positively in COP, COG, CAT, AVD, BOD, and TCR when compared to normative values across other athletic populations. **CONCLUSION:** While the limited sample size may have affected the results, observed power was deemed adequate (1- β = .156 to .951), with data indicating that female ultrarunners respond positively under an adverse competitive environment. Further research is warranted to assess coping skills with larger ultra populations, as well as to determine the efficacy of coping skills interventions on ultra performance.

2106   June 1 10:30 AM - 10:45 AM

Exercise For Improving Pain Sensitivity: Comparing Moderate-intensity Continuous And High-intensity Interval Training (HIIT).

Stefan Håkansson. *Karolinska Institutet, Stockholm, Sweden.*
(No relevant relationships reported)

Aerobic exercise training appears to promote hypoalgesia, with larger effects on pain tolerance than pain threshold. However, little is known about the optimal exercise training intensity for improving pain sensitivity. High-intensity interval training (HIIT) is becoming popular as a time-efficient alternative to moderate-intensity continuous training (MICT), with evidence of similar or greater efficacy across a range of cardiovascular and metabolic adaptations, but its effect on pain sensitivity has not been examined.
PURPOSE: To compare the effects of 6 weeks of HIIT or MICT on pressure pain sensitivity in overweight or obese, sedentary males.
METHODS: Twenty-eight males (age 28 ± 7, BMI 28.6 ± 2.9) were randomly allocated to moderate (n=12) or high intensity (n=16) aerobic exercise training. Participants trained 3 sessions/week for 6 weeks on cycle ergometers. HIIT sessions involved 10 × 1minute intervals at 90-100% workload at maximal aerobic capacity (Wmax), interspersed with 1minute of active rest at 35% of Wmax. MICT sessions involved 30minutes continuous cycling at 65-75% heart rate maximum. Training protocols were matched for total workload. Pressure pain threshold (PPT) was measured pre- and post-training using algometry over the trapezius, thigh and tibialis anterior.
RESULTS: Following training, PPT increased (i.e. less pain) in MICT participants over the thigh (% change: $52\% \pm 60$, $d = 1.08$, $p = 0.004$) and tibialis anterior ($62\% \pm 58$, $d = 1.06$, $p = 0.003$) but not the trapezius ($28\% \pm 55$, $d = 0.44$, $p = 0.08$). For HIIT participants, PPT was unchanged at all sites following training (all d -0.05 to -0.17, all $p > 0.52$). The magnitude of the change in PPT after training for MICT compared to HIIT was greater at the thigh ($d = 1.14$, $p = 0.005$) and tibialis anterior ($d = 1.37$, $p = 0.001$) but not the trapezius ($d = 0.64$, $p = 0.1$).
CONCLUSION: Moderate but not high-intensity exercise training increases PPT in sedentary overweight males. The effect was largest at the worked muscles, suggesting regional-specific pain adaptations to exercise training. Inter-individual differences in PPT in response to training were prominent.

2107   June 1 10:45 AM - 11:00 AM

Preferred Versus Novel Exercise Modalities on Endogenous Pain Inhibition Following Exercise

Jessica Peterson, Daniel Schubert, Michael Bemben, FACSM, Jason Campbell, Christopher Black, FACSM. *University Of Oklahoma, Oklahoma City, OK.* (Sponsor: Christopher Black, FACSM)
(No relevant relationships reported)

Athletes have been shown to be less sensitive to pain than sedentary individuals. However, it is unclear whether their ability to modulate pain via conditioned pain modulation (CPM) differs. Exercise-induced hypoalgesia is a phenomenon related to CPM where pain sensitivity decreases following a bout of exercise. Little data exist on whether the EIH response differs between athletes and non-athletes. **PURPOSE:** The study examined the effects of aerobic training status of sensitivity to pressure pain following a familiar (running) and unfamiliar (handgrip) exercise. **METHODS:** The pressure pain response of highly aerobically trained (N=13; T) and untrained participants (N=10; UT) were tested before and after performance of an isometric hand grip exercise to failure, a 30-min run at 110% of gas exchange threshold, and placing their foot in an ice bath (2°C) for 1-min. Pressure pain thresholds (PPT) were assessed in the vastus lateralis (VL) and brachioradialis (BR) using a pressure algometer. The difference between post and pre measures was defined the EIH response (exercise conditions) and CPM response (ice bath). **RESULTS:** The groups differed on $VO_{2\,peak}$ (T = 72.2 ± 4.6; UN = 44.0 ± 8.0 ml·kg^{-1}·min^{-1}; p < 0.001). PPT did not differ between groups in the VL or BR following both exercise modalities or following the ice bath (p ≥ 0.05). A significant main effect for time was observed for VL PPT's with values increasing $18.2 \pm 14.3\%$ following 30-min of running (p < 0.001), $14.8 \pm 14.6\%$ following handgrip (p < 0.001), and 19.7 ± 22.0 following the ice bath. In the BR EIH occurred following handgrip ($26.5 \pm 23.2\%$ increase; p < 0.001) and the ice bath ($17.6 \pm 21.5\%$ increase; p < 0.001), but not the treadmill run (10.4 ± 19.2; p = 0.057). **CONCLUSIONS:** Training status and exercise type had no effect on EIH or CPM when PPT were assessed in the VL. Interestingly running was not a sufficient stimulus to evoke EIH in the BR. While familiarity with the exercise modality appeared to play no role in the EIH response, the exercise modality did play a role in systemic pain modulation with isometric exercise yielding a more robust response.

2108   June 1 11:00 AM - 11:15 AM

Pain Modulation in Response to Resistance Exercise Training in Gulf War Veterans with Chronic Pain

Stephanie M. Van Riper[1], Aaron J. Stegner[1], Jacob B. Lindheimer[2], Ryan J. Dougherty[3], Neda E. Almassi[3], Jacob V. Ninneman[3], Laura D. Ellingson[4], Patrick J. O'Connor, FACSM[5], Dane B. Cook, FACSM[1]. *[1]US Department of Veterans Affairs, Madison, WI. [2]US Department of Veterans Affairs, East Orange, NJ. [3]University of Wisconsin-Madison, Madison, WI. [4]Iowa State University, Ames, IA. [5]University of Georgia, Athens, GA.*
(No relevant relationships reported)

United States military Veterans of the Persian Gulf War (GV) suffer unresolved chronic musculoskeletal pain (CMP) that significantly impacts their functional ability and quality of life. Pain modulation is impaired in some groups with CMP and can be augmented with acute exercise. Whether chronic exercise training influences pain modulation in GV with CMP is unknown. **PURPOSE:** To examine the effects of a 16-week resistance exercise training (RET) program on pain modulation in GV with CMP. **METHODS:** Forty GV with CMP were randomly assigned to RET (n=19) or a wait-list control group (WLC; n=21). The RET program was individualized to begin at a low intensity and involved standardized progression. Pain modulation was evaluated at baseline and 3 subsequent time points by comparing pain ratings to a series of painful heat stimuli delivered alone or concurrently with the Stroop color word task, which has two levels of cognitive difficulty: congruent (CS) and incongruent (IS). Variance to mean ratios (VMR) of pain modulation scores were calculated as an indicator of dispersion. Separate repeated measures MANOVA were used to examine the effect of group (RET vs. WLC) and time (1-4) on pain modulation (change in pain ratings) for both types of Stroop presentation. **RESULTS:** Groups did not differ on age, height, weight, or gender (p < 0.05). Whole body strength improved with training (average 1-RM% change from baseline across 10 upper & lower body exercises = 28.95%). No significant main or interaction effects were detected for either Stroop presentation (p > 0.05). The proportion of individuals demonstrating a pain modulatory response did not differ at any time point, X^2 (1, N=40) = 0.14-2.10, p > 0.05. Pain modulation scores where highly variable for both groups across each time point (VMR Range: CS 1.77-1.96; IS 2.74-5.07). **CONCLUSION:** The degree to which GVs with CMP modulate pain at baseline does not appear to change as a result of RET, however pain modulation scores were highly variable across groups and time points. The lack of a change in pain modulation suggests that resistance exercise training in GVs with CMP does not influence the pain regulatory mechanism assessed here. Supported by US Department of Veterans Affairs grant #I01CX000383.

The Effects of Mirthful Laughter on Pain Tolerance and Delayed Onset Muscle Soreness.

Stephanie Lapierre, Brett Baker, Hirofumi Tanaka, FACSM. *The University of Texas at Austin, Austin, TX.* (Sponsor: Hirofumi Tanaka, FACSM)

(No relevant relationships reported)

Chronic pain is a debilitating disease that affects more people than any other chronic disease. Currently, there is not a singular treatment known to cure or assure relief from chronic pain. Accordingly, the management of patients' discomfort is an integral part of treating chronic pain. Such treatment, however, is not effective for many patients. **PURPOSE:** We determined if mirthful laughter provided by comic relief can influence pain tolerance and muscle soreness in young healthy participants**. METHODS:** Forty participants underwent a randomized controlled cross-over designed experiment. Each participant was exposed to a comedy video eliciting mirthful laughter and a boring documentary. Delayed onset muscle soreness was induced in one leg at a time by eccentric exercises to mimic chronic pain. Pain tolerance was tested using the blunt force application**. RESULTS:** Watching the comedy video elicited a significantly greater irregular breathing pattern compared with watching the documentary video ($p<0.001$). After watching the comedy, the participants' positive affect was increased ($\Delta 2\pm1$) while it was largely decreased (Δ-11±2) after watching the documentary video ($p<0.001$). Pain tolerance was decreased by 17±5 N after viewing the documentary video ($p<0.001$), but did not change significantly after watching the comedy. There were no significant changes in the visual analogue pain/soreness score from viewing either video. **CONCLUSION:** Thirty-minutes of watching a comedy eliciting laughter favorably influenced pain tolerance in healthy humans.

Physical Activity Levels and Smoking Status in Relation to Weight Control after Bariatric Surgery

Ryan E.R. Reid, Nathan A. Chiarlitti, Alexandra Sirois, Patrick Delisle-Houde, Nicolas V. Christou, Ross E. Andersen, FACSM. *McGill University, Montreal, QC, Canada.* (Sponsor: Ross E Andersen, FACSM)

(No relevant relationships reported)

Smokers typically exhibit lower body weights than non-smokers despite poorer metabolic and physiologic profiles. Nicotine, an appetite suppressant found in cigarettes and cigars, may play a role in weight control. Physical activity also contributes to lower body weights; however, this simultaneously reduces all-cause mortality, risk of coronary artery disease, and other chronic conditions. **PURPOSE:** To investigate if smoking status has an impact on weight loss and physical activity levels in patients 1-17 years after Roux-en-Y gastric bypass (RYGB). **METHODS:** A total of 509 individuals who had previously undergone RYGB (1-17 years post) were recruited for this study. To assess physical activity habits, participants were asked, "How many times per week do you exercise for 30 min or more at an intensity that makes you sweat or breathe hard?" Participants were also asked if they were a current smoker, ex-smoker or never smoked. **RESULTS:** The sample consisted of 22% smokers (114 total, 81 females), 47% never-smokers (239 total, 190 females) and 31% ex-smokers (156 total, 120 females). There were no significant differences in smoking status ($p=.45$) or physical activity ($p=.57$) between sexes. Current smokers had the highest BMI change (-21.2$\pm$.8kg/m^2) compared to both never-smokers (-18.8$\pm$.6kg/m^2; $p=.01$) and ex-smokers (-18.7$\pm$.7kg/m^2; $p=.02$) while there was no significant difference between never-smokers and ex-smokers ($p=.97$). Ex-smokers reported being significantly more active (1.7$\pm$1.9bouts) compared to current smokers (1.1$\pm$1.7bouts; $p=.01$) while there were no differences in activity between never-smokers (1.5$\pm$1.7bouts) and current smokers ($p=.07$). **CONCLUSIONS:** Although smokers lost the greatest amount of weight post-surgery, they also reported being inadequately active. Post-surgical follow-ups should evaluate numerous health measures as indicators of surgical success, as long term weight change may also be equally affected by both healthy and unhealthy habits.

2112　June 1 9:45 AM - 10:00 AM

The Effect Of Changes In Physical Activity After Bariatric Surgery On Health Outcomes.

Malou AH Nuijten[1], Rens Wolf[2], Onno Tettero[2], Esmée A. Bakker[1], Ignace MC Janssen[2], Maria TE Hopman, FACSM[1]. *[1]Radboud University Medical Center (RUMC), Nijmegen, Netherlands. [2]Dutch Obesity Clinic, Arnhem, Netherlands.*

(No relevant relationships reported)

BACKGROUND:The prevalence of obesity is increasing at an alarming rate, as is the number of morbidly obese individuals (i.e. BMI>40) in our society. Bariatric surgery is considered an effective treatment for morbid obesity with promising results on weight control, quality of life and health. However, the success of bariatric surgery in terms of health outcomes varies largely, which might be related to changes in physical activity from pre- to post-surgery. **PURPOSE**: This study aims to determine whether pre- to post-surgery changes in physical activity were associated with health outcomes such as, excessive weight loss, VO$_2$max, fat-free mass and quality of life up to two years after surgery.
METHODS: 3879 post-bariatric patients were divided into three groups based on pre- to post-surgery change in physical activity: decrease, stable and increase. Measurements regarding physical activity (Baecke questionnaire), body composition (bioelectrical impedance analysis), cardiorespiratory fitness (Astrand) and quality of life (SF-36) were performed pre-surgery and two years post-surgery. Linear regressions between change in physical activity and change in health outcomes were conducted. **RESULTS**: Increasing physical activity was associated with larger excessive weight loss ($\beta=3.17$; 95%CI=1.40-4.93; $P<0.001$) and greater increases in VO$_2$max ($\beta=2.01$; 95%CI=0.51-3.51; $P=0.009$) and %fat-free mass ($\beta=1.05$; 95%CI=0.50-1.60; $P<0.001$) compared to stable- and declining physical activity. Decreasing physical activity was associated with a decrease in VO$_2$max ($\beta=-3.91$; 95%CI=-6.40- -1.43; $P=0.002$). The increase-group showed greater increases in all quality of life subscales compared to stable- and decrease-group ($P<0.05$), except for physical functioning. Change in physical activity was not related to changes in absolute fat-free mass.
CONCLUSIONS: Increasing physical activity from pre- to post-surgery was associated with greater excessive weight loss and greater improvements in body composition, cardiorespiratory fitness and quality of life. Therefore, increasing physical activity after bariatric surgery seems essential for bariatric success in terms of health outcomes.

Effect of Obesity Coupled with Resting Alveolar-capillary Function on Exercise Capacity and Ventilatory Efficiency in Adult Heart Failure

Erik H. Van Iterson[1], Joshua R. Smith[1], Bruce D. Johnson[1], Katelyn Uithoven[2], Eric J. Bruhn[1], Thomas P. Olson, FACSM[1]. *[1]Mayo Clinic, Rochester, MN. [2]University of Minnesota, Minneapolis, MN.* (Sponsor: Thomas P. Olson, FACSM)

(No relevant relationships reported)

PURPOSE: Impaired oxidative capacity and exercise ventilatory inefficiency are primary features of human heart failure (HF). Although commonly assessed at rest, pulmonary limitations at the alveolar-capillary level also impact exercise. While it remains unclear how these interdependent features of HF contribute to exercise intolerance; obesity may further confound this issue. This study aimed to assess the impact of resting alveolar-capillary function on exercise capacity and ventilatory efficiency in obese (O) and non-obese (NO) HF patients.
METHODS: Male HF undergoing cardiopulmonary exercise testing (CPET) were stratified as NO or O (N=55 vs N=31; age 57$\pm$13 vs 55$\pm$13 yrs; LVEF 28$\pm$11 vs 30$\pm$11 %; BMI 26$\pm$2 vs 34$\pm$2 kg/m^2; NYHA class I-IV: 23 vs 5, 20 vs 16, 11 vs 9, 1 vs 1, respectively). Breath-by-breath ventilation and gas exchange were continuously measured via open circuit spirometry during CPET. Lung diffusion capacity for carbon monoxide (DL$_{CO}$) and alveolar volume (V$_A$) were measured at rest. The mixed expired CO$_2$ and end-tidal CO$_2$ ratio was used to estimate global ventilation-perfusion matching (PECO$_2$/P$_{ET}$CO$_2$~0.60 airway limited; ~0.70 airway/perfusion limited). The ventilatory equivalent for CO$_2$ (V$_E$/VCO$_2$) slope was calculated rest to peak exercise. RESULTS: NO and O resting DL$_{CO}$ (25$\pm$5 vs 24$\pm$5 mL/min/mm Hg), V$_A$ (6$\pm$1 vs 6$\pm$1 L) and DL$_{CO}$/V$_A$ (4$\pm$1 vs 4$\pm$1 mL/min/mm Hg/L) were similar (all P>0.05). Peak exercise RER (1.14$\pm$0.12 vs 1.12$\pm$0.15), VO$_2$ (1.8$\pm$0.7 vs 1.8$\pm$0.7 L/min), PECO$_2$/P$_{ET}$CO$_2$ (0.74$\pm$0.05 vs 0.76$\pm$0.04) and V$_E$/VCO$_2$ slope (35$\pm$12 vs 32$\pm$5) did not differ in NO and O (all P>0.05). Peak VO$_2$ correlated with DL$_{CO}$ and V$_A$ in NO and O (r=0.66 vs 0.48; r=0.62 vs 0.49; all P<0.05), but not for DL$_{CO}$/V$_A$ (r=0.11 vs 0.08). V$_E$/VCO$_2$ slope correlated with DL$_{CO}$ and V$_A$ in NO (r=-0.54 and -0.49; both P<0.05), but not O (r=-0.26 and -0.06); whereas DL$_{CO}$/V$_A$ was similar (r=-0.15 vs -0.25). Peak PECO$_2$/P$_{ET}$CO$_2$ correlated with DL$_{CO}$ and V$_A$ in NO (r=0.33 and 0.37), but only V$_A$ in O (r=0.37) (all P<0.05); whereas DL$_{CO}$/V$_A$ was similar (r=-0.06 vs -0.05).

CONCLUSION: These data suggest that exercise capacity, ventilation-perfusion matching, and ventilatory efficiency are similar in NO and O HF. However, the translation of resting alveolar-capillary function to these interdependent measures of exercise capacity may be confounded by obesity.

2114   June 1 10:15 AM - 10:30 AM

Obstructive Sleep Apnea Negatively Impacts Objectively Measured Physical Activity

Trent A. Hargens, FACSM, Ryan A. Martin, Courtney L. Strosnider, Gabrielle Giersch, Christopher J. Womack, FACSM. *James Madison University, Harrisonburg, VA.*
(No relevant relationships reported)

Obstructive sleep apnea (OSA) is a disorder that results daytime sleepiness and fatigue. Additionally, OSA increases the risk for cardiovascular disease and diabetes, which is exacerbated by sedentary behavior. Obesity and OSA are frequent co-morbid conditions, so the impact of OSA, independent of obesity, on physical activity (PA) is not clear.
PURPOSE: To examine the effect of OSA on objectively measured PA via accelerometer.
METHODS: Overweight-to-obese individuals were recruited and screened for the presence of OSA via portable diagnostic device and divided into an OSA group [n = 35; Age = 45.2 ± 12.0; body mass index (BMI) = 33.0 ± 5.7 kg/m^2] and a Control group (n = 24; Age = 35.0 ± 11.7; BMI = 30.5 ± 4.3 kg/m^2). Daytime sleepiness was assessed with the Epworth Sleepiness Scale questionnaire. Body composition was assessed with dual-energy X-ray absorptiometry. Subjects wore an accelerometer for a minimum of 4 and maximum of 7 days, including at least 1 weekend day.
RESULTS: The OSA group's mean OSA severity (Apnea-Hypopnea Index = 20.4 ± 17.6) classifies as "moderate OSA". There were no group differences in BMI, percent fat, or daytime sleepiness. Waist (106.4 ± 11.7 vs. 98.6 ± 9.1) and neck circumference (41.9 ± 3.3 vs. 38.8 ± 2.7) were higher in the OSA group. The OSA group was significantly older than the control group. Pearson correlation analysis showed that age was not related to any PA variable except for the total number of moderate or greater PA bouts (PA for ≥ 10 consecutive minutes) and the average number of bouts per day. The OSA group had fewer steps (6409.0 ± 2317.6 vs. 7856.8 ± 2942.7, P = 0.04), moderate intensity minutes (29.9 ± 15.1 vs. 44.2 ± 25.4, P < 0.01), moderate-to-vigorous minutes (33.0 ± 3.0 vs. 46.0 ± 5.4, P = 0.03), total number of bouts (3.2 ± 3.4 vs. 5.9 ± 5.0, P = 0.02), and number of bouts per day (0.5 ± 0.5 vs. 1.0 ± 0.8, P = 0.01). When adjusted for age, the PA bout data was no longer significant.
CONCLUSION: Individuals screened as likely possessing OSA were less physically active than individuals without OSA when measured through objective means. We found no group differences in daytime sleepiness, BMI or percent fat, suggesting other mechanisms than obesity and sleepiness for this difference.

2115   June 1 10:30 AM - 10:45 AM

Patterns of Prolonged, Uninterrupted Sedentary Bouts in the First Month after Acute Coronary Syndrome

Andrea T. Duran[1], Carol Ewing Garber, FACSM[1], Joseph E. Schwartz[2], Keith M. Diaz[2]. *[1]Teachers College, Columbia University, New York, NY. [2]Columbia University Medical Center, New York, NY.*
(No relevant relationships reported)

Total volume of sedentary behavior (SED) and its accrual in prolonged, uninterrupted bouts are crucial health risk behaviors to target in U.S. adults. Acute coronary syndrome (ACS) survivors engage in high volumes of SED post-hospitalization, but their accrual of prolonged, uninterrupted bouts is unclear.
PURPOSE: Characterize patterns of SED time accrued in prolonged, uninterrupted bouts and their trajectories of change in ACS patients over the first month post-discharge. **METHODS:** Participants (n=162) with confirmed ACS (myocardial infarction or unstable angina) from a university hospital in Manhattan were examined. SED was objectively measured for 28-days post-discharge via Actical wrist accelerometry. SED bout characteristics were quantified at the day-level and averaged over the 28-day period. Group-based modeling at the day-level was used to characterize the trajectories of change in SED bouts (% of total SED time accrued in ≥ 30 min) over the 28-days. **RESULTS:** Participants spent a mean (SD) of 9.5 ± 2.0 hrs/day in SED time, with a mean (SD) SED bout length of 7.1 ± 2.4 mins/bout, over one month post-discharge. The total number of SED bouts ≥30, ≥60 and ≥90 mins were, on average, 4.9 ± 2.3, 1.2 ± 0.8, and 0.3 ± 0.3 bouts/day, accounting for 31.8 ± 12.8%, 12.1 ± 8.2%, and 4.9 ± 4.8% of total SED time, respectively. Four distinct SED bout trajectory groups were identified (Fig 1). The very high (12.2%), high (38.3%), and moderate (38.9%) trajectory groups accrued, on average, 52.0%, 38.1%, and 25.7% of total SED time from bouts ≥30 min, respectively, with little change in day-level SED bouts post-discharge. The low trajectory group (10.6%) accrued, on average, 9.8% of total SED time from bouts ≥30 min, with a decline in SED bouts post-

discharge. **CONCLUSION:** ACS survivors accrued ~30% of total SED in prolonged, uninterrupted bouts ≥ 30 min, on average, after hospitalization, with the majority showing little day-level change in such bouts over the first month post-discharge.

Figure 1. Trajectories of total sedentary time accrued in bouts ≥ 30 minutes in ACS survivors post-discharge.

Abstract Withdrawn

2117   June 1 10:45 AM - 11:00 AM

Effects of Eccentric and Concentric Cycling on Markers of Oxidative Stress and Inflamation in Elderly

Luis Peñailillo[1], Karen Mackay[1], Roberto Gonzalez[1], Denisse Valladares[1], Ariel Contreras-Ferrat[1], Hermann Zbinden-Foncea[1], Kasunori Nosaka[2]. *[1]Universidad Finis Terrae, Santiago, Chile. [2]Edith Cowan University, Perth, Australia.* (Sponsor: Alvaro Gurovich, FACSM)
(No relevant relationships reported)

PURPOSE: The aim of this study was to examine the plasma concentration of oxidative stress and inflammation markers before and immediately after a moderate intensity concentric cycling bout, a moderate intensity eccentric cycling bout and high intensity eccentric cycling bout. **METHODS:** Ten healthy elderly participants (60.36 ± 6.79 years) performed 30 min of a concentric cycling bout (CONC) at 50% of the maximum power output (POmax), an eccentric cycling bout at 50% of POmax (ECC ISO PO) and an eccentric cycling bout at 50% of peak oxygen consumption (~100% POmax; ECC ISO VO2). Each bout was separated with one-week washout period. Before and after cycling blood samples were collected and plasma was stored at -80ºC until analyzes. Oxidative stress markers (MDA; protein carbonyl), antioxidant markers (total antioxidant capacity; glutathione peroxidase) and inflammatory markers (IL-6 and TNF- α) were analyzed using ELISA kits. Furthermore, indirect muscle damage markers were assessed before, immediately after and 24 and 48 h after exercise.
RESULTS: Average power output of ECC ISO VO2 was 48.8% and 41.8% higher than CONC and ECC ISO PO, respectively. Oxygen consumption during ECC ISO PO was 50% and 40% lower than CONC and ECC ISO VO2, respectively. Heart rate during ECC ISO PO was 16.8% and 23% lower than CONC and ECC ISO VO2, respectively. MDA concentration decreased immediately after CONC (-28%) and ECC ISO PO (-21.8%), but not after ECC ISO VO2. Glutathione peroxidase concentration increased after all three bouts of exercise (CONC=20.2%, ECC ISO PO= 27.2% and ECC ISO VO2=26.8%). IL-6 increased (+18%) only after ECC ISO VO2. Muscle damage was greater after ECC ISO VO2 than ECC ISO PO and CONC. **CONCLUSION:** Moderate intensity eccentric cycling (ECC ISO PO) showed lower metabolic cost than concentric cycling for the same power output. Interestingly, moderate eccentric cycling induced similar oxidative stress than concentric cycling at lower metabolic cost. However, high intensity eccentric cycling (ECC ISO VO2) induces moderate muscle damage and inflammation, which may blunt the decrease of oxidative stress induced by lighter bouts of cycling. The moderate eccentric cycling exercise is safe with low risk of increasing inflammation and oxidative stress on elderly people.

2118   June 1 11:00 AM - 11:15 AM

Impact of 10-weeks Of High Intensity Interval Training On the Myokine METRNL And Inflammatory Markers In Older Adults With Rheumatoid Arthritis Or Prediabetes

David Bartlett. *Duke University, Durham, NC.* (Sponsor: William E. Kraus, FACSM)

(No relevant relationships reported)

PURPOSE: Rheumatoid arthritis (RA) and diabetes are inflammatory diseases associated with physical inactivity. Physical inactivity and inflammation are augmented by dysregulated skeletal muscle remodeling. During exercise, skeletal muscle produces a number of factors, termed 'myokines', which enhance exercise adaptations. One such myokine, meteorin-like protein (METRNL), regulates both muscle and systemic adaptations. The purpose of this study was to examine the effects of high-intensity interval training (HIIT) in older adults with RA or prediabetes on muscle and plasma METRNL.
METHODS: Twenty-two older adults (67 ± 7 years) with either RA (n=12) or prediabetes (n=10) completed 10 weeks of HIIT consisting 3 x 30 min sessions/week of ≥ 60 second intervals at 80-90% interspersed by 50-60% VO_{2peak}. Clinical characteristics, blood and skeletal muscle METRNL and inflammatory markers were assessed before and after HIIT.
RESULTS: Following 10 weeks of HIIT, plasma METRNL increased in those with RA ($p=0.02$) but not in those with prediabetes ($p=0.568$). Muscle METRNL mRNA increased following exercise in those with prediabetes ($p=0.002$) but not RA ($p=0.986$) while muscle METRNL concentrations increased in both groups ($p<0.05$). Greater plasma METRNL with exercise was associated with a reduced percentage of inflammatory CD14+/CD16+ monocytes in those with RA ($p<0.05$). Greater METRNL mRNA with exercise was associated with greater muscle IL-8 ($r =.571$; $p=0.007$). Greater muscle METRNL with exercise was associated with greater concentrations of muscle IL-10 and IL-6 (both $r >.663$; $p<0.003$); greater muscle IL-6 with exercise was associated with better grip strength and 30-second chair stands (both $r >.443$; $p<0.05$).
CONCLUSIONS: Although METRNL was not associated with changes in disease indices, exercise-induced increased plasma and muscle protein and mRNA were associated with improved inflammatory profiles. Our data suggest METRNL is associated with a beneficial inflammatory response to exercise training in patients with inflammatory disease; although protein translation responses may differ depending on the disease. Thus, HIIT may improve the coordination of cytokines and myokines critical for skeletal muscle and systemic exercise-induced adaptations. *Funding: EU Marie Curie (PIOF-GA-2013-629981).*

E-13   Clinical Case Slide - **Hip and Pelvis II**

2122   June 1 9:30 AM - 9:50 AM

Pelvic Injury - Weightlifting

Erin S. Barnes. *Temple University, Philadelphia, PA.* (Sponsor: Mark Lavallee, FACSM)

(No relevant relationships reported)

HISTORY: A 34-year-old female was competing in the 90 kilogram weight-class at a national weightlifting competition. During her 3rd snatch attempt at 80 kilograms, the athlete was able to bring the barbell overhead. She failed to control the barbell and missed the lift behind her head, which resulted in the bar landing on her left posterior hip and lower back. She fell forward on both hands and knees and then to the platform. Medical team was present and immediately assessed the athlete.
PHYSICAL EXAMINATION: Urgent examination revealed an athlete lying on her back with her left hip slightly flexed with severe pain at rest and with passive movement of the hip joint. She was unable to move her left hip voluntarily. Her bilateral lower extremity sensory exam was intact and reflexes were symmetric. She was able to flex and extend both knees and ankles. There were no deformities on palpation of her lumbar spine and sacroiliac joints.
DIFFERENTIAL DIAGNOSIS: Posterior hip dislocation, Iliac Crest fracture, Hip Pointer, Acetabular Fracture, Femoral Neck Fracture

TEST AND RESULTS: XR AP Pelvis: showed a left comminuted acetabular fracture with an associated posterior hip dislocation
FINAL WORKING DIAGNOSIS: Acetabular pelvic fracture and posterior hip dislocation
TREATMENT AND OUTCOMES: She was transported to the local Emergency Room where she was evaluated and imaging was performed. She required a higher level of care and was transferred to a high level trauma center where she was admitted. The next morning (Monday), she underwent a surgical reduction of the posterior hip dislocation. She remained in traction until Tuesday when she had an additional CT scan and was taken back to the operating room for an open reduction, internal fixation of the acetabular fracture. She was up on crutches the next morning after surgery and spent one additional night in the hospital until being released on Thursday evening before flying home the next afternoon (Friday). After being admitted on Sunday night, she spent 4 days/nights total in the hospital and one night in a hotel. 5 days after the incident, she returned home to Utah.
The patient was non-weight bearing for 8 weeks. She was in formal physical therapy for 10 weeks and was able to ambulate without assistance 2.5 months after accident. She has slowly begun to return to weightlifting by 11 months post-injury.

2123   June 1 9:50 AM - 10:10 AM

Groin Injury- Football

Amanda Chaney[1], Amanda Goodale[1], Richard Okragly[1], Henry Stiene, FACSM[2]. [1]*Trihealth Sports Medicine, Cincinnati, OH.* [2]*Beacon Orthopedics and Sports Medicine, Cincinnati, OH.* (Sponsor: Henry Stiene, MD, FACSM)

(No relevant relationships reported)

HISTORY: A 22 year old division III college football player was running during practice and tried to make a cut on 8/22/17 and felt a pull in his left groin. The patient was evaluated by the athletic trainer and was diagnosed with adductor strain. He met with the athletic trainer frequently over the next few weeks to treat his pain with modalities such as laser therapy, electrical stimulation and cupping as well as doing strengthening exercises and activity modification. During game on 9/9/17, athlete played most of the game but had great amount of pain. He woke up the morning of 9/11 and noticed that he was severely bruised at the left groin region and was unable to walk without discomfort. The athlete said that he felt pain radiating into his abdomen and down into his left leg. At that point, he was referred to our Sports Medicine clinic.
PHYSICAL EXAMINATION:General: under no acute distress; alert and oriented Heart: regular rate and intact distal pulses; Lungs: CTA bilaterally; Abdomen: soft, mildly tender at right and left lower quadrants, non-distended, normal bowel sounds in all four quadrants; Groin- diffuse ecchymosis at left groin region & at pubic symphysis and left pubic tubercle; tender to palpation at left side of pubic region as well as at left lower quadrant of abdomen; weak left hip adductors & hip flexors noted on exam and pain with hip adduction and hip flexion **DIFFERENTIAL DIAGNOSIS**: 1. Left hip Adductor strain 2. Left hip Adductor tear 3. Left pubic tubercle bone contusion 4. Left Iliopsoas strain **TEST AND RESULTS**: Left Hip X-ray AP and Lateral: no acute fracture or abnormal findings MRI of Pelvis w/o contrast: left adductor longus tear with 2.5cm of retraction **FINAL WORKING DIAGNOSIS**: Left adductor tendon avulsion with approximately 2.5 cm of tendon retraction.
TREATMENT AND OUTCOMES: The athlete had approximately two weeks of rest after time of diagnosis. The consulting orthopedic surgeon recommended conservative treatment with activity modification and rehab exercises as he was desiring to finish his senior season. He continue to report pain with activity and at the conclusion of the season, will likely be reimaged to determine if conservative treatment is still acceptable or if injury has worsened further to the point of requiring surgery.

2124   June 1 10:10 AM - 10:30 AM

Testicular Pain- Football

Mary Iaculli, DO. *Evergreen Sports Medicine Fellowship, Augusta, ME.* (Sponsor: Peter Sedgwick, MD, FACSM)

(No relevant relationships reported)

HISTORY: 21 year-old collegiate football player presents to the clinic with recurrent, intermittent, severe left testicular pain occurring at rest for the past two weeks. The first episode was so severe it prompted him to go to the emergency department. There, urinary studies were performed which were negative for infection and he underwent a scrotal ultrasound. The ultrasound showed decreased left testicular vascularity, but negative for torsion. The pain had mostly resolved at the time of imaging. He returned to the ED the following day with another severe episode and underwent a second scrotal ultrasound, which showed swelling of epididymis. He was treated empirically for epididymitis with ciprofloxacin and asked to follow up.
At follow up, he reports his testicular pain is gradually improving but is still sore. Denies swelling or redness of testicle. No urinary symptoms. Denies risk factors for sexually transmitted infections. Denies history of genitourinary surgery. He admits to third episode that occurred one year prior and self-resolved with ice.
PHYSICAL EXAMINATION: Well appearing, no acute distress. Abdomen soft. No inguinal, femoral, ventral hernia. Normal scrotum bilaterally without erythema or rash. Normal vas deferens bilaterally, normal spermatic cord bilaterally. Left epididymidis

FRIDAY, JUNE 1, 2018

not enlarged, but mildly tender to palpation. Right normal. Left testes with Bell Clapper deformity, non-tender, no mass. Right testes normal. Circumcised penis with normal meatus.
DIFFERENTIAL DIAGNOSIS: Testicular torsion-detorsion syndrome; Epididymitis; Torsion of testicular appendage; Orchitis Inguinal hernia; Varicocele; Hydrocele; Epididymal hypertension
TEST AND RESULTS Urinalysis: negative; Urine culture: negative; Scrotal US 9/22/17: Left epididymitis. Normal testicles with symmetric blood flow; Scrotal US 9/23/17: modestly decreased but present vascularity of left testicle of uncertain significance but incompatible with torsion at this time. **FINAL WORKING DIAGNOSIS**: Testicular torsion-detorsion syndrome
TREATMENT AND OUTCOMES:
Referred to urology; Withheld from contact play until evaluated by urology; Urology recommended orchiopexy, which was performed within 1 week of specialty evaluation; Per urology, can return to aerobic and contact activity 2 weeks after procedure

---

2125   June 1 10:30 AM - 10:50 AM
Hip Pain - Hiking
Cory Mitchell, Caitlin Waters, Herb Stevenson. *UMass Memorial Medical Center, Worcester, MA.* (Sponsor: Pierre Rouzier, FACSM)
(No relevant relationships reported)

HISTORY: A 78-year-old male is seen for evaluation of left lateral thigh pain. Symptoms present over the past few years but have worsened over the past six months. Recalls no specific onset. Pain is 3/10 and aching in quality. It is located over the lateral hip and thigh. Symptoms are worse with lifting and hiking, particularly on an incline. Pain is better with rest and does not radiate. He has associated burning, also with activity, in the same distribution. Denies back pain. He has no allergies, is a former smoker and takes medications for high blood pressure and cholesterol. Denies prior injuries or surgeries of the back, hip or legs.
PHYSICAL EXAMINATION: GEN: A&Ox3, in NAD. Central obesity. HEENT: NCAT. EOMI. CV: RRR, 2+ peripheral pulses PULM: CTAB SKIN: No rashes or signs of infection. NEURO: Symmetric strength and sensation in all 4 extremities. MSK: No deformity of the left hip. He has tenderness over the anterior greater trochanter but is otherwise nontender. External/internal rotation full, passive flexion to 110. Resisted abduction causes pain without reproduction of burning sensation. Negative FABER and FADIR. Antalgic gait. Lumbar spine non-tender. Full flexion/extension. Negative straight leg raise.
DIFFERENTIAL DIAGNOSIS: Gluteus medius/minimus tendinopathy Left hip osteoarthritis IT Band syndrome Piriformis syndrome
TEST AND RESULTS: Left hip x-ray: Mild degenerative changes Rheumatologic consult: Negative screening labs Left hip MRI: Partial tear of the gluteus minimus tendon Neurosurgery consult: Lumbar spine MRI - negative Physiatry consult: EMG left leg - normal, cannot rule out lateral femoral cutaneous neuropathy
FINAL WORKING DIAGNOSIS: Gluteus minimus tendinopathy with partial tear Meralgia paresthetica
TREATMENT AND OUTCOMES:
12-week course of physical therapy: 40% decrease in pain, burning feeling unchanged. Palpation-guided greater trochanteric bursa cortisone injection: minimal relief. Ultrasound-guided needle tenotomy of gluteus minimus tendon: resolution of antalgic gait with 50% improvement in pain without an effect on burning sensation. Ultrasound-guided nerve block and cortisone injection: resolved burning symptom without effect on lateral hip pain. Returned to regular daily activities and household chores. Yet to resume hiking due to lack of muscular endurance.

2126   June 1 10:50 AM - 11:10 AM
Left Hip Pain and Swelling Following a Bicycle Accident
George A. Ceremuga[1], Edward R. Laskowski, FACSM[2], Kristina M. Colbenson[2]. *[1]Mayo School of Graduate Medical Education, Rochester, MN. [2]Mayo Clinic, Rochester, MN.* (Sponsor: Edward Laskowski, FACSM)
(No relevant relationships reported)

HISTORY
A 45-year-old male bicyclist presented for evaluation of left hip pain and swelling following a bicycle accident that occurred approximately one week prior to presentation. His chief complaint was left groin and posterolateral gluteal region pain that increased with activity and improved with rest and anti-inflammatory medications. Radiographs were performed revealing no definite acute fractures of the left hip. MRI revealed nondisplaced fractures of right sacral ala and left superior and inferior pubic rami as well as a large lentiform fluid collection overlying left gluteal musculature.
PHYSICAL EXAMINATION: Healthy-appearing individual in no apparent distress. Normal gait cadence and stride. Significant ecchymosis with underlying, ballotable, fluid collection of left lateral hip and gluteal region. Tenderness to palpation in this

region. Joint range of motion is full. Strength is full and sensation is grossly intact throughout. Discomfort with hip internal rotation and Stinchfield's and FABER tests on left. Straight leg raise is negative bilaterally.
DIFFERENTIAL DIAGNOSIS:
1.Morel-Lavallee Lesion
2.Gluteus maximus contusion
3.Fracture of the greater trochanter
TESTS AND RESULTS
Left hip radiographs: No definite acute fractures involving left hip.
Left hip MRI: Nondisplaced fractures of the right sacral ala and left superior and inferior pubic rami. Large lentiform fluid collection overlying the left gluteal musculature with surrounding subcutaneous edema, consistent with a Morel-Lavallee lesion.
FINAL/WORKING DIAGNOSIS:
Moral-Lavallee Lesion
TREATMENT AND OUTCOMES
1. Touch weightbearing crutch ambulation for left lower extremity and use of compression shorts.
2. Ultrasound-guided needle aspiration of gluteal fluid collection: 180 cc of serosanguineous fluid obtained; compression dressing applied afterwards.
3. Two weeks later, surgical evaluation revealed 15 x 10 cm reaccumulation of fluid in the same location. Advised to undergo incision and drainage and partial capsulectomy. Surgery was without complications and a JP drain was placed.
4. Left thigh JP drain exchange performed for clogged drain.
5. Drain removed but 4 days later repeat aspiration of 32 cc was performed.
6. One week later, repeat aspiration of 32 cc was performed, followed by complete resolution.

2127   June 1 11:10 AM - 11:30 AM
"Hip Pop"- Acute Anterior Thigh Pain in an Adolescent Soccer Player
Jonathan Koretoff. *University of Minnesota, Minneapolis, MN.* (Sponsor: Suzanne Hecht, FACSM)
(No relevant relationships reported)

HISTORY: 15 year-old male club soccer athlete reported acute onset of left proximal thigh pain after sprinting straight ahead while playing in a game in a soccer tournament. He was the starting goalie for the team. While running, he felt a pop in his proximal thigh with inability to bear weight. Reported the sensation occurred while sprinting. He collapsed on the field and was evaluated by a sideline sports medicine physician as well as a certified athletic trainer. He was then transported to the on-site medical clinic. No numbness and tingling. No prior pain or injury.
PHYSICAL EXAM:
GEN: Mild distress while sitting in wheelchair. No distress while lying flat. Awake, alert, and oriented x 3
MSK: LEFT HIP: No bruising or gross deformity. Tenderness over proximal hip flexors. Tenderness on posteromedial aspect of hip adductor musculature. Unable to raise leg from the exam table unassisted. Marked pain with active range of motion in flexion with knee extended. Moderate pain with passive hip flexion. Unable to bear weight. 2/5 strength in hip flexion. FABER/FADIR elicited pain over proximal quadriceps. No bony pelvic tenderness
LUMBAR SPINE: No bruising or gross deformity. Non tender spinous processes and paraspinal musculature. No radicular pain with straight leg raise. Achilles and patellar reflexes bilaterally symmetrical
DIFFERENTIAL DIAGNOSIS: 1) Apophyseal avulsion fracture 2) Proximal quadriceps tendon rupture 3) Pathologic femoral fracture 4) Referred pain secondary to lumbar spinal pathology
TEST AND RESULTS: Xray left hip (AP and lateral): Lesser trochanteric apophyseal avulsion fracture, minimally displaced
FINAL WORKING DIAGNOSIS: Lesser trochanteric apophyseal avulsion fracture
TREATMENT AND OUTCOMES: He was placed non-weight bearing on crutches. At follow-up 1 week post injury he lacked active range of motion of his left hip. After his initial clinic visit, further follow up occurred at 2 weeks, 1 month, and 2 months. At 2 weeks he could bear weight with pain but lacked active range of motion. At 1 month he could bear weight without pain but lacked active range of motion. At 2 months he could bear weight and hop without pain but had 3/5 hip strength and had active range of motion with no pain. Referred to physical therapy. He is now enrolled in return to run program. Imaging at 6 weeks and 2 months showed stable fracture.

E-14   Clinical Case Slide - **Shoulder and Elbow**

Friday, June 1, 2018, 9:30 AM - 10:50 AM
Room: CC-200F

Suprascapular Nerve Entrapment or Compression in a Kayaker

Christa L. LiBrizzi, Jorge Rojas, Uma Srikumaranan, Edward G. McFarland. *The Johns Hopkins University, Lutherville, MD.* (Sponsor: Brian Krabak, FACSM)

(No relevant relationships reported)

HISTORY:
A 20-year-old male kayaker presented for a second opinion for increasing pain and dysfunction in his right, dominant shoulder joint for five months. The pain had begun insidiously with no history of trauma. The patient described the pain as aching, sharp, and burning which progressed to become constant in nature. The patient's pain was exacerbated specifically by kayaking and had become so severe that he had to cease participation. **PHYSICAL EXAMINATION**: The active range of motion of his shoulders was normal and symmetric. He had normal range of motion of his cervical spine. To inspection he had notable atrophy of his supraspinatus and infraspinatus of his right but not left shoulder. He had no winging but did have scapular dyskinesis. He had weakness to external rotation in the right shoulder with the arm at the side, but he had a negative external rotation lag sign. He had weakness to resisted abduction with the shoulder abducted 90 degrees and the elbow extended. He otherwise was neurologically intact for sensory, motor and reflex testing in both upper extremities. He had a negative Spurling's test. He had pain with elevation of the arm, but was not tender anywhere around the shoulder. **DIFFERENTIAL DIAGNOSIS**: 1. Suprascapular nerve entrapment or compression
2. Cervical radiculopathy
3. Facioscapulohumeral Muscular Dystrophy 4. Rotator cuff tear
TEST AND RESULTS:Cervical spine and shoulder radiographs: normal EMG-NCS: severe right suprascapular neuropathy MRI shoulder: muscle atrophy c/w nerve injury; multi-loculated synovial cyst base of coracoid MRI cervical spine: normal
FINAL WORKING DIAGNOSIS: Suprascapular nerve entrapment and compression
TREATMENT AND OUTCOMES:
1. Arthroscopic subacromial decompression, suprascapular nerve release at the transverse scapular ligament and spinoglenoid notch, and ganglion cyst excision
2. Sling for 1-2 weeks, early passive range of motion ok, no pendulums 3. No strengthening until 2 months post-op. 4. Cleared for PT, 8 days-post-op 5. Cleared to return to activities as tolerated, 4 weeks-post-op. 6 Returned to kayaking

---

2132   June 1 9:50 AM - 10:10 AM

Shoulder Weakness In A 24-year-old Body Builder

Ryan Woods[1], Edward R. Laskowski, FACSM[1], James C. Presley[2], Jeff Strauss[1]. *[1]Mayo Clinic, Rochester, MN. [2]Mayo Clinic, Jacksonville, FL.* (Sponsor: Edward R. Laskowski, FACSM)

(No relevant relationships reported)

HISTORY: 24-year-old male body builder with a six month history of insidious right shoulder pain localized to the right deltoid. He reports increased shoulder discomfort working at his job as a physical therapy assistant. He also describes a one-year history of progressive right shoulder weakness noted most during bench pressing which decreased from 300 pounds to 135 pounds. No sensory symptoms present. Initial x-rays were negative. Physical exam demonstrated intact rotator cuff strength with positive impingement testing. He was diagnosed with rotator cuff tendinopathy and started on a rehab program with instructions to avoid overhead lifts, deep drop bench press, and dips. His pain improved with therapy, however he returned six months later after experiencing two to three months of painless atrophy of the right pectoralis region with continued weakness.

PHYSICAL EXAMINATION: Inspection: Visible atrophy of the right pectoralis major. Palpation: Unremarkable. Joint ROM: Full range of motion. Strength: Normal upper extremity strength. Provocative Tests: Negative Neer's, Hawkin's, Speed's and labral testing. Reflexes: Normal. Sensation: Intact to light touch throughout.
DIFFERENTIAL DIAGNOSIS:
Parsonage Turner Syndrome
Brachial Plexopathy
Radiculopathy, mononeuropathy
Inflammatory Myopathy
Facioscapulohumeral muscular dystrophy
TEST AND RESULTS: EMG: Isolated right pectoral nerve mononeuropathy. MRI: Denervation changes within the right pectoralis major muscle. No abnormalities of the right brachial plexus. Ultrasound: Atrophy of the right pectoralis major. Visualized elements of the lateral and medial pectoral nerves are normal.
FINAL WORKING DIAGNOSIS: Right pectoralis major atrophy in the context of isolated right pectoral nerve mononeuropathy.
TREATMENT AND OUTCOMES: Patient was referred back to physical therapy with recommendations to hold off on bench pressing exercise until he demonstrates neurologic recovery. At the one month follow up improved bulk and muscle quivering of his right pectoralis major was seen. He was allowed to pursue low resistance pectoral strengthening with recommendations to continue to avoid any heavy load pectoralis exercise for one to three months after which he can initiate a gradual return to normal activity.

2133   June 1 10:10 AM - 10:30 AM

Shoulder - Why So Weak? - Track And Field

William L. Patterson Jr.. *Maine Medical Center, Portland, ME.* (Sponsor: William Dexter, FACSM)

(No relevant relationships reported)

History:
20 yo M right hand dominant decathlete at a division III college presents with left shoulder weakness. Started 2 months prior, the morning after a routine weight lifting workout. Began with an ache in the shoulder followed by a tight feeling with some radiation to the trapezius up the neck, and finally with some weakness lifting and externally rotating the arm that slowly increased over a week then plateaued. He had no paresthesias. The pain slowly subsided and resolved over approximately 3 weeks, but the weakness persisted.
PMHx, PSHx, FMHx are non-contributory, not taking any medications.
ROS: fully negative and has not had any illnesses prior or since.
Physical examination:
BP 108/70 mmHg | Pulse 60 | Ht (5'9") | Wt 170 lb | BMI 25.16 kg/m2
Left shoulder exam reveals atrophy of infraspinatus and supraspinatus, non-tender to palpation in neck, shoulder or upper arm. Normal active and passive ROM in all motions of the shoulder and neck. Resisted ROM was painless and yielded 4+/5 strength in external rotation & abduction. Neer's, Hawkin's, AC compression, O'Brien's, labral shear, Yergason's, Speeds, stability testing, Spurling's are all negative. Neurovascular: dermatomes intact to light touch in B/L upper extremities, 2+ reflexes biceps, triceps, brachioradialis, 2+ radial pulses
Differential Diagnosis:
Suprascapular nerve impingement, brachial plexitis (Parsonage Turner syndrome), rotator cuff tear(infraspinatus and/or supraspinatus), cervical radiculopathy (C6), thoracic outlet syndrome.
Tests and Results:
#Limited bedside MSK US of left shoulder: no obvious entrapment at the spino-glenoid notch.
Patient was referred to Neurology for EMG who then ordered an MRI to rule out cervical radiculopathy.
#EMG of left upper extremity.
Suprascapular nerve - Right was normal. Left had normal latency, but CMAP was distorted. Median nerve normal. Needle exam - abundant acute denervation in infraspinatus, less so in supraspinatus. Both with decreased recruitment. Deltoid muscle demonstrated decreased recruitment with minimal polyphagia.
#MRI CERVICAL SPINE: Normal MRI scan of the cervical spine.
Final/Working Diagnosis: Parsonage turner syndrome with primary involvement of the suprascapular nerve.
Treatment: PT
Outcomes: Strength slowly improving. No pain.

2134   June 1 10:30 AM - 10:50 AM

Management of a Patient with Lateral Elbow Pain Secondary to Acute Adverse Neural Irritation

Sean Harris[1], James Gregory[2], Alexis Ortiz, FACSM[3]. *[1]Memorial Hermann, Houston, TX. [2]UT Health, Houston, TX. [3]Texas Woman's University, Houston, TX.* (Sponsor: Alexis Ortiz, FACSM)
(No relevant relationships reported)

HISTORY: A 38 y/o female reports to physical therapy with gradual onset of R lateral elbow pain. She received corticosteroid injection to lateral elbow from her PCP, which caused immediate exacerbation of symptoms. Additionally, she started feeling radiating/burning symptoms down anteromedial forearm. Upon initial evaluation, she presented with extremely reduced grip strength (reproduction of radiating pain), loss of full elbow extension, and shooting pain.
PHYSICAL EXAMINATION: Examination revealed full and pain-free cervical ROM, with no reproduction of symptoms. Resting postural assessment revealed increased thoracic kyphosis with segmental hypomobility from T1-6. Elbow assessment revealed bilateral elbow hyperextension of 20deg. Upper-limb tension testing was + for radial and median n. on right, with reproduction of radiating symptoms into forearm. Lateral epicondylalgia tests were all + on right (Cozen's, Mill's, Maudsley's), but did not reproduce radiating symptoms. She had painful supination, with mild reproduction of radiating symptoms. Performing Tinel percussion over supinator during elbow extension/pronation reproduced radiating pain from elbow to medial forearm.
DIFFERENTIAL DIAGNOSIS:
1.Lateral epicondylalgia
2.Cervical radiculopathy
3.Peripheral neuropathy
TEST AND RESULTS:
Elbow anterior to posterior and lateral radiograph
• Congenitally deepened olecranon fossa, resulting in excessive elbow hyperextension
Lateral corticosteroid injection
• Immediate onset of radiating symptoms into medial forearm; no improvement in lateral elbow symptoms
Grip strength measured with hand-held dynamometer
• Pain-free grip on right measured at 15# (50# on L)
FINAL/WORKING DIAGNOSIS:
Lateral epicondylalgia with underlying acute peripheral nerve irritation, and possible distal sensory overlap of radial/median nerves.
TREATMENT AND OUTCOMES:
6 PT sessions over 6 weeks consisting of:
1) Thoracic manipulation
2) Radio-humeral distraction
3) Distal radial nerve sliders
5) Closed-chain tendon loading progression
Outcomes at 6 weeks:
1) Improved Quick DASH from 34 to 3
2) Normal adverse neural testing
3) Pain-free grip improved to 45# on right
4) Return to normal functional activities

E-15   Clinical Case Slide - **Wrist and Hand**

Friday, June 1, 2018, 9:30 AM - 11:10 AM

Wrist Pain and Hand Numbness -- Football

Jonathan Harvey. *University of Minnesota Sports Medicine Fellowship, Minneapolis, MN.* (Sponsor: Dr. Suzanne Hecht, FACSM, FACSM)
(No relevant relationships reported)

HISTORY: 17 yo defensive lineman presents with new onset right hand numbness, tingling, and mild discomfort during a high school football game. He denies any known injuries to the affected extremity during the game but endorses that he uses his hands a lot during play. He had not noticed swelling, redness, or weakness. Denies elbow, forearm, shoulder or neck pain. He described the paresthesias as limited to the back of his hand and thumb. The discomfort is described as generalized pain over the back of his wrist. He denies any prior injury to the hand, wrist, elbow, shoulder, or neck; however, he does tape both his wrists to "prevent injury" during gameplay and recently bought new football gloves. PHYSICAL EXAMINATION: Right hand: No deformity, swelling, erythema, or ecchymosis. Bony prominences non-tender to palpation. Notable paresthesias and decreased sensation over the dorsal aspect of the hand with intact sensation of the ulnar side of the hand, palm, and digits. 5/5 strength in intrinsic muscles of hands, grips strength, and thumb strength. No thumb instability. Wrists: Bilateral wrists are wrapped with athletic tape. No obvious deformity or skin changes. 5/5 strength with flexion, extension, eversion, inversion, pronation and supination. Anatomic snuff box was non-tender. Mild discomfort with Finkelstein test and resisted extension of thumb. Neck non tender to palpation with full ROM.
DIFFERENTIAL DIAGNOSIS: Cheiralgia Parasthetica, DeQuervain's tenosynovitis, Intersection syndrome, Lateral antebrachial cutaneous nerve neuritis, Radial tunnel syndrome,.Brachial plexus injury, Cervical injury TEST: Gloves and wrist tape removed with partial improvement of hand/wrist discomfort. FINAL WORKING DIAGNOSIS: Cheiralgia Parasthetica "Wartenberg Syndrome" TREATMENT AND OUTCOMES: 1. Right wrist tape and football gloves were removed. 2. After evaluation and improvement in symptoms he was released to return to play in the same game without restrictions. 3. One hour later he had complete resolution of paresthesias when re-evaluated at half time 4. Symptoms at halftime could be reproduced with pronation, flexion, and ulnar deviation 5. Discontinued future wrist taping 6. The patient was symptom-free and had a normal exam at 1 week follow-up appointment. 7. He was advised to avoid overtightening of football gloves

---

2139   June 1 9:50 AM - 10:10 AM

Bilateral Cubital Tunnel Syndrome in a Female Ice Hockey Player

Kiran Bojedla, Damian Mosher. *Millcreek Community Hospital, Erie, PA.* (Sponsor: Patrick Leary DO, FACSM)
(No relevant relationships reported)

Bilateral Arm Injury ---- Women's Ice Hockey
Kiran Bojedla DO, Millcreek Community Hospital Sports Medicine, Erie, PA
e-mail:Kiran.bojedla@gmail.com
(Sponsor: Patrick Leary DO, FACSM)
HISTORY: A 20 year old female junior ice hockey collegiate athlete presented with bilateral distal arm pain and grip strength weakness, developed while lifting weights during offseason conditioning. Patient had been doing front squats with increasingly heavy loads put onto flexed elbows and wrists. Complained of pain waking her up at night and worsening recently, and with hand numbness/tingling during the day.
PHYSICAL EXAMINATION: Examination in the Training Room revealed bilateral grip strength weakness, left worse than right, numbness on the medial side of the wrists and 4th/5th fingers, and positive Tinel's Sign / Phalen's Test. At the shoulder, strength was 5/5 throughout and ROM was full bilaterally. Symptoms of grip strength weakness and paresthesias worsened over several visits.
DIFFERENTIAL DIAGNOSIS
1. Carpel Tunnel Syndrome
2. Cubital Tunnel Syndrome
3. Central spinal cord lesion
4. Multiple Sclerosis
TEST AND RESULTS:
Electromyelogram: Disruption of ulnar nerve conduction velocity through cubital tunnel bilaterally
Cervical MRI: Possible Tarlov cyst at C5-C6 on left, no stenosis appreciated at any level, no herniations
Chest X-ray: No acute abnormalities
WORKING DIAGNOSIS:
Bilateral Cubital Tunnel Syndrome
TREATMENT AND OUTCOMES
1. Keep arms extended at elbow as much as possible
2. Completely shut down from hockey activities (no skating / stickhandling)
3. Plan for L ulnar nerve release with Orthopedic Surgeon 11/2017
4. RTP to be determined depending on response to therapy

2140   June 1 10:10 AM - 10:30 AM

Wrist Injury - Tae Kwon Do

Claire Gross[1], Holly J. Benjamin, FACSM[2], Daniel P. Mass[2]. *[1]MacNeal Hospital, Berwyn, IL. [2]University of Chicago, Chicago, IL.* (Sponsor: Holly J. Benjamin, MD, FACSM)
(No relevant relationships reported)

History: An 18-year-old right-hand dominant male, nationally-ranked Tae Kwon Do competitor presented with a 4 year history of left wrist pain. Four years prior to presentation, he was kicked on the ulnar wrist while sparring. At that time, he had tenderness over the ulnar styloid and distal physis, no tenderness at the ulnar-carpal

articulation, and full wrist range of motion. Wrist X-Rays were read by radiology as negative for fracture, but interpreted by the sports medicine team as a possible ulnar Salter-Harris I injury in addition to a wrist contusion. He returned to sport after three weeks of relative rest and use of a wrist brace. He presented to clinic four years later due to worsening symptoms that inhibited his level of competition in Tae Kwon Do. He had not sustained any further wrist injuries in the interim. There was increased pain with active range of motion and he felt an occasional click in his wrist and intermittent tingling in his fifth digit.

Physical Examination: Left wrist exam demonstrated no gross deformity, swelling, erythema, or ecchymosis. The limb was neurovascularly intact. There was tenderness to palpation of the hook of the hamate and the triangular fibrocartilage complex. Full wrist and hand range of motion. Mild weakness noted in fifth digit flexion and wrist flexion; strength otherwise intact. Wrist extension with ulnar deviation reproduced the patient's pain. There was increased dorsal instability of the ulnar styloid at the distal radioulnar joint (DRUJ) (positive piano key sign).

Differential Diagnosis: 1. TFCC tear 2. Post-traumatic arthritis 3. Hook of the hamate fracture 4. Flexor carpi ulnaris strain 5. Ulnar neuropathy at the wrist

Tests and Results: MR arthrogram: There is contrast extension into the distal radioulnar joint indicating disruption of the triangular fibrocartilage complex (TFCC). The TFCC appears irregular and demonstrates intermediate signal. These findings were interpreted by the Sports Medicine team to represent concomitant central and peripheral TFCC tears.

Final Diagnosis: Central and peripheral TFCC tears

Treatment and Outcomes: After consultation with orthopedic surgery, the patient is currently scheduled for arthroscopic debridement of the central tear and repair the peripheral tear of his TFCC.

2141   June 1 10:30 AM - 10:50 AM
Forearm Pain- Gymnastics

Melissa Faubert[1], Holly Benjamin, FACSM[2], Daniel Mass[2].
[1]NorthShore University HealthSystem/University of Chicago, Chicago, IL. [2]University of Chicago, Chicago, IL.
(No relevant relationships reported)

HISTORY: 14 year old right handed level 8 gymnast presents with complaints of progressive right greater than left elbow and forearm pain over the past four months. Despite bracing, activity modification and three months of physical therapy she still reported progressive worsening of pain and development of tingling in her hands and forearms. She notes she has a constant feeling of tightness over her anteromedial forearms and pain and tingling of her arm occurs the worst while writing in school or vaulting. Pain and numbness resolve with a few minutes of rest and elbow extension. She does not have any nighttime pain. **PHYSICAL EXAMINATION**: - Well appearing female adolescent - Full ROM of elbow, forearm, wrist and fingers - Sensation intact to light touch in the radial, medial and ulnar nerve distribution bilaterally - 5/5 strength in the radial, medial, ulnar, anterior interosseous and posterior interosseous nerves bilaterally - Mild TTP of proximal forearm and medial elbow bilaterally - Positive compression test at the proximal forearm - Positive Tinel's test over the pronator teres - Positive Tinel's test over cubital tunnel - Negative Tinel's, Durkan's and Phalen's at the wrist bilaterally **DIFFERENTIAL DIAGNOSIS:**- Pronator syndrome - Cubital tunnel syndrome - Chronic exertional compartment syndrome of the forearm - Anterior interosseous nerve syndrome - Brachial plexus neuritis - Cervical radiculopathy **TEST AND RESULTS**: MRI elbow Left: MRI findings normal but noted presence of accessory anconeous epitrochlearis muscle. MRI elbow Right: Normal MRI. **FINAL WORKING DIAGNOSIS**: Pronator syndrome bilaterally. Left arm with accessory anconeous epitrochlearis muscle also causing ulnar neuropathy. **TREATMENT AND OUTCOMES**: Patient's older sister previously had pronator syndrome as well as chronic exertional compartment syndrome for which she underwent median nerve release and fasciotomy. Patient and her parents elected to forgo compartment testing suspecting she also had both conditions. She underwent surgery on her left elbow with a median nerve release, ulnar nerve release and fasciotomy. She is due to have surgery on her right arm for median nerve release and fasciotomy three weeks after her left.

2142   June 1 10:50 AM - 11:10 AM
Metacarpal Stress fractures Presenting As Dorsal Hand Pain In A High School Tennis Player: A Case Report

John K. Evans, Keith A. Bengtson, Cara C. Prideaux, Edward R. Laskowski, FACSM. *Mayo Clinic, Rochester, MN.*
(No relevant relationships reported)

HISTORY:
A 17 year-old right-hand dominant male tennis player presented to the hand clinic for a two week history of right dorsal hand pain. The patient noticed hand pain while at practice the day following a one-day tennis tournament involving three separate matches. Severe pain in the dorsum of the wrist was noted with forehands, serves, and volleys, but was less notable during backhands. The pain was sharp and severe for about three seconds after each hit and then quickly resolved to a pain-free baseline.

The patient continued to practice through pain for the following week. He was able to perform all activities of daily living without discomfort. The patient denied swelling, pain in other joints, weakness, and paresthesias.

PHYSICAL EXAMINATION:
Examination revealed tenderness to palpation at the base of the second and third metacarpals and pain with stressing the second and third carpometacarpal joints. There was severe pain to use of a tuning fork over the proximal second and third metacarpal. Finger and wrist ranges of motion were full and pain-free, and there was no swelling.

DIFFERENTIAL DIAGNOSIS:
1. Wrist extensor tenosynovitis
2. Ganglion cyst
3. Rheumatoid arthritis
4. Metacarpal stress fracture
5. Crystal arthropathy

TEST AND RESULTS:
PA, oblique, and splayed lateral radiographs of the right hand: -Negative for fracture; there were no erosions or degenerative change.
Noncontrast MRI of the right hand: -Stress fracture of the right second metacarpal in the proximal shaft with extension to the proximal articular surface; also observed was a stress fracture in the adjacent trapezoid. -Less prominent stress fracture/stress reaction of the right third metacarpal with no cortical break.

FINAL/WORKING DIAGNOSIS:
Right second metacarpal proximal shaft stress fracture and right third metacarpal shaft stress fracture/reaction.

TREATMENT AND OUTCOMES:
1. Hold from tennis activities for 6 weeks.
2. Racket grip type changed from Western to Eastern grip type.
3. Gradual return to tennis starting 6 weeks after cessation of sport with focus on maintaining optical tennis mechanics and low-intensity groundstrokes.
4. Serves were initiated at 7 weeks after tolerating groundstrokes without discomfort.
5. Full return to sport by 3 months after being able to meet demands of his sport with pain-free high-intensity tennis shots.

Associations Between Land-Based Performance Assessments and Maximal Effort Combat Swim Force Production

Meaghan Beckner[1], Elizabeth Nagle, FACSM[1], Anne Beethe[1], Takashi Nagai[1], Meghan Schmidt[1], Chris Connaboy[1], John Abt, FACSM[2], Scott Lephart, FACSM[2], Bradley Nindl, FACSM[1].
[1]University of Pittsburgh, Pittsburgh, PA. [2]University of Kentucky, Lexington, KY.
(No relevant relationships reported)

Combat swimming (CS) requires military personnel dressed in full combat gear to swim while holding or towing additional weight (i.e. ammunition, rucksack, etc.). Reportedly, additional gear can amount to over 40 kg and increases the demand on muscle force production to overcome water resistance. Limited research has explored relationships between limb length, strength, and anaerobic power assessments and CS flutterkick performance during a 30-second maximal effort tethered swim test (TST). **PURPOSE:** To examine relationships between limb length, strength, and anaerobic power assessments and maximum effort CS force production. **METHODS:** Six female (26 ± 9.2 years, 169.7 ± 3.9 cm, 67.5 ± 9.4 kg) and six male (30 ± 8.0 years, 179.4 ± 7.6 cm, 80.8 ± 15.4 kg) skilled swimmers participated in isometric muscular hip strength (HS) testing using a handheld dynamometer, and a 30-second Wingate cycle ergometer anaerobic test (WAnT). Limb length (LL) was measured from the Anterior Superior Iliac Spine to the medial malleolus. For TST, subjects wore full military gear weighing approximately 12 kg, including combat boots and fins, and performed a maximal effort flutterkick in a prone position holding a flotation device for 30 seconds. After testing for normality, correlations between HS, LL, WAnT, and TST were determined using Pearson's correlation ($p<0.05$). **RESULTS:** Absolute Wingate mean power was significantly correlated to TST mean force (TST_{mf}) (0.883, $p<0.001$). Correlations were identified between LL and TST peak force (TST_{pf}) (right: 0.653, $p=0.021$; left: 0.659, $p=0.020$). There was no significant correlation between isometric peak HS and TST_{pf}. **CONCLUSION:** LL and absolute WAnT mean power are associated with CS anaerobic kicking performance more so than isometric HS. Findings should not dismiss the relevance of strength, but promote specificity of the assessment. Identifying significant relationships between power and strength assessments and swimming force during CS flutterkick is important to help to improve training for optimal CS anaerobic performance.

Predictors of 2 Kilometer Rowing Ergometer Time Trial Performance

Jason Metz[1], Fredric Goss, FACSM[2], Robert Robertson, FACSM[2], Elizabeth Nagle, FACSM[2], Jonathan Abt[3]. [1]*West Liberty University, West Liberty, WV.* [2]*University of Pittsburgh, Pittsburgh, PA.* [3]*University of Kentucky, Lexington, KY.*
(No relevant relationships reported)

ABSTRACT

Predictors of performance can aid coaches and trainers in prescribing exercise programs for rowing athletes. To date, most of the prediction models have been developed for runners and cyclists. **PURPOSE:** The aim of this study was to develop a regression model to predict performance of a simulated 2 kilometer rowing ergometer time trial. **METHODS:** A group of mixed gender rowing athletes (n=12) completed in a counterbalanced order a 2 Kilometer rowing time trial and a continuous progressively incremented graded exercise test on a rowing ergometer. Subjects were 23.91±4.99 years old, weighed 79.14±12.85 kg, were 187.38±12.60 cm, had a VO_2max of 55.48±10.32 ml/kg/min and had 3.17±2.79 years of rowing experience. Physiological measures were recorded during both testing protocols. **RESULTS:** Maximum Power/ Stroke Ratio (r = -0.96, p<0.001), Power/Stroke Ratio at the ventilatory breakpoint (r = -0.90, p<0.001), Maximal Oxygen Uptake (r = -0.84, p<0.001) and Oxygen Uptake at the ventilatory breakpoint (r = -0.82, p<0.001) were found to be strong and significant predictors of 2 kilometer rowing performance. **CONCLUSION:** The four significant predictors of rowing performance suggest training should focus on improving both aerobic capacity and strength.
Statement of Disclosure: This study was not funded and has no conflicts of interest.

Influence Of Leg, Arm And Trunk Lean Mass On Aerobic Fitness And Performance In Rowers

Kristin Haraldsdottir, Stacey Brickson, Jennifer Sanfilippo, Andrew Watson. *University of Wisconsin, Madison, WI.*
(No relevant relationships reported)

Rowing is a full body exercise requiring upper body, lower body, and core strength. It has been shown that total lean mass is a predictor of maximal oxygen consumption (VO_{2max}) in athletes. However, the relative contribution of upper extremity, lower extremity and trunk lean mass to VO_{2max} has not been explored. **Purpose:** To determine the relative influence of total lean body mass (LBM), body fat percentage (BF%), upper extremity lean mass (ULM), lower extremity lean mass (LLM) and trunk lean mass (TLM) on maximal aerobic capacity (VO_{2max}) and time to exhaustion (T_{max}) in female collegiate rowers. **Methods:** 107 female collegiate rowers (ages 18-22) performed maximal progressive rowing ergometer testing to determine VO_{2max} and T_{max}. Body mass, LBM, BF%, ULM, LLM, and TLM were determined by dual-energy X-ray absorptiometry. Separate multivariable linear regression models were performed to predict VO_{2max} and T_{max} using LBM and BF% as predictors. When LBM was found to be a separate predictor, separate linear regression models were used to predict VO_{2max} and T_{max} using ULM, LLM and TLM as predictors. **Results:** Subjects were 20.2 ± 1.1 years old, with a VO_{2max} of 3.9 ± 0.5 L/min, T_{max} of 12.7 ± 2.6 minutes, BF% of 23.8 ± 4.8% and LBM of 51.3 ± 6.4 kg. After inclusion in the multivariable model, it was found that VO_{2max} was significantly predicted by LBM (r^2= 0.29, p<0.001) but not BF% (r^2=0.002, p=0.79). Similarly, T_{max} was significantly predicted by LBM (r^2=0.25, p<0.001) but not BF% (r^2=0.003, p=0.19). When evaluating the sources of LBM separately, it was found that VO_{2max} was significantly predicted by LLM (r^2=0.12, p<0.01), but not ULM (r^2=0.08, p=0.68) or TLM (r^2=0.09, p=0.17), and T_{max} was significantly predicted by TLM (r^2=0.09, p=0.02), but not ULM (r^2=0.07, p=0.89) or LLM (r^2=0.08, p=32). **Conclusion:** Among female collegiate rowers, whole body LBM is a significant predictor of both VO_{2max} and T_{max}. However, LLM is a significant predictor of VO_{2max}, while TLM significantly predicts T_{max}. This suggests that the trunk muscles play a significant role in the ability to prolong intense rowing exercise, while the legs consume the most oxygen during rowing. These results may be taken into consideration by coaches and athletes when prescribing in-season training to maximize rowing performance.

Longitudinal Changes in Elite Swimmers' 200 m Freestyle Pacing

Curtis S. Goss, Joel T. Greenshields, Robert F. Chapman, FACSM, Joel M. Stager, FACSM. *Indiana University - Bloomington, Bloomington, IN.* (Sponsor: Joel Stager, FACSM)
(No relevant relationships reported)

PURPOSE: To understand the evolving strategies of elite competitors and to characterize longitudinal changes in pacing parameters in the 200 m freestyle at recent international competitions. **METHODS**: 416 swims from the top 16 finishers in the 200 m freestyle for men and women at 11 Olympic Games and World Championships from 2000-2017 were analyzed. A mixed linear model was used to characterize pacing with 5 different parameters: linear and quadratic parameters for the effect of lap number, differences between predicted and observed time for the first and last laps, and the residual standard error of the estimate summarizing random and systematic deviations from the model. The mean and the 17-year linear trend of final race time and pacing parameters were evaluated using standardization and non-clinical magnitude-based inferences with standardized thresholds of small, moderate, large, very large, and extremely large effects (0.2, 0.6, 1.2, 2.0 and 4.0, respectively). Optimization plots of final time versus each parameter were created. **RESULTS**: Data are presented as mean linear trend change (%) ±90% confidence interval, unless otherwise specified. Men exhibited a very large decrease in final time (-2.27 s; ±0.55 s), with a moderate increase in linear parameter (1.06; ±1.25) and small decrease in quadratic parameter (-0.1; ±0.25). Women exhibited an extremely large decrease in final time (-3.10 s; ±0.49 s), with a small increase in linear parameter (0.61; ±1.05). The first (0.02; ± 0.06) and last lap (-0.07; ±0.23) parameters both displayed small changes. Optimization plots displayed no clear optimum for each parameter for either sex. **CONCLUSIONS**: The sizable decreases in final time coupled with the apparent changes in pacing parameters suggest that swimmers have not only swum faster times from 2000 to 2017, but seem to have also adopted a "starting fast" strategy, evidenced by the increase in linear parameter over this period. The lack of optima in finishing time versus parameter plots suggests that elite swimmers accomplish elite times with a variety of strategies and that pacing can be optimized for individuals but not populations.

Variation in Critical Speed and Finite Distance Capacity of Elite Swimmers

Joel T. Greenshields, Curtis S. Goss, Joel M. Stager, FACSM. *Indiana University, Bloomington, IN.* (Sponsor: Joel M. Stager, FACSM)
(No relevant relationships reported)

Purpose: The purpose of this study was to assess variability in critical speed (CS) and the maximum finite distance capacity above critical speed (D') of elite swimmers using longitudinal performance data.
Methods: Top 100 results from the FINA World Rankings from 2011 - 2017 in the 200, 400, 800, and 1500-meter freestyle events were used to produce CS models. Swimmers with a top 100 time in a minimum of three of the four events within a given year were included in the analysis. Linear regression models were calculated using distance as the dependent variable and performance time of the race as the independent variable. From the regression model, D' was expressed as the intercept and CS as the slope of the line. Repeated measures analysis of the log-transformed calculated values provided the typical variation of a D' and CS values.
Results: On average, 45 (37-49) men swimmers and 45 (40-54) women swimmers per year were eligible for inclusion in the analysis. Average calculated D' was (M = 25.22 ± 3.60 m; W = 23.51 ± 2.80 m) and CS was (M = 1.62 ± 0.02 m*s[-1]; W = 1.51 ± 0.02 m*s[-1]). The linear trend over the seven-year time period in D' was (M = 3.22; ±8.15 %; W = 2.42; ±7.95 %) and CS was (M = 0.48; ±0.41 %; W = 0.35; ±0.51 %). The within-swimmer variability between-year expressed as a coefficient of variation (CV) with 90 % confidence limit of D' was (M = 25.35; ±2.37 %; W = 29.05; ±3.0 %) and CS was (M = 1.05; ±0.1; W = 1.48; ±0.13 %). The between-swimmer variability expressed as CV of D' was (M = 29.0 %; W = 34.64 %) and CS was (M = 1.41 %; W = 1.74 %). The smallest worthwhile change in D' (M = 2.55 %; W = 2.97 %) and CS (M = 0.14 %; W = 0.17 %) were calculated. All selected distances showed strong correlations between performance time with D' and CS (*r* > 0.63). The 1500 m distances showed near perfect but inverse correlations between performance time and CS (M: *r* = -0.96; W: *r* = -0.99).
Conclusions: Changes in performance trends over the seven-year time period can be attributed largely to changes in CS. Potential causes of the large amount of within and between swimmer variations in D' should be explored further in relation to changes in pacing strategies. Additionally, the smallest worthwhile change values of D' and CS provide practical applications regarding the effectiveness of training interventions and athlete progression.

Fitness-Related Benefits: Land Versus Aqua

Rachel Williams[1], Ryan Swiezy[1], Maddison Patterson[1], Rachel McCormick[1], Blair Bonner[1], Amber Ausley[1], Raechel Santee[1], Aubrey Burgess[1], Virginia Wilson[1], Hayley Grimes[1], Michel Heijnen[1], Tiago Barreira[2], Wayland Tseh[1]. [1]*University of North Carolina Wilmington, Wilmington, NC.* [2]*Syracuse University, Syracuse, NY.* (Sponsor: Robert Boyce, FACSM)
(No relevant relationships reported)

PURPOSE: To compare fitness-related benefits between land-based (LAND) versus aqua-based (AQUA) courses. **METHODS:** Informed consent was received from

154 volunteers (N = 76 LAND; N = 78 AQUA) who were asked to exercise within each respective course 2 days per week, 50-min per day, for 15 weeks. Pre- and post-fitness assessments obtained were body composition, muscular endurance, muscular strength, cardiorespiratory endurance, and flexibility. **RESULTS:** Mixed ANOVA was used to investigate mean differences between pre- and post-fitness assessments and between groups. There was a main effect (p = 0.003) and interaction (p = <0.001) for body composition in which, overall, participants decreased percent body fat, however, paired t-test revealed that LAND (20.4% ± 7.3% to 19.0% ± 7.4%) had a significant reduction in mean percent body fat while AQUA did not (20.1% ± 8.7% to 20.2% ± 8.9%). A main effect for both muscular strength (p = <0.001) and muscular endurance (p = <0.04) was revealed, but no interactions, therefore, both groups improved on aforementioned variables. Lastly, no significant main effect or interaction for neither cardiorespiratory endurance nor flexibility assessments were revealed. **CONCLUSIONS:** Individuals participating in land-based courses displayed greater decreases in percent body fat when compared to aqua-based courses, whereas both land- and aqua-based displayed improvements in muscular strength and muscular endurance. There were no changes in cardiorespiratory endurance and flexibility within both groups.

Reliability and Validity of Swimming Flume Protocol to Measure Maximal Aerobic Power of Healthy Adults

Elizabeth F. Nagle, FACSM[1], Takashi Nagai[1], Anne Beethe[1], Mita T. Lovalekar[1], Jacquelyn N. Zera[2], Christopher Connaboy[1], John P. Abt[3], Robert J. Robertson, FACSM[1], Scott M. Lephart[3], Brad D. Nindl, FACSM[1]. *[1]University of Pittsburgh, Pittsburgh, PA. [2]John Carroll University, Cleveland, OH. [3]University of Kentucky, Lexington, KY.*

(No relevant relationships reported)

A modality specific swimming protocol to assess maximal aerobic power (MAP) is essential to accurately quantify swimming training and performance. A graded intensity MAP swimming protocol executed in a swimming flume controls swimming speed (i.e. velocity), and may facilitate kinematic and metabolic assessments. **PURPOSE:** To assess: 1) reliability of a swimming flume maximal oxygen consumption ($VO2max_{fl}$) (i.e. MAP) protocol; and 2) validity of a $VO2max_{fl}$ protocol using a swimming pool performance swim (PS) test as the criterion. **METHODS:** Nineteen healthy males (n=9) and females (n=10) (age, 28.5±8.3 yrs; height, 174.7 ± 8.2 cm; weight, 72.9 ± 12.5 kg; %body fat, 21.4 ± 5.9) performed two swimming flume $VO2max_{fl}$ tests ($VO2max_{fl}A$ and $VO2max_{fl}B$), and one PS test [500 meters (444.7 ± 139.4 seconds)]. Test-retest reliability of $VO2max_{fl}$ (ml·kg^{-1}·min^{-1}), HRmax (b·min^{-1}), cardiorespiratory efficiency (O2 pulse; $VO2max_{fl}$/HRmax), maximal respiratory exchange ratio (RERmax), ventilation (Vemax) (L·min^{-1}), and PS test time was assessed by ICC's (2,1). Test validity was determined by correlating $VO2max_{fl}A$ with the PS using Pearson's coefficients. **RESULTS:** Intra-subject reliability (ICC) for cardiorespiratory responses during the $VO2max_{fl}A$ and $VO2max_{fl}B$ tests are presented in Table 1. For validity, a moderate correlation was found between $VO2max_{fl}A$ and 500 PS (r =-0.478; p<0.05). **CONCLUSIONS:** The $VO2maxfl$ test employed presently is a reliable and functionally valid assessment of MAP. It is proposed that a swimming flume-based protocol to measure MAP will facilitate mode specific comparisons of test responses with performance outcomes for military, clinical, or athletic populations.

Table 1					
Variable	N	$VO_2max_{fl}A$	$VO_2max_{fl}B$	ICC	p-value
VO_2max_{fl}(ml·kg^{-1}min^{-1})	18	46.7± 8.6	47.9±8.5	0.628**	.002
HRmax, (b·min^{-1})	19	172 ± 18	174 ± 11.8	0.403*	.041
O2pulse (ml· b^{-1})	19	0.3 ± 0.1	0.3 ± 0.1	0.502*	.014
RERmax	19	1.2 ± 0.3	1.1 ± 0.2	0.559**	.002
Vemax (l·min^{-1})	19	103.5 ± 20.2	111.6 ± 25.3	0.671**	.000

Physiological Responses to Swimming Pool and Swimming Flume Maximal Aerobic Power Protocols

Jacquelyn N. Zera[1], Elizabeth Nagle, FACSM[2], Takashi Nagai[3], Mita Lovalekar[2], Christopher Connaboy[2], Anne Beethe[2], John Abt, FACSM[4], Scott Lephart, FACSM[4], Bradley Nindl, FACSM[2]. *[1]John Carroll University, University Heights, OH. [2]University of Pittsburgh, Pittsburgh, PA. [3]Mayo Clinic, Rochester, MN. [4]University of Kentucky, Lexington, KY.* (Sponsor: Elizabeth Nagle, FACSM)

(No relevant relationships reported)

The importance of a swimming specific test of maximal aerobic power (VO_{2max}) to assess aerobic fitness, track training adaptations, and predict performance is well established. The ability to incrementally and systematically regulate intensity with changes to flow has made swimming flume tests (VO_{2maxfl}) a desirable laboratory tool, although few exist due to the complexity and cost of equipment. Pool tests (VO_{2maxsw}) simulate free swimming and are more cost effective. However, little research has compared these modes. **Purpose:** To examine the relationship between physiological responses to VO_{2maxsw} and VO_{2maxfl}. **Methods:** Fifteen males (n=5) and females (n= 10) (age= 25.1 ± 8.5 years; BMI = 23.5 ± 3.4 kg·m²; body fat = 20.6 ± 7.0%) performed two volitional maximum swimming tests: (VO_{2maxsw}) a multi-stage swimming pool test of increasing self-regulated intensities and (VO_{2maxfl}) a graded swimming flume test of increasing flow rates, both previously described in the literature. Oxygen consumption (VO_2, ml·kg^{-1}·min^{-1}), ventilation (VE, L·min^{-1}), heart rate (HR, b·min^{-1}), and respiratory exchange ratio (RER) were measured continuously, and ratings of perceived exertion (RPE), blood lactate (BLa; mmol^{-1}), and test duration (T$_{time}$; seconds) were measured post-test. Normality was assessed, and a paired samples t-tests or Wilcoxon signed rank test, and Pearson or Spearman correlation coefficients were used, as appropriate. **Results:** VO_{2max} (p= 0.005), VE$_{max}$ (p= 0.008), RER (p= 0.011), and T$_{time}$ (p=0.001) were significantly higher, and RPE (p=0.004) was significantly lower in the VO_{2maxfl}. Additionally, no significant differences were detected for HR$_{max}$, and BLa. Finally, strong correlations were reported between the two tests for VO_{2max} (r= 0.908; p<0.001) and VE$_{max}$, (r= 0.853; p<0.001), and a moderate correlation for BLa (r= 0.634; p= 0.020). There were no significant correlations between the two tests for RER, HRmax, RPE, and T$_{time}$. **Conclusions:** Results indicate that a VO_{2maxfl} elicited higher maximal physiological responses compared to a VO_{2maxsw}, indicating that VO_{2maxfl} may provide a better mode for assessing maximal aerobic capacity in swimmers. Future research should explore the swimming flume's flow and propulsion characteristics on kinematics and its impact on the ability to predict performance.

Changes in Collegiate Swim Anaerobic Performance Between Pre-season and Post-season

Haoyan Wang[1], Guillaume Spielmann[1], Brian Irving[1], Jack Marucci[1], Shelly Mullenix[1], Brian Harrell[2], Rick Sharp, FACSM[3], Neil Johannsen[1]. *[1]Louisiana State University, Baton Rouge, LA. [2]Baton Rouge General Sport Medicine, Baton Rouge, LA. [3]Iowa State University, Ames, IA.*

(No relevant relationships reported)

PURPOSE: To examine the cyclical nature of collegiate swim training on anaerobic performance. **METHODS:** Ten NCAA Division 1 swimmers (n=4 women, age 20.3±0.5 y, weight 64.8±12.3 kg; n=6 men, age, 20.0±0.6 y, weight, 82.6±6.9 kg; mean±SD) participated in 3 testing sessions: immediate post-season (V$_1$), mid-offseason (V$_2$), and early season (V$_3$) separated by 8 weeks between V$_1$ and V$_2$, and 14 weeks between V$_2$ and V$_3$. Each testing session was comprised of an in-pool power test consisting of incrementally-loaded 25-m swims at maximal effort. During the test, participants were attached to a pulley system ending with a 20-gallon bucket. Initial load was set at 40 lbs for men and 20 lbs for women, and increased by 20 lbs and 15 lbs respectively after each trial completion. Swimmers were allowed to rest for 3 min after each trial. Speed, work, and power were calculated using the distance traveled per second factoring in the additional weight in bucket. Heart rate (HR), lactate (La$^-$), and rating of perceived exertion (RPE) were assessed within the first minute of each rest period. Two-way RM-ANOVAs (visits×bucket weight) were used to compare the effect of training across the primary outcomes. **RESULTS:** A main effect of visit was observed for average speed whereby V$_2$ was faster in women (V$_1$: 1.08±0.26 m/s, V$_2$: 1.19±0.18 m/s, V$_3$: 1.11±0.31 m/s; P<0.001) and men (V$_1$: 1.20±0.26 m/s, V$_2$: 1.41±0.29 m/s, and V$_3$: 1.25±0.26 m/s; P<0.001) compared to V$_1$ and V$_3$. In addition, an interaction for speed at higher weights was observed and post-hoc analysis revealed higher speeds during V$_2$ in women at 65 lbs (V$_1$:0.75±0.22 m/s, V$_2$: 0.99±0.06 m/s, V$_3$: 0.73±0.25 m/s; P<0.02) and men at 120 lbs (V$_1$: 0.83±0.09 m/s, V$_2$: 1.45±0.57 m/s, V$_3$: 0.77± 0.14 m/s; P<0.001). A main effect of visit was seen for HR demonstrating a higher average HR during V$_2$ in women (165.3±14.4 bpm) compared to V$_1$ (156.7±17.1 bpm) and V$_3$ (156.2±14.8

bpm; P<0.02). RPE and La⁻ were not different between the three visits (P>0.05). Total work per stroke was also higher at 65 lbs in women across visits (V$_1$: 11.9±1.5 Nm, V$_2$: 16.8±2.9 Nm, V$_3$: 12.1±1.6 Nm; P<0.04).
CONCLUSIONS: Swimmers had better anaerobic performance during mid-offseason while their overall training load was reduced in both women and men. The greater swimming speeds at similar RPE and La⁻ suggest that the swimmers may benefit from altered training.

Acute Cardiometabolic Responses to Medicine Ball Exercise in Children

Avery D. Faigenbaum, FACSM, Jie Kang, FACSM, Anne Farrell, Nicholas A. Ratamess, Nicole Ellis, Ira Vought, Jill Bush, FACSM. *The College of New Jersey, Ewing, NJ.*
(No relevant relationships reported)

Medicine ball (MB) exercises are effective for strength and conditioning in adults, but the cardiometabolic demand of this training modality for children is unknown. **PURPOSE**: To examine the acute cardiometabolic responses to MB exercise in children. **METHODS**: 14 children (10.1 ± 1.3 yr) were tested for peak oxygen uptake (VO$_2$) on a treadmill and subsequently (> 48 hours later) performed a progressive 10 min MB protocol of 5 exercises (EX): standing marches (EX1), alternating lunges (EX2), squat swings (EX3), chest passes (EX4) and double arm slams (EX5). A 2.3 kg MB was used for all trials and each MB exercise was performed twice for 30 sec with a 30 sec rest interval between sets and exercises. Participants exercised while wearing a heart rate (HR) monitor and connected to a metabolic system. Comparisons between exercises were made using one-way analysis of variance with repeated measures. **RESULTS**: Peak values for HR and VO$_2$ during the treadmill test were 198.9 ± 8.3 bpm and 54.9 ± 10.1 ml · kg⁻¹ · min⁻¹, respectively. During the MB protocol, mean HR significantly (p<0.05) increased from 121.5 ± 12.3 bpm during EX1 to 178.3 ± 9.4 bpm during EX5 and mean VO$_2$ significantly (p<0.05) increased from 15.5 ± 2.9 ml · kg⁻¹ · min⁻¹during EX1 to 34.9 ± 5.1 ml · kg⁻¹ · min⁻¹during EX5. Mean HR and VO$_2$ values during the MB protocol ranged from 61.1% to 89.6% and 28.2% to 63.5% of HRpeak and VO$_2$peak, respectively. **CONCLUSION**: These descriptive data indicate that MB exercise can pose a moderate-to-vigorous cardiometabolic stimulus in children and may serve as a worthwhile compliment to youth strength and conditioning programs.

Dynamic Stretching Can Impair performance Of Adolescent Male handball Players For at Least 24 Hours.

Monoem Haddad[1], Mohammad Shoaib Prince[1], Nidhal Zarrouk[2], Karim Chamari[2], David G Behm[3]. *[1]Qatar University, Doha, Qatar. [2]Aspetar, Doha, Qatar. [3]Memorial University of Newfoundland, Newfoundland, NL, Canada.*
(No relevant relationships reported)

PURPOSE: There are many adult studies reporting static stretch (SS)-induced deficits and dynamic stretch (DS) performance improvements shortly after the intervention. However, there is only a single study examining stretch-induced performance changes with children at 24 hours' post-stretch. The objective of this study was to examine physiological responses of adolescent trained athletes at 24 hours after experiencing SS or DS protocols. **METHODS**: Ten male adolescent, elite handball players (age: 16±05 years) were tested prior to-, 3 minutes- and 24 hours- following the three conditions (DS, SS, Control). Tests included (i) two 4s MVCs at 60⁰ of knee flexion with 2 min rest, (ii) two isokinetic contractions each at 60⁰/sec and 300⁰/sec with 1 min rest, and (iii) two drop jumps with 30s rest. To simulate a full warm-up, dynamic aerobic activity was instituted before the pre-tests and following the interventions. **RESULTS**: Three-way repeated measures ANOVAs revealed that 1) both the SS and control conditions exhibited knee extensor 60⁰.s⁻¹ (-8.7 to -16.3%) and 300⁰.s⁻¹ (-10.3 to 12.9%) isokinetic force and power-related deficits at post-test, 2) DS impaired knee flexor 60⁰.s⁻¹ isokinetic force (-9.9 to -10.1%) and power-related (-9.6 to 19.1%) measures at post-test and at 24 hours' post-test, 3) DS (12.07% and 10.47%) and SS (13.7% and 14.6%) enhanced knee flexor 300⁰.s⁻¹ isokinetic force and power-related measures compared to control. **CONCLUSIONS**: Testing-induced knee extensor isokinetic impairments were counterbalanced by DS, however the hip flexion DS could have produced minor muscle damage decreasing knee flexor forces and power at 600.s-1.

Recently, the need for acquiring the habit of exercise since childhood is increasing. As its background, the awareness of likes and dislikes pertaining to, and strengths and weaknesses of exercise is sometimes clarified in childhood. In order to resolve the decrease in children's physical fitness, it is necessary to convey children the pleasures of exercise at an early stage. Therefore, educators should promote exercise opportunities that exclude children's awareness of weaknesses and prioritize expressing the pleasures of exercise. Hence, we ought to understand exactly what kind of scene and situation makes children find pleasure in exercise. **PURPOSE:** The purpose of this study was to examine the difference in the kind of scenes and situations that make children find pleasure in exercise between children who like and dislike exercise. **METHODS:** The subjects of this study were 1846 elementary school children who belonged to the 5th or 6th grade. Data from seventeen items related to liking or disliking exercise, scenes and situations that make children find pleasure in exercise, and value of exercise were analyzed. The difference between children who liked and disliked exercise was analyzed using chi-square test. The most sensitive item to distinguish between children who liked and disliked exercise was examined using decision tree analysis. **RESULTS:** The ratio of children who liked exercise was 81.9% in boys and 69.1% in girls. Children who liked exercise understood the value of exercise for health and a good life significantly more than children who disliked exercise. A significant relationship was confirmed between all items related to scenes and situations that make children find pleasure in exercise and like or dislike exercise. The item "it is fun to exercise with many friends" was used to classify children who liked and disliked exercise most sensitively using decision tree analysis. In addition, 90.3% of the children who did not find pleasure in winning the game answered that they disliked exercise. **CONCLUSIONS:** It was confirmed that most of the children who dislike exercise did not understand the value of exercise since childhood. Conveying the pleasures of exercise since childhood was important. However, it was suggested that focusing excessively on winning or losing has the risk of promoting dislike of exercise.

Development and Validation of the Chinese Assessment of Adolescent Physical Literacy

Yan Peng[1], Ming Yang[2], Liangqiu Yang[3], Chuandong Wei[1], Jindong Chang[2]. *[1]SiChuan Aerospace Vocational College, Chengdu, China. [2]Southwest University, Chongqing, China. [3]Northeast Normal University, Changchun, China.*
(No relevant relationships reported)

PURPOSE: China's physical fitness has been declining for nearly 30 years. How to improve the quality of youth fitness into a focus. The Canadian assessment of Physical Literacy (CAPL) provided a path to evaluate Chinese adolescent physical. The purpose of developing and validating an evaluation system of Chinese adolescent physical literacy.
METHODS: Through the database of Web of Science, PubMed, and CNKI, the primary institutional resources of Physical literacy at home and abroad were collected, and the index system of adolescent physical literacy was constructed by Delphi method and mathematical statistics way.
RESULTS: Using the Likert 5 point scale designed the Chinese Evaluation of physical literacy (CEPL). Using exploratory factor analysis (EFA) method explored the reliability of the CEPL that Cronbach's alpha coefficients were 0.85. Three factors were extracted that the cumulative contribution rate was 60.6%, three elements were verified by the adolescent's physical literacy self-measurement scale of the three dimensions, each coefficient was above 0.82, and the re-test reliability range of three factors was between 0.80-0.82. The version of ESCAPL was composed of four parts, daily behavior, physical ability, knowledge and understanding and motivation, and confidence. The results of the assessment were divided into four grades as follows, Initial level <41.5, Development level 41.5 ~ 62.5, Higher level 62.6 ~ 78.5, and the highest level> 78.5.
CONCLUSIONS: The evaluation index system of adolescent physical literacy evaluation is judged by expert two rounds, and the indexes are effective. After the empirical test, the adolescent physical literacy self-test scale and the physical ability measurement table have the high reliability and the validity can be used for the young athletic level measurement and the appraisal. The research was supported by NPOPSS Grant 15CTY011, and Fundamental Research Funds for the Central Universities Grant 1709240.

Physical Activity Guideline Adherence and Physical Fitness: The NHANES National Youth Fitness Survey

Matthew P. Smudde, Kelly R. Laurson, Dale D. Brown, FACSM, Karen K. Dennis. *Illinois State University, Normal, IL.*
(No relevant relationships reported)

Encouraging regular physical activity (PA) is a major public health objective in the United States for several reasons, including the promotion of physical fitness. As such, the first edition of federal Physical Activity Guidelines for Americans (PAG) was released in 2008. For youth, these PAG include recommendations for aerobic and muscle-strengthening (MS) activity. **PURPOSE:** To examine the association between adherence to PAG and physical fitness in a nationally-representative sample of children and adolescents. **METHODS:** The NHANES National Youth Fitness Survey (NNYFS) collected fitness test and PA questionnaire data on children and adolescents (ages 3-15 years, n = 1,576). Fitness testing was completed for the plank (3-15 years), modified pull-up (5-15 years), handgrip strength (6-15 years), and aerobic fitness (12-15 years) by trained test administrators. Fitness test results were converted into age-specific percentile scores. All subjects reported the number of previous days of the week that included 60 minutes of PA, while 12-15 year olds also reported the number of previous days that included MS activities. Independent *t*-tests were used to compare the mean physical fitness percentile of youth reporting 7 days of 60 minutes of PA to those reporting ≤ 6 days and adolescents reporting 2 or more days of muscle-strengthening activity to those reporting ≤ 1 day. **RESULTS:** Youth reporting 7 days/week of PA had a higher mean relative grip strength (53.8 vs. 46.8 percentile), modified pull-up (53.7 vs. 47.1 percentile), and VO$_2$max (48.9 vs. 40.8 percentile) compared to those with ≤ 6 days/week (all $p < 0.05$). Those participating in MS activity 2 days/week had a higher relative grip strength (54.7 vs. 45.3 percentile), modified pull-up (54.2 vs. 46.8 percentile), plank (54.5 vs. 44.4 percentile), and VO$_2$max (45.7 vs. 39.8 percentile) compared to the ≤ 1 day/week group (all $p < 0.05$). **CONCLUSION:** In this nationally-representative sample, meeting PAG's were associated with measures of aerobic capacity, muscular strength, and muscular endurance. Future prospective research is needed to investigate the impact of changing PA level to meet (or not meet) the PAG on physical fitness.

Three-Year Tracking of Moderate-to-Vigorous Physical Activity During Structured and Unstructured Play In Youth

Michael J. Wierenga[1], Kimberly A. Clevenger[1], Rebecca W. Moore[2], Karin A. Pfeiffer, FACSM[1]. *[1]Michigan State University, East Lansing, MI. [2]Eastern Michigan University, Ypsilanti, MI.* (Sponsor: Karin Pfeiffer, FACSM, FACSM)
(No relevant relationships reported)

Tracking is the maintenance of a relative position within a group over time. Previous studies indicate that habitual, moderate-to-vigorous physical activity (MVPA) tracks at low to moderate levels in youth, but there is limited research on specific contexts of MVPA, such as during structured and unstructured play. **PURPOSE:** To characterize tracking of MVPA in youth across four time points during a three-year period for both structured and unstructured play. **METHODS:** Youth (N=108), 58.3% female, 6-15 years old, visited the laboratory four times over three years. During each visit, participants engaged in 30 minutes each of structured and unstructured play. Youth wore a uniaxial accelerometer on an elastic belt over their right hip (data collected in 1-second epochs). MVPA minutes were determined using Evenson cut-points (≥574 counts/15-sec). Tracking of MVPA minutes was evaluated using tracking coefficients (Pearson's r) between each pair of time points [classified as low ($r<0.30$), moderate (r=0.30-0.60), or moderately high ($r>0.60$)] and intra-class correlations (ICC) via ANOVA. ICCs provided an overall correlation across the four time points [classified as poor (ICC<0.50), moderate (ICC=0.50-0.75), good (ICC=0.75-0.90), or excellent (ICC>0.90)]. Participants were classified into quartiles of MVPA for each visit, and percent agreement and weighted kappa [classified as poor (κ≤0.20), fair (κ=0.21–0.40), moderate (κ=0.41–0.60), good (κ=0.61–0.80), or very good (κ=0.81–1.0)] were calculated. **RESULTS:** Tracking coefficients were non-significant to moderate for structured play (r=-0.20-0.30) and moderate to moderately high for unstructured play (r=0.38-0.66, p's<0.05). The ICC was classified as poor (0.42) for structured play and excellent (0.80) for unstructured play ($p<0.05$). Percent agreement ranged from 24.0-36.6% for structured play and 30.1-44.3% for unstructured. Weighted kappa for structured play ranged from non-significant to poor (-0.09-0.19), but was fair to moderate (0.24-0.49, p's<0.05) for unstructured. **CONCLUSION:** We found evidence of low to moderate tracking for participation in MVPA during structured and unstructured play. Results suggest that MVPA during structured and unstructured play tracks similarly to habitual physical activity in youth.

2180   Board #16   June 1 9:30 AM - 11:00 AM

Association Between Tri-Ponderal Mass Index and FITNESSGRAM Aerobic Capacity Classification in Sixth-Grade Children

John L. Walker, FACSM[1], Tinker D. Murray, FACSM[1], James Eldridge, FACSM[2], William G. Squires, Jr., FACSM[3]. *[1]Texas State University, San Marcos, TX. [2]University of Texas at the Permian Basin, Odessa, TX. [3]Texas Lutheran University, Seguin, TX.*
(No relevant relationships reported)

FITNESSGRAM has established criterion standards for body composition and body mass index (BMI) according to gender and age in children. Standards for aerobic capacity (AC) have also been established to assess cardiorespiratory function. Tri-Ponderal Mass Index (TMI) has been shown to better classify overweight and obesity than BMI in youth. **PURPOSE**: The purpose of this study was to determine the association between TMI and FITNESSGRAM AC classification in sixth-grade children. **METHODS**: Subjects were 528 sixth-grade boys and girls, ages 11-13, who completed each of the FITNESSGRAM components as a part of their yearly assessment. In addition to height and weight, subjects' AC was determined from one-mile run/walk times, age, gender and BMI. 52% percent of these students were classified within the Healthy Fitness Zone (HFZ) for AC. 31% percent of these students were classified as High Risk for AC. **RESULTS**: The correlation between TMI and BMI was .98, and the correlation between BMI and AC was -.75. The correlation between TMI and AC was -.73. Receiver Operating Characteristic (ROC) analysis indicated that a TMI of 13.94 represents the best cut-off score for classifying girls within the HFZ for AC, with 90% classified correctly, and AUC = .96. Also, a TMI of 15.05 represents the best cut-off score for classifying boys within the HFZ for AC, with 90% classified correctly, and AUC = .95. For determining High Risk classification for AC, a TMI of 16.53 represents the best cut-off score for classifying girls as High Risk for AC, with 92% classified correctly, and AUC = .96. Also, a TMI of 17.75 represents the best cut-off score for classifying boys as High Risk for AC, with 93% classified correctly, and AUC = .97. **CONCLUSIONS**: TMI is strongly associated with classification according to FITNESSGRAM AC standards in sixth-grade children. These data suggest that a TMI of 13.94 for girls and 15.05 for boys are the best criteria for HFZ classification for FITNESSGRAM AC. Also, a TMI of 16.53 for girls and 17.75 for boys are the best criteria for High Risk classification for FITNESSGRAM AC. Appropriate evaluation of body size is important since body size has been shown to be highly related to aerobic capacity and performance, especially in weight-bearing exercises.

The Influence Of Non-cognitive Functional Characteristics At Age 6 On Physical Fitness Characteristics At Age 10

Kosho Kasuga[1], Takahiro Nakano[2], Kazuo Oguri[3], Tomoaki Sakai[2]. *[1]Gifu University, gifu, Japan. [2]Nagoya Gakuin University, seto, Japan. [3]Gifu Shotoku Gakuen University, gifu, Japan.* (Sponsor: Kiyoji Tanaka, FACSM)
(No relevant relationships reported)

Human non-cognitive functioning is developed mostly in early childhood. It may be that physical characteristics during childhood affected by daily exercise behaviors are also affected by non-cognitive functional characteristics in the early childhood. **PURPOSE**: The purpose of this study was to examine the influence of non-cognitive functional characteristics at the age of 6 years on the physical fitness characteristics at the age of 10 years.
METHODS: Subjects included 223 children (110 boys and 113 girls) who performed the physical fitness test (eight exercises) at 10 years of age. In order to understand non-cognitive functional characteristics at 6 years of age, a questionnaire of 21 questions consisting of 8 items (self-recognition, motivation, perseverance, self-control, social appropriateness, resilience and coping ability, creativity, and personality) was used. Evaluation of non-cognitive function was carried out by three kindergarten teachers who had the experience of being their homeroom teacher. From the evaluation obtained, grouping was performed with the upper group (UG), the middle group (MG), and the lower group (LG) based on the evaluation value of each non-cognitive function. Statistical analysis of the data was conducted using a one-way ANOVA and multiple comparisons (Tukey's HSD test) to compare physical fitness among the groups.
RESULTS: Results of the analysis revealed significant differences in physical fitness in all items except "nervous" among the 21 questions. UG of each item was significantly higher than LG. In particular, there was a very high effect size (ES) in "persistent efforts" (ES: 1.99), "ingenuity" (ES: 1.92), and "ability to pull out" (ES: 1.85).

CONCLUSIONS: It was suggested that children with increased non-cognitive functions such as condition judgment ability and tenacity in early childhood have a good effect on physical fitness at school age.

A Comparison of Health Related Fitness Variables between Youths in Singapore and Hong Kong

Yew Cheo Ng[1], Govindasamy Balasekaran, FACSM[1], Stanley Sai-Chuen Hui, FACSM[2], Visvasuresh Victor Govindaswamy[3], Jolene Lim[1], Peggy Boey[1]. [1]Nanyang Technological University, Singapore, Singapore. [2]The Chinese University of Hong Kong, Shatin, Hong Kong. [3]Concordia University Chicago, Illinois, IL.
(No relevant relationships reported)

Physical fitness encompasses health-related fitness (HRF) variables which may reduce cardiovascular risk factors if identified early in youths. **Purpose:** To compare HRF variables between youths in Singapore (SGP) and Hong Kong (HK). **Methods:** A total of 1559 youths from SGP (age: 13.49 ± 1.21 years, height: 159.76 ± 8.94 cm, weight: 51.91 ± 13.38 kg, Body Fat (BF) %: 21.51 ± 10.25 %) and 1530 youths from HK (age: 13.51 ± 0.98 years, height: 160.69 ± 8.40 cm, weight: 52.20 ± 12.43 kg, BF%: 21.16 ± 9.99 %) participated in this study. Body Mass Index (BMI) and BF% were measured by bio-electric impedance analysis. Cardiovascular fitness, lower limb flexibility, arm strength, abdominal endurance were tested using the 15m youth Progressive Aerobic Cardiovascular Endurance Run test (PACER), one-legged sit-and-reach test for both legs (SRT), handgrip strength test for both hands (HS), and 1-minute sit-up test (SUT) respectively. **Results:** Using the Independent T-Test, significant differences were found between SGP and HK youths for height (SGP: 159.76 ± 8.94 cm, HK: 160.69 ± 8.40 cm, $p < 0.0005$), SRT (SGP: 54.14 ± 10.15 cm, HK: 49.59 ± 12.04 cm, $p < 0.0005$), HS (SGP: 25.18 ± 7.77 kg, HK: 26.01 ± 6.96 kg, $p = 0.002$), SUT (SGP: 38.94 ± 11.92, HK: 30.56 ± 10.14, $p < 0.0005$) and PACER (SGP: 40.93 ± 23.90 laps, HK: 35.49 ± 18.44 laps, $p < 0.0005$). There were no significant differences in weight, BMI, and BF% between youths in both countries, with low obesity rates in both countries (SGP: 12.7%, HK: 10.32%). **Conclusion:** Results indicated similar body composition results in both countries. SGP youths had lesser arm strength as compared to HK youths. However, SGP youths had higher abdominal endurance, better flexibility and were more aerobically fit as compared to HK youths. Both SGP and HK youths need to maintain their physical activities to improve their cardiovascular fitness as this will help to reduce cardiovascular diseases in youths in the future.

2183   Board #19   June 1 9:30 AM - 11:00 AM

Effects of Jump Rope Exercise on Stretch-Shortening Cycle Ability in Elementary School Students

Kazufumi Terada[1], Tatsuki Nakagawa[2], Nobuyuki Miyai[3], Miyoko Utsumi[3], Toshiaki Nakatani[1], Mikio Arita[3]. [1]Tenri University, Tenri, Japan. [2]Tenri University Graduate School, Tenri, Japan. [3]Wakayama Medical University, Wakayama, Japan.
(No relevant relationships reported)

PURPOSE: Not much research has investigated how jump rope exercise can lead to improvements in physical abilities, including stretch-shortening cycle (SSC) ability, in children. This study examined whether the maximum number of jumps elementary school students could perform in a jump rope exercise ("max jump count": MJC below) was associated with their jumping performance, short-distance sprint performance, and other fitness indicators, as well as whether a jump rope training program led to improvements in those abilities.
METHODS: Seventy-four elementary school students (34 boys, 40 girls) aged from 6 to 12 years old participated in this study (mean height: 138+11 cm, mean weight: 33+8 kg). In addition to MJC, all students were assessed in terms of 20-m sprint time (ST), rebound jump index (RJI), vertical jump (VJ), and grip strength (GS). For RJI, students were measured with an optical measurement system as they performed five consecutive rebound jumps with both legs: RJI was calculated as jump height divided by ground contact time. Pearson's product-moment correlation coefficients (r) were determined to check for associations between MJC and the other fitness indicators. The training effects of jump rope exercise were investigated by comparing students' performance before and after completing four weeks of training. Students were allowed to decide for themselves how often to jump rope during these four weeks.
RESULTS: Before training, students achieved a mean MJC of 93+98 jumps, with a range of 2-459 jumps. A negative correlation was observed between MJC in before training and ST ($r=-0.46$, $p<0.01$). Additionally, positive correlations were observed between it and RJI ($r=0.57$, $p<0.01$), VJ ($r=0.33$, $p<0.01$) and GS (left-hand: $r=0.31$, $p<0.01$; right hand: $r=0.34$, $p<0.01$). Four weeks of training resulted in significant improvements in MJC ($+43\%$, $p<0.001$), RJI ($+7\%$, $p<0.05$), and VJ ($+5\%$, $p<0.01$). However, jump rope exercise frequency did not result in any apparent differences in training effects.

CONCLUSIONS: These results suggest that MJC was associated with a variety of physical abilities in elementary school students. However, it could not be clearly demonstrated that jump rope training improve performance indicators related to SSC ability in elementary school students.

A Comparison Of Health Related Fitness Variables Between The Youths Of Singapore And Bangkok

Govindasamy Balasekaran, FACSM[1], Stanley Sai-Chuen Hui, FACSM[2], Kallaya Kijboonchoo[3], Visvasuresh Victor Govindaswamy[4], Jolene Lim[1], Ng Yew Cheo[1], Peggy Boey[1]. [1]Nanyang Technological University, Singapore, Singapore. [2]The Chinese University of Hong Kong, Shatin, Hong Kong. [3]Institute of Nutrition, Mahidol University, Salaya, Thailand. [4]Concordia University Chicago, Chicago, IL.
(No relevant relationships reported)

Obesity is identified as a worldwide issue and thus assessing health related components of physical fitness in youths may help in identifying risk factors associated with obesity. **Purpose:** To compare fitness variables between the youths of Singapore (SGP) and Bangkok (BKK). **Methods:** A sample of 1559 (Age: 13.49 ± 1.21 yrs; Height: 159.76 ± 8.94 cm; Weight: 51.91 ± 13.38 kg) youths from SGP and 1098 (Age: 13.95 ± 0.85 yrs; Height: 158.88 ± 7.98 cm; Weight: 53.01 ± 14.13 kg) youths from BKK were recruited for this study. Body composition was measured using a bio-impedance analysis (BIA) machine. A one-legged sit-and-reach test for both legs (SRT), handgrip strength test for both hands (HST), sit-up test (SUT), and 15m youth Progressive Aerobic Cardiovascular Endurance Run (PACER) test was conducted to measure flexibility, arm strength, abdominal endurance, and cardiorespiratory endurance respectively. **Results**: There was a significant difference in body composition between the youths in SGP and BKK, as indicated by their body mass index (SGP: 20.19 ± 4.21 kg.m^{-2}, BKK: 20.85 ± 4.64 kg.m^{-2}, $p < 0.0005$) and body fat percentage (SGP: 21.51 ± 10.25 %, BKK: 23.43 ± 11.23 %, $p < 0.0005$). Significant differences were found between the youths of both countries for SRT for both legs (SGP: 108.27 ± 20.31 cm, BKK: 103.59 ± 18.25 cm, $p < 0.0005$), HST for both hands (SGP: 50.32 ± 15.53 kg, BKK: 52.20 ± 12.72 kg, $p = 0.001$), SUT (SGP: 38.94 ± 11.92, BKK: 27.19 ± 9.72, $p < 0.0005$), and PACER (SGP: 40.93 ± 23.90 laps, BKK: 30.37 ± 16.26 laps, $p < 0.0005$). **Conclusions:** The youths of SGP had lower body composition, were more flexible, had higher abdominal endurance, and were more aerobically fit compared to the youths of BKK. This indicated a lower risk of obesity and cardiovascular risk in SGP youths as compared to BKK. More research is needed to identify the reasons for these differences which may help youths to continue participating in high levels of physical activity and exercise to reduce cardiovascular risks.

2185   Board #21   June 1 9:30 AM - 11:00 AM

Assessment Of Quality Of Movement Patterns In Spanish Pediatric Population During Classes Of Physical Education

Miguel García-Jaén[1], Juan M. Cortell-Tormo[1], Iván Chulvi-Medrano[1], Sergio Selles[1], Roberto Cejuela[1], Tamara Rial[2]. [1]University of Alicante, Alicante, Spain. [2]International Hypopressive and Physical Therapy Institute, Vigo, Spain.
(No relevant relationships reported)

The Functional Movement Screen(FMS) test has become increasingly popular as a tool designed to evaluate the quality of fundamental whole-body movement patterns, for the assessment of the normal function and for identifying limitations and asymmetries in basic functional movements. Although there are already considerable data analyzing FMS outcomes in adults, this research is currently scarce in pediatric population.
PURPOSE: This exploratory and descriptive study was undertaken to evaluate the physical functional capacity in school-aged pediatric population, in order to assess the prevalence of asymmetries and confirm feasibility of performing the FMS in a sample of children from Spanish primary school. **METHODS**: 136 elementary school children, 69 girls and 67 boys between 8-13 years old, took part in this investigation (age: 9.96 ± 1.22 years, weight: 39.21 ± 7.01 kg, height: 1.35 ± 0.097 m, BMI: 21.36 ± 2.69). Each participant performed the FMS during the classes of Physical Education in a primary school of Spain. Throughout data collection, information was digitally recorded for later data analysis. Statistical analysis was made using a two-way ANOVA with repeated measures. **RESULTS**: Obtained results showed that girls scored highest in all the FMS tests, compared with boys (14.38 ± 3.078 vs. 11.91 ± 2.58) and these outcomes indicate significant differences between both genders, throughout all studied age range ($P = 0.000$). The mean of total FMS score from all the study participants was 12.76 ± 2.89. **CONCLUSION**: Girls presented higher quality of fundamental movement skills than boys, which indicates more optimal function, and boys scored lowest, which indicates lower quality of basic movement patterns and, therefore, higher prevalence of limitations and asymmetries. The low values of total FMS scores in both genders showed throughout all the age range studied indicate suboptimal physical functional capacity and high prevalence of asymmetries. Finally, the results

of this study highlight that FMS can be a feasible screen test for evaluating functional movement skills and asymmetries in pediatric population, in order to reduce the risks of orthopaedic abnormality arising from suboptimal movement patterns in adult lifespan.

2186   Board #22   June 1 9:30 AM - 11:00 AM

Impact of Flag Football Intervention on Fitness Outcomes among 9-11 Years Old Chinese Children

Jie Zhuang[1], XinZhao Cao[1], Peijie Chen[1], Yong Gao[2]. [1]*Shanghai University of Sport, Shanghai, China.* [2]*Boise State University, Boise, ID.* (Sponsor: Weimo Zhu, FACSM)
(No relevant relationships reported)

PURPOSE: To examine the impact of a 10-week flag football intervention on aerobic fitness, muscular strength and speed among 9-11 years old Chinese children. **METHODS**: A total of 122 9-11 years old Chinese children were randomly divided into intervention group (IG; n=62) and control group (CG; n=60). The IG received ten-week flag football (FF) lessons (60-90 mins per lesson, twice a week), including throwing and catching balls, positioning, attacks,defending, game rules and games while CG took conventional PE lessons (35 mins per lesson, 3 times a week). Participants took 20-m shuttle run (20-m SRT), jump rope (for muscular power) and 50-meter dash (for speed) tests before and after intervention. VO_{2max} was estimated from 20-m SRT using Pacer equation. Mixed model Repeated Measures ANOVAs were used for data analysis.
RESULTS: A significant group-by-time interaction was observed for jump rope test (turns/min), p=0.03: no difference between IG and CG at baseline, but jump rope performance was significant improved among IG while no change among CG after intervention. There was also a significant group-by-time interaction for 50-meter dash (in sec), p=0.013: no difference at baseline between IG and CG, but 50-meter dash performance improved among IG while no change in CG after intervention. Although VO2max and 20-m SRT scores of both IG and CG participants increased from baseline to after intervention, there was no group difference in the improvement, p>0.05.
CONCLUSIONS: 10-week FF training effectively improves muscular power and speed among 9-11 years old Chinese children.

Effect of Injury Prevention Program on Performance Measures in Middle School Boys Soccer Players

Stuart McCrory, Shane Caswell, Nelson Cortes. *George Mason University, Manassas, VA.*
(No relevant relationships reported)

Lower extremity injuries are common in boys' youth soccer. Lower extremity injury prevention programs (IPPs) have been shown to be effective in reducing injury risk and increasing performance among high school and adult soccer players. To date, little research has examined the effectiveness of IPPs to change physical performance characteristics among middle school-age (10-14 years) athletes.
PURPOSE: To determine the effectiveness of a novel 16 exercise IPP in male middle school soccer players on vertical jump (VJ), single-leg long jump (SLLJ), and single-leg anterior reach (SLAR).
METHODS: Students (N=49, 12.6 ± 0.7 years, 1.59 ± 0.1 m, 53 ± 13 kg) playing on 3 separate boys' middle school soccer participated in this study. During the season and at the beginning of each practice session all athletes completed a 16-exercise IPP that lasted 6 weeks. Each IPP session was supervised by the team's coach and the athletic trainer. The IPP involved dynamic movements with the aim of improving physical performance for the athletes including power, core stability, balance, and agility. Performance testing was conducted pre- and post-season and included VJ, SLLJ, and SLAR. The VJ and SLLJ were completed on a turf field with the athletes in cleats

to produce a more realistic environment during testing. The SLAR was completed indoors with the athletes standing barefoot on a flat, hard surface. The SLAR and SLLJ tests were normalized to participant's leg length. Paired t-tests were conducted to compare pre- and post-intervention groups (p<.05).
RESULTS: A statistically significant improvement in VJ (pre = 41.3 ± 9.8 cm, post = 46.9 ± 13.9 cm; p<.05) and a reduction in SLAR for both right and left limbs (Right pre = 66.8 ± 7.5, post = 65.8 ± 6.2 cm; Left pre = 68.0 ± 6.9 cm, post = 61.2 ± 8.3 cm; p<.05) was attained. No significant differences were found for SLLJ (p>.05).
CONCLUSION: The findings suggest that our IPP was effective in improving VJ in middle school soccer players, but was detrimental for SLAR. Coaches and other professionals should ensure that performance improvements are not at the cost of injury risk. Future research should be conducted to determine which aspects of the injury prevention program affects the various tests performed so that more comprehensive and effective IPPs can be implemented.

Season Long Changes in Training Load Metrics for a World Champion Youth Ice-Hockey Team

Brandon Bastianelli, Davor Stojanov, Dakota Burke, Andrea Workman, Kenneth Martel, Stephen Mcgregor. *Eastern Michigan University, ypsilanti, MI.*
(No relevant relationships reported)

With increasing use of player worn sensors (PWS) in team sports, previously unknowable information is now within grasp. The team sport of ice hockey presents numerous challenges with regard to the assessment of training load. More specifically, the differences in training load experienced by skaters of different positions is of interest to optimize player development and avoid injury.
PURPOSE:
Use (PWS) to measure on-ice physiological exertions and quantify training load differences between forwards (F) and defensemen (D) members of a national junior ice hockey team over the course of a season.
METHODS:
19 members of the US National Team Development Program (17.5+.21 y, 1.82+0.8 m, 83.1+7.6 kg) consented to procedures approved by the EMU-HSRC. Zephyr bioharness-3 (Zephyr, MD) PWS measured triaxial accelerations and heart rate for all on-ice practices and games. Exponentially weighted session Dynamic Accelerations (DYNAs) were used to determine Intensity Factor (IF) that was expressed relative to a player's Dynamic Functional Threshold (DFT; 30 min maximal acceleration). Dynamic Training Load (DTL) was calculated using the individualized IF and session duration to reflect training load of a single session. DTL was used as the input for an impulse-response performance model to calculate Chronic Training Load (CTL), Acute Training Load (ATL) and Performance Readiness (PR) over a given period of time. MANOVA statistical tests compared metrics by session type and position for main effects and a Bonferoni *post hoc* in the event of statistical differences (α=.05).
RESULTS:
Overall, differences by position were observed with F being higher than D for both DA (.311+.001 v .303+.001) and IF (0.82+.002 v 0.81+.003)(p<.05). No differences were observed, overall, for DTL, CTL, ATL or PR by position. Interactions were also observed for DA and IF by position and session. For F, DA was greater for games than practice, while practices were greater than games for D.
CONCLUSION:
F appeared to perform greater accelerations and relative intensities in games and practices than D, but this did not result in significantly different training loads between positions. It also appears as though F exhibited greater accelerations and intensities in games than practices, while D exhibited the converse. Supported by the USA Hockey Foundation

Season Long Changes in Training Load Metrics for a World Champion Junior Ice-Hockey Team

Dakota J. Burke, Davor Stojanov, Andrea Workman, Kenneth Martel, Stephen McGregor. *Eastern Michigan University, Ypsilanti, MI.*
(No relevant relationships reported)

PURPOSE: Use player worn sensors (PWS) to measure on ice physiological exertions and quantify training load changes for players on a Junior National ice hockey team over the course of a single season which culminated in a World Championship.
METHODS: 19 members of a National Team Development Program (17.5+.21 y, 1.82+0.8 m, 83.1+7.6 kg) consented to procedures approved by the EMU-HSRC. Zephyr BH3 (Zephyr, MD) PWS measured triaxial accelerations (g's) for all on ice practices (P) and games (G). Dynamic Accelerations (DYNAs) were generated from exponentially weighted accelerations and Dynamic Functional Threshold (DFT) from peak 30 min DYNAs within a 2 week moving window. Intensity Factor (IF) was based on session DYNAs relative to DFT. Dynamic Training Load (DTL) for a single session

was calculated using the IF and the session duration. DTL was used as the input for an impulse response performance model to calculate Chronic Training Load (CTL), Acute Training Load (ATL) and Performance Readiness (PR) over a given amount of time. MANOVA was used to compare metrics by session type, (G) vs (P), and by month (M1 - M7) for main effects and Bonferoni *post hocs* in the event of statistical differences (α=.05)

RESULTS: **RESULTS:** All training load metrics were different between G and P, by month and an interaction for session by month (p<.05). When P were examined separately, DTL was not different across M1-M4, but declined during M5-M7 (108.5+2.5, 116.3+29.2, and 58.4+2.5, respectively; p<.05) with M7 being lower than M1-M6. IF was highest during M1 (.86+.01) and significantly declined over the season and was lowest at M7 (.74+.01). In contrast, for G, DTL increased for M1 (193.0+1.9) and M2 (200.0+2.2) but were not different for the remainder of the year, while IF peaked at M3 (.83+.01) and was lowest (p<.05) at M7 (.79+.01). For performance modeling metrics, CTL peaked at M3 (p<.05), but despite the reduced DTL for P in M7, CTL, ATL and PR were not different during M7 compared to M6 (p>.05)

CONCLUSIONS: In the last month before the World Championships, training loads and intensities of practices were reduced substantially, while game loads remained constant but intensities were reduced. The training loads imparted by games were sufficient to maintain CTL, but ATL was not reduced and PR was not increased leading into the primary objective of the season

Implementing a Progressive Resistance Training Program in Youth Junior Olympic Women's Gymnastics.

Michael M. Lockard, Tynan F. Gable. *Willamette University, Salem, OR.*

(No relevant relationships reported)

Competitive gymnasts in the Women's Junior Olympic (JO) program are highly conditioned, typically training 8-20 hours per week. Training often consists of high-repetition body-weight activities with little variability in the exercises performed. This method of training lacks progressive resistance training (PRT), a cornerstone to adaptation for specific training goals. **PURPOSE**: To investigate the benefits of 10 wks of PRT, 1 day/wk, on muscular strength and power in women's JO child and adolescent gymnasts. A program was implemented for all competitive levels during regular practice, while minimizing time away from normal training. **METHODS**: 47 females aged 7-17 yrs (mean 10.2±2.7 yrs), competing on JO levels 3-10 participated. 15 exercises were each completed for 1 set of 10 reps. Tests for upper- and lower-body power included vertical leap, medicine ball-put, and an arm-ergometer modified Wingate anaerobic test (Arm-WAnT). Analysis: Gymnasts must have attended at least 70% of the training sessions during the 10-week study. Level 3 gymnasts (n=19) underwent the control condition, completing normal body-weight non-progressive conditioning. They were compared to the Level 4 gymnasts who were of similar age and gymnastics training experience. Level 4-10 gymnasts were separately analyzed in a quasi-experimental repeated measures design. **RESULTS**: Compared to the Level 3 controls, Level 4 gymnasts had greater improvement in vertical power (p=0.003), and Arm-WAnT peak power and mean power (p=0.044 and 0.023), but no difference in medicine ball-put distance or Arm-WAnT fatigue index. Gymnasts Levels 4 to 10 similarly improved vertical power (2224±756W to 2473±688W, p<0.001), Arm-WAnT peak power (80.9±30.1W to 93.2±40.6W, p<0.001), and mean power (62.8±23.2 to 70.1±27.3, p<0.001), with no change in medicine ball-put distance or Arm-WAnT fatigue index. **CONCLUSION**: 10-wks of PRT will improve upper- and lower-body power in child and adolescent female JO gymnasts.

E-28   Free Communication/Poster - Cerebral Blood Flow

Ipsilateral and Contralateral Posterior Cerebral Artery Blood Velocities During Handgrip Exercise

Kazuya Suzuki, Takuro Washio, Masato Hatanaka, Hiroki Sakurai, Shigehiko Ogoh, FACSM. *Toyo University, kawagoe, Japan.*

(No relevant relationships reported)

Previous studies reported that an increase in the contralateral middle cerebral artery mean blood velocity was larger than mean blood velocity in the ipsilateral side during handgrip (HG) exercise. These findings suggest a significant increase in blood flow for the artery supplying the cortical projection of the exercising limb. On the other hand, the response of posterior cerebral blood flow (CBF) to exercise

is significantly different from anterior CBF. However, it remains unknown whether there is different CBF response to HG exercise between ipsilateral and contralateral posterior cerebral arteries. **PURPOSE:** The purpose of this study was to examine the effect of HG exercise on CBF in ipsilateral and contralateral posterior cerebral arteries. **METHODS:** Six healthy male subjects performed HG exercise of the right hand for 3 min at 30% maximum voluntary contraction in a semi-supine position. Arterial pressure and posterior cerebral artery blood velocity (PCAv) were measured by finger photoplethysmography and the Transcranial Doppler Sonography, respectively. Cerebral vascular conductance index (CVCi) was estimated using the ratio of PCAv to mean arterial pressure (MAP). **RESULTS:** MAP significantly increased from rest during HG exercise (+26.9%, P=0.02). During HG exercise, both ipsilateral and contralateral PCAv significantly increased, but there was no significant difference between sides (P = 0.87). Also, CVCi decreased significantly during HG exercise. Similarly, there was no difference in CVCi between ipsilateral and contralateral arteries (P=0.96). **CONCLUSION**: The findings of the present study suggest that the blood flow response in the posterior regional CBF during HG exercise is different from that in the anterior cerebral circulation.

Age-related Differences in Cerebral Oxygen Diffusive Capacity during Normobaric Hypoxia Exposure

Xiangrong Shi, FACSM, Xiaoli Liu, Hannah Schenck, Shande Chen, James Hall, Sarah Ross, Geoffrey Kline, Robert T. Mallet. *UNT Health Science Center, Fort Worth, TX.*

(No relevant relationships reported)

Purpose: Cerebral perfusion and oxygen diffusive capacity were enhanced in young adults during hypoxia-induced hypoxemia. This study examined cerebral oxygenation and perfusion in elderly adults during exposure to normobaric hypoxia. **Methods**: Eight elderly (70 ± 2 yr, 4 women) and eight young adults (25 ± 1 yr) were exposed to 5 min 10% O_2. During the test, heart rate (HR, electrocardiogram), arterial blood pressure (ABP, NIBP100D), O_2 saturation (SaO_2, Radiometer), middle cerebral arterial blood flow velocity (V_{MCA}, Ez-Dop) and cerebral tissue oxygenation (ScO_2, Somanetics 5100C INVOS) were continuously monitored. **Results**: Baseline SaO_2, HR, and mean ABP were not significantly different in elderly vs. young subjects (SaO_2 96.9±0.3 vs 97.0±0.3%; HR 71±4 vs 63±2 bpm; ABP 93±3 vs 89±2 mmHg). However, baseline V_{MCA} (43.5±2.2 vs 53.7±1.8 cm/s, P=0.005) and ScO_2 (68.6±0.7 vs 75.4±0.9%, P<0.001) were lower in elderly than young adults. During hypoxia exposure, HR was significantly increased with decreases in SaO_2; the rate of tachycardia per unit hypoxemia was smaller (P<0.001) in elderly (-0.48 ±0.05 bpm/%) than young (-0.84 ±0.02 bpm/%) group. ABP was not altered during hypoxia-induced hypoxemia in either group. SaO_2 during 5-min hypoxia exposure fell appreciably, to 77.5±2.3% and 75.9±1.4% in elderly and young groups, respectively; the rate of decrease in SaO_2 per unit time was not significantly different between the groups. However, in terms of unit hypoxemia, the rate of decrease in ScO_2 was smaller (P = 0.002) in elderly (0.69±0.01 %/%) than young (0.85±0.03 %/%) adults, while the rates of increase in V_{MCA} were similar between elderly and young groups (-0.28±0.05 vs -0.37±0.07 cm/s/%, P = 0.325). Fractional cerebral oxygen extraction during hypoxemia declined in elderly subjects (P = 0.038), but progressively increased in young adults (P <0.05). **Conclusions**: Aging diminishes cerebral oxygenation and perfusion at rest. During exposure to normobaric hypoxia, elderly adults depend solely on an activated cerebral vasodilation to maintain O_2 delivery, but cerebral oxygen diffusive capacity is not enhanced as in young group.

Cerebral Blood Flow Pulse Is Influenced By Ascending Aortic Flow During Acute Hypotension

Tomoya Suda[1], Ai Hirasawa[1], Takahiro Uechi[1], Kazukuni Hirabuki[1], Noritaka Hata[1], Yuki Sano[1], Takeaki Matsuda[1], Shigeki Shibata[1], Shigehiko Ogoh, FACSM[2]. [1]*Kyorin University, Tokyo, Japan.* [2]*Toyo University, Saitama, Japan.*

(No relevant relationships reported)

Purpose: Recently, it has been suggested that cardiac function is one of important physiological factors to determine cerebral blood flow (CBF). However, dynamic relationship between cardiac outflow and CBF is still unknown. The purpose of the present study was to assess the dynamic relationship between arterial blood pressure (BP) or ascending aortic blood flow and CBF.
Methods: Six male healhy subjects participated (age, height, and weight; 33±6 yrs, 173±3 cm, and 72±8 kg) in the present study. Continuous beat-by-beat arterial BP was recorded from a finger using the Penaz method. Ascending aortic blood flow velocity (Ao-BFV) and middle cerebral artery blood flow velocity (MCA-BFV) were continuously measured using supra-sternum and transcranial Doppler ultrasound. After 10 min of resting condition, bilateral thigh cuffs were rapidly inflated to 200 mmHg and maintained for 2 min. Then both cuffs were rapidly deflated, and data were subsequently collected for 1 min. The same measurements were performed in the

Abstracts were prepared by the authors and printed as submitted.

FRIDAY, JUNE 1, 2018

supine and 45-degree semi-Fowler's positions. Pearson's correlation coefficients were calculated to identify the relationship between relative change of BP or Ao-BFV and those of MCA-BFV among individuals.

Results: Correlation coefficient of mean BP and mean MCA-BFV was much larger than that of mean Ao-BFV and mean MCA-BFV in both the supine and semi-Fowler's positions (R=0.615 vs. 0.009 and 0.353 vs. -0.753). In contrast, the correlation coefficient of pulse BP and pulse MCA-BFV was much smaller than that of pulse Ao-BFV and pulse MCA-BFV in the supine position (R=-0.068 vs 0.659), while it was comparable in the semi-Fowler's position (R=0.555 vs 0.435).

Conclusions: Dynamic change in mean CBF are likely to be only influenced by mean BP. However, dynamic change in pulse CBF seems to be more influenced by that of pulse ascending aortic blood flow rather than pulse BP especially in the supine position.

Effect Of Postural Stimulation On Cerebral Hemodynamics

Yuka Ninomiya[1], Tsubasa Tomoto[2], Tomoko Imai[3], Shigehiko Ogoh, FACSM[4], Koki Takahashi[1], Jun Sugawara[2]. [1]Tokyo Ariake University of Medical and Health Sciences, Tokyo, Japan. [2]National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan. [3]Aichi Institute of Technology, Toyota, Japan. [4]Toyo University, Kawagoe, Japan. (Sponsor: Shigehiko Ogoh, FACSM)

(No relevant relationships reported)

The previous prospective study identified that prolonged sleep could be associated with the increased future stroke risk in an apparently healthy aging population. However, the underlying mechanism is unknown. Chronic excessive pulsatile flow is thought to be a risk for cerebrovascular disease. In the supine posture, stroke volume (SV) is greater than that in upright posture since decrease in hydrostatic pressure increases venous return and consequently cardiac preload.

PURPOSE: We determined whether greater SV in the supine posture is associated with the augmented mechanical stress (characterized by cerebral pulsatile hemodynamics) in the cerebral vasculature. **METHODS**: To test this hypothesis, we applied -30 mmHg of lower body negative pressure (LBNP) as mild orthostatic stimulus in 18 healthy men (mean age = 21.9 ± 1.9yrs). TCD-determined MCAV was used to evaluate cerebral hemodynamics. SV was estimated from the radial arterial pressure waveforms using the Modelflow method. **RESULTS**: SV, peak and pulsatile MCA velocity, and PI of MCA velocity were significantly decreased during LBNP stimulation (P<0.05 for all, vs. supine posture), whereas mean MCA velocity and cardiac output remained unchanged. Importantly, the change in SV during LBNP significantly correlated with corresponding changes in peak and pulsatile MCA velocity (r=0.50, P=0.034; r=0.63, P=0.005, respectively). **CONCLUSIONS**: These results suggest that orthostatic stress (or postural change)-induced modified pulsatile component of cerebral hemodynamics (or augmented cerebral vascular stress) are partly due to change in SV. Our findings may partly support the phenomenon that long-time sleep is a risk for cerebrovascular disease.

2195   Board #31   June 1 11:00 AM - 12:30 PM

Effect Of Muscle Metaboreflex On Anterior and Posterior Cerebral Blood Flow

Shigehiko Ogoh, FACSM[1], Ai Hirasawa[2], Kohei Sato[3]. [1]Toyo University, Kawagoe-shi, Saitama, Japan. [2]Kyorin University, Tokyo, Japan. [3]Tokyo Gakugei University, Tokyo, Japan.

(No relevant relationships reported)

Previous study demonstrated that post-exercise muscle ischemia (activation of muscle metaboreflex) following leg cycling failed to elevate anterior cerebral blood flow (CBF) despite a higher arterial blood pressure and this result was associated with hyperventilation-related decrease in the partial pressure of end-tidal carbon dioxide. However, the effect of muscle metaboreflex on posterior CBF remains unknown. **PURPOSE**: The purpose of the present study was to test the hypothesis that the response of posterior CBF to activation of muscle metaboreflex is different from that of anterior CBF. **METHODS**: Eleven healthy participants performed one-legged static knee extension exercise at 30 % maximal voluntary contraction for 2 min. The muscle metaboreflex was activated for 2 min by post-exercise muscle ischemia (PEMI). Blood flow to the internal carotid and vertebral arteries (ICA/VA) were evaluated by duplex ultrasonography. **RESULTS**: The both ICA and VA blood flow increased and reached to the peak value at 60 s after the start of exercise (+19±15 and 26±14%, P<0.05, respectively). Thereafter, ICA blood flow gradually decreased to the end of exercise (P<0.05) despite no change in VA blood flow (P=0.710). During PEMI immediately after exercise, both ICA and VA blood flow returned to the baseline level despite a high blood pressure. **CONCLUSIONS**: VA circulation has a low cerebral autoregulation and carbon dioxide CBF reactivity. However, similarly with anterior CBF, VA

blood flow was not affected by metaboreflex-induced elevated blood pressure. This phenomenon may be important for protecting posterior cerebral circulation from high blood pressure but the mechanism remains unclear.

2196   Board #32   June 1 11:00 AM - 12:30 PM

Effect of Acute Sleep Deprivation on Dynamic Cerebral Autoregulation

Masato Hatanaka, Takuro Washio, Hiroki Sakurai, Shigehiko Ogoh, FACSM. *TOYO UNIVERSITY, Kawagoe-shi, Japan.*

(No relevant relationships reported)

Sleep disorders increase the risk of cardiovascular disease. For example, previous cohort studies suggested that sleep deprivation contributed to the onset of cerebrovascular disease. However, its physiological mechanism remains unknown. We hypothesized that sleep disorders attenuated dynamic cerebral autoregulation (CA), which is one physiological mechanism of cerebral blood flow regulation.

PURPOSE: To test our hypothesis, the present study investigated if there was an effect of acute sleep deprivation on dynamic CA. **METHODS:** Six healthy young men participated in the present study. Each subject was instructed to shorter his individual sleep duration (individual averaged sleep duration minus 2 hours) to created sleep deprivation condition. Following manipulating sleep duration, each subject visited the laboratory to perform experiments in the morning (between 8 and 10 am). Mean arterial pressure (MAP) and middle cerebral artery blood velocity (MCAv) were measured during the experiment. Dynamic CA was assessed by transfer function analysis of spontaneous oscillations between MAP and MCAv in the low-frequency range (LF, 0.07-0.20 Hz) in each subject under these two different sleep conditions: control (averaged sleep duration, 6.5 ± 0.9 h) and sleep deprivation conditions (3.9 ± 0.4 h). **RESULTS:** Acute sleep deprivation did not change either MCAv or MAP. Also, unexpectedly, there was no difference in the LF phase shift (P=0.46) and gain (P=0.53) of transfer function analysis between conditions, indicating that dynamic CA was not affected by acute sleep deprivation. **CONCLUSIONS:** In the present study, the manipulated acute sleep deprivation did not change dynamic CA. This finding suggests that an insufficient sleep-induced cerebrovascular disease may be associated with other physiological factors, but two hours less sleep or acute change in sleep deprivation may not be enough to alter cerebral circulation.

2197   Board #33   June 1 11:00 AM - 12:30 PM

Effect of Sympathetic Activation on Dynamic Cerebral Autoregulation in Posterior Cerebral Circulation

Takuro Washio, Masato Hatanaka, Kazuya Suzuki, Shigehiko Ogoh, FACSM. *Toyo university, kawago, Japan.* (Sponsor: Shigehiko Ogoh, FACSM)

(No relevant relationships reported)

The previous study reported that cold stimulation-induced acute high sympathetic nerve activity (SNA) impaired dynamic cerebral autoregulation (CA) in anterior cerebral circulation using transfer function analysis. However, the effect of acute change in SNA on dynamic CA in posterior cerebral circulation remains unknown. The posterior cerebral circulation has insufficient sympathetic innervation compared to anterior cerebral circulation; therefore, we hypothesized that the effect of sympathetic activation on dynamic CA in posterior cerebral circulation may be different from that in anterior cerebral circulation. **PURPOSE**: The purpose of the present study was to examine the effect of cold stimulation-induced high sympathetic activation on dynamic CA in posterior cerebral circulation. **METHODS**: Six healthy young subjects participated in this study. Mean arterial pressure (MAP), left middle cerebral artery blood velocity (MCAv) and right posterior cerebral artery blood velocity (PCAv) were measured throughout the experiment. At 90 sec after left hand immersion in cold water (2℃), dynamic CA was evaluated using thigh cuffs occlusion and release technique. To quantify dynamic CA, the rate of regulation (RoR) was calculated from the change in cerebral vascular conductance index during occluded-cuffs release. **RESULTS**: The cold stimulation increased MAP (mean ± SD; +14.6 ± 10.8 %,P = 0.02), while there was no change in MCAv (P=0.52) and PCAv (P = 0.75) compared with control condition. The RoR in both middle cerebral artery (MCA) and posterior cerebral artery (PCA) was not changed by cold stimulation (MCA and PCA, P=0.26 and P=0.30). In addition, there was no difference in the change in RoR between MCA and PCA (P=0.224). **CONCLUSIONS**: The cold stimulation-induced high SNA did not modify dynamic CA in both anterior and posterior cerebral circulation. These findings suggest that the role of SNA on dynamic CA in posterior cerebral circulation may be similar to anterior cerebral circulation.

2198   Board #34   June 1 11:00 AM - 12:30 PM

Aerobic Exercise Training and Cerebral Vasomotor Reactivity in Patients with Mild Cognitive Impairment

Tsubasa Tomoto[1], Takashi Tarumi[2], Jason Chen[1], Evan Pasha[1], Marcel Turner[1], Justin Repshas[1], Rong Zhang[2]. *[1]Texas Health Presbyterian Hospital Dallas, Dallas, TX. [2]University of Texas Southwestern Medical Center, Dallas, TX.*

(No relevant relationships reported)

Aerobic exercise training (AET) may improve cerebral blood flow (CBF) regulation and reduce the risk of dementia. CBF is sensitive to changes in the arterial partial pressure of carbon dioxide (CO_2), which is assessed as cerebral vasomotor reactivity (CVMR). Currently, the effect of AET on CVMR in patients with mild cognitive function (MCI) is unclear. **PURPOSE**: To determine 1) effects of AET on CVMR in MCI patients, and 2) the reproducibility of CVMR over 12 months. **METHODS**: Seventy MCI patients were randomized to 12 months of moderate-intensity AET or stretching program. CBF velocity (CBFV) via transcranial Doppler, mean arterial pressure (MAP) via plethysmograph, and end-tidal CO_2 ($EtCO_2$) via capnograph were measured during hyperventilation (hypocapnia) and with a modified rebreathing protocol (hypercapnia). Cerebrovascular conductance index (CVCi) was calculated by CBFV/MAP, and CVMRs were calculated by $\Delta CBFV/\Delta EtCO_2$ and $\Delta CVCi/\Delta EtCO_2$. In addition, blood pressure response to hypo- and hypercapnia was determined by $\Delta MAP/\Delta EtCO_2$. Cardiorespiratory fitness was assessed by maximal oxygen uptake (VO_2max) using a modified Astrand-Saltin treadmill protocol. Intraclass correlation (ICC) was used to test the reproducibility of CVMRs over 12 months. **RESULTS**: Data were available from 16 patients in AET program and 17 patients in stretching program. After intervention, VO_2max significantly increased in AET group compared with stretching group. Mean CBFV, MAP, and $EtCO_2$ at rest remained at similar levels in both groups. Hypocapnic CVMRs increased significantly over time in both groups but no effect of AET or stretching intervention. Hypercapnic CVMRs did not change with treatment or time. The ICCs of $\Delta CBFV/\Delta EtCO_2$ and $\Delta CVCi/\Delta EtCO_2$ were 0.553 (*P*<0.001) and 0.74 (*P*<0.001) during hypercapnia and 0.316 (*P*=0.008) and 0.545 (*P*<0.001) during hypocapnia, respectively. **CONCLUSIONS**: In MCI patients, a 12-month AET program did not alter hypo- or hypercapnic CVMRs compared with stretching group. Although hypercapnia CVMRs were reproducible over 12 months, hypocapnic CVMRs showed lower reproducibility. Supported by the NIH (R01AG033106)

Cerebral Autoregulation Is Impaired In Recurrent Syncope Patients

Ai Hirasawa, Tomoya Suda, Kazukuni Hirabuki, Takahiro Uechi, Noritaka Hata, Yuki Sano, Takeaki Matsuda, Shigeki Shibata. *Kyorin University, Tokyo, Japan.* (Sponsor: Shigehiko Ogoh, FACSM)

(No relevant relationships reported)

PURPOSE: Cerebral autoregulation is a homeostatic mechanism that serves to maintain cerebral blood flow constant over a wide range of perfusion pressure. Syncope is thought to be caused by cerebral hypoperfusion due to the transient blood pressure drop, and thus impairment of cerebral autoregulation may facilitate syncope. A previous study has reported that a past history of syncope is a strong predictor of future syncope recurrence. However, it is unclear whether impaired cerebral autoregulation would be related with recurrent syncope. The purpose of this study was to test our hypothesis that cerebral autoregulation would be impaired in syncope patients with a past history of syncope as compared with those for the first time. **METHODS**: We evaluated cerebral autoregulation in 24 syncope patients for the first time (age; 64±19 years old, male/female; 15/9) and 20 syncope patients with a past history of syncope (age; 52±26 years old, male/female; 11/9). In patients with recurrent syncope, the number of past syncope was 2.9±1.6 times (range 2-7 times). Middle cerebral artery mean blood flow velocity (MCA Vmean) and mean arterial pressure (MAP) were measured by transcranial Doppler ultrasound and tonometry on right radial artery for 3 min in the supine position. In offline analysis after the measurement, the transfer function gain between MAP and MCA Vmean were calculated at very low frequency (0.023-0.07 Hz, VLF) and low frequency (0.07-0.2 Hz, LF) ranges to estimate dynamic cerebral autoregulation. **RESULTS**: LF gain did not differ between syncope patients with a past history of syncope and those for the first time (P=0.23). In contrast, VLF gain was significantly higher in patients with a past history of syncope than in those for the first time (1.81±1.17 cm/s/mmHg vs. 1.09±0.65 cm/s/mmHg, P=0.02). **CONCLUSIONS**: These data suggest that impaired cerebral autoregulation at least in part explains physiological mechanisms underlying recurrent syncope.

PURPOSE: To determine the differences in cerebral microvascular reactivity (CVR) and neurocognition between childhood cancer survivors (CCS) and matched controls (CON). **METHODS**: Seven cancer survivors and seven matched [age, sex, and body mass index (BMI)]; healthy cancer-free controls were enrolled in the study. Each participant completed neurocognitive testing (i.e., IQ screening, memory, attention/executive, and fine motor) and a self-report survey of executive/self-regulation skills. A computer-controlled gas-blending device was used to evaluate baseline and manipulate end-tidal carbon dioxide ($P_{et}CO_2$). To alter brain blood flow, a $P_{et}CO_2$ gas challenge consisting of two square wave increases of 10 mmHg above baseline $P_{et}CO_2$ and a ramp protocol that decreased $P_{et}CO_2$ to 32 mmHg and then increased linearly to 50 mmHg over 7 mins was utilized. $P_{et}O_2$ was maintained at 100 mmHg. Each participant underwent brain imaging using a 3T MRI for structural and functional (BOLD) imaging. CVR (%BOLD signal change/mmHg CO_2) was computed by using the robust linear least squares fit to the correlation between the two time courses. **RESULTS**: By design, CCS and CON were similar in age (27.1±1.1 vs. 26.0±0.8 y) and BMI (25.2±1.2 vs. 25.2±0.7 kg/m²) (all p>0.05). Baseline $P_{et}CO_2$ (37.0±1.1 vs. 38.0±0.9 mmHg, *p*=0.34) was not significantly different between the two groups. Whole brain gray matter CVR was also not significantly different in CCS vs. CON groups for the full sequence (0.36±0.01 vs. 0.35±0.02 %BOLD/mmHg), squares waves only (0.37±0.02 vs. 0.36±0.02 %BOLD/mmHg) and ramp only (0.35±0.01 vs. 0.34±0.01 %BOLD/mmHg) (all p>0.05). The CVR variability (dCVR) was increased and model fit (R²) was significantly decreased in CCS compared with CON (p=0.004 and p=0.01, respectively) in the full sequence, but not in the square or ramp waveforms independently. No significant between-group differences were observed in neurocognitive testing. **CONCLUSIONS**: The data from this study suggest that childhood cancer survivors may have long-term treatment effects on microcirculation of the brain that affect CVR stability. Although this decline in brain microcirculation did not result in neurocognitive deficits, the long-term consequences of this decline in brain microvascular function have yet to be determined.

Augmented Mechanoreflex In Type 2 Diabetic Rats: Piezo Channels, An Important Part Of The Puzzle?

Ann-Katrin Grotle, Yu Huo, Audrey J. Stone. *University of Texas at Austin, Austin, TX.* (Sponsor: Philip R. Stanforth, FACSM)

(No relevant relationships reported)

Type 2 diabetics (T2DM) have an abnormal cardiovascular response to exercise. The exercise pressor reflex, which is evoked by metabolic and mechanical stimuli arising from the contracting muscle, is a critical cardiovascular regulatory mechanism during exercise and is exaggerated in hypertension, heart failure and peripheral artery disease. A recent study found that T2DM patients have an augmented metaboreflex. However, whether the mechanoreflex is also altered in T2DM is not known. **PURPOSE:** The purpose of the study was to test whether the mechanoreflex is exaggerated in T2DM. Furthermore we tested the contribution of mechano-gated Piezo1 and 2 channels to the mechanoreflex in T2DM. **METHODS**: In unanaesthetized, decerebrated rats we stretched the Achilles tendon for 30 s and measured changes in mean arterial pressure (MAP) and heart rate (HR) in 12 mo old male T2DM rats (BW=546±26 g, glucose=549±28 mg/dl, HbA1c=12.82±0.18%) and healthy male controls (CTL: BW=453±22 g, glucose=229±31 mg/dl, HbA1c=4.6±0.1%). To test the contribution of Piezo channels, we injected GsMTx-4 (10 μg), a known antagonist of Piezo1 and 2 channels, into the arterial supply of the hindlimb and repeated the stretch maneuver. **RESULTS:** We found that the pressor (T2DM: ΔMAP=69±6 mmHg, n=5; CTL: ΔMAP=13±2 mmHg, n=5) and cardioaccelerator (T2DM: ΔHR=28±4 bpm, n=5; CTL: ΔHR=5±3 bpm, n=5) responses to tendon stretch were significantly greater in T2DM rats compared to CTL; p<0.05. Injection of GsMTx-4 into the arterial supply of the hindlimb reduced the pressor response (before GsMTx-4; MAP: 80±7 mmHg; after GsMTx-4; MAP: 55±9 mmHg, n=2) to tendon stretch by approximately 30%. Likewise, GsMTx-4 lowered the cardioaccelerator response (before GsMTx-4; HR:

Abstracts were prepared by the authors and printed as submitted.

FRIDAY, JUNE 1, 2018

31±9 bpm; after GsMTx-4; HR: 12±2 bpm, n=2) by approximately 61%; p<0.05.
CONCLUSION: We conclude that T2DM significantly exaggerates the pressor and cardioaccelerator response to mechanoreflex activation and that Piezo channels play an important role in evoking the mechanoreflex in T2DM rats.

Aerobic Exercise Improved Cardiac and Mitochondrial Function in Chronic Heart Failure in Rats

Yungang Zhao[1], Can Li[1], Xiangyao Wang[1], Lili Wang[1], Li Li Ji, FACSM[2]. [1]Tianjin University of Sport, Tianjin, China. [2]University of Minnesota, Minnesota, MN. (Sponsor: Li Li Ji, FACSM)

(No relevant relationships reported)

Purpose: The purpose of this study was to investigate whether aerobic exercise can improve cardiac and mitochondrial functions of heart failure induced by pressure overload in rats. We explored the mechanism of adaptational changes at the post-transcriptional level with the experimental model. **Methods:** The rat model of heart failure was accomplished by abdominal aorta constriction (AC). Eight weeks after the operation, the animals were divided into 4 groups: sham control (SC), sham plus training (ST), AC without training, and AC plus training (AT). Training was performed on treadmill at 25m/min, 0º grade for 60 min per day and last for 8 weeks. Heart structural and functional parameters were measured with echocardiography. Mitochondrial respiratory functions were measured with high-resolution respirometry. The miRNAs expression profiles were investigated by Affymetrix® Microarray. RT-PCR was used to validate the expression levels of miRNAs. **Results:** Compared with AC, the cardiac structure index LVID were significantly decreased, while the cardiac functional indexes ejection factor (EF) and fractional shortening (FS) were significantly increased in AT hearts. Mitochondrial state 3 respiration and respiratory control ratio (RCR) decreased significantly in AC vs. SC, whereas the reductions were restored by AT to SC level. Mitochondrial complex I activity in AC was significantly lower than that in SC, but such reduction was not observed in AT. MiR-10a-5p and miR-542-5p levels in AT hearts were significantly higher than those in AC, and some target mRNA of these two miRNAs were related to mitochondrial function and dynamic. For example, Coa 7 and Creb1 were affected by miR-10a-5p, and Tfrc by miR-542-5p. **Conclusion:** Aerobic exercise can ameliorate the pathogenesis of heart failure and improve heart function in experimental animals. This effect is largely achieved by improvement of mitochondrial function, especially complex I function in electron transfer chain. miR-10a-5p and miR-542-5p may be involved in this process through regulating key components of mitochondrial dynamic.

Waist Circumference and BMI Are Associated With Cardiovascular Disease Risk Markers In Police Officers

John S. Green, FACSM, Steven E. Martin, Stephen F. Crouse, FACSM. *Texas A&M Univ., College Station, TX.*

(No relevant relationships reported)

INTRODUCTION: Christou et al. (Circulation. 2005; 111:1904-1914) has shown that body fatness is a better predictor of cardiovascular disease (CVD) risk than aerobic fitness in a cohort of healthy men. We sought to replicate their findings in a cohort of police officers. **PURPOSE:** The purpose of this study is to determine whether fatness or aerobic fitness is more highly associated with selected CVD risk markers in a cohort of police officers. **METHODS:** Six female and 49 male police officers underwent screening for 9 selected metabolic and hemodynamic risk markers for CVD along with a maximal treadmill test to determine aerobic fitness. Waist circumference (WAIST), fat mass (FATMASS), percent body fat (%FAT), and body mass index (BMI) were chosen as indicators of fatness. Multiple linear regression models using WAIST, BMI, FATMASS, and %FAT as dependent variables were used to obtain partial correlation coefficients to determine the independent association of fatness to CVD risk while controlling for fitness and age. **RESULTS:** The regression models for FATMASS and %FAT were not statistically significant. The model for WAIST showed an association with 5 of the 9 risk markers after partialling out the effects of aerobic fitness and age (r=.13 to .27, p<.01). The model for BMI demonstrated similar associations with 4 of the 9 risk markers (r=.10 to .15, p<.05). In contrast, aerobic fitness was not independently associated with any of the risk markers in either of the significant regression models. **Conclusions:** In police officers, body fatness is associated with CVD risk while aerobic fitness is not.

Pulmonary Artery Sling And Exercise Capacity : A Longitudinal Study In A Young Girl

Merav Zucker Toledano[1], Lea Bentur Bentur[2], Gur Mainzer[3], Ronen Bar-Yoseph[1]. [1]Rambam Health Care Campus, Haifa, Israel. [2]Rambam Health Care Campus, The Bruce Rappaport Faculty of Medicine, Technion–Israel Institute of Technology, Haifa, Israel. [3]The Baruch Padeh Medical Center, Poriya, Israel.

(No relevant relationships reported)

Introduction: Pulmonary artery sling is a rare congenital vascular malformation that consists of an anomalous origin of the left pulmonary artery from the posterior aspect of the right pulmonary artery. The anomalous left pulmonary artery crosses the mediastinum posterior to the trachea or carina and anterior to the esophagus, compressing both organs. Respiratory complaints predominates over esophageal symptoms. In asymptomatic patients, surgical repair is controversial. Data regarding exercise capacity and other cardiopulmonary parameters is scarce.
Aim: To evaluate exercise parameters in an early pubertal girl with uncorrected pulmonary artery sling at baseline and 3 years later (late puberty).
Methods: Maximal cardiopulmonary exercise testing (CPET) was completed on a cycle ergometer at age 11 y/o and 14 y/o by a girl with uncorrected pulmonary artery sling. Data was processed and analyzed retrospectively.
Results: Peak oxygen uptake (VO$_2$) was higher in the first test (41.9 ml/kg/min, 119% predicted) than in the second test (30.6 ml/kg/min, 87% of predicted). Maximal and submaximal pulmonary exercise parameters improved in the second test (breathing reserve; 9.7 liters, 15% predicted in the first test vs. 31.5 liters, 39% predicted in the second test and for lowest VE/VCO$_2$ and VE/VCO$_2$ slope; 28.7 and 34.9 vs 25.7 and 27.7 respectively), with no similar expected improvement in cardiovascular parameters (oxygen pulse (VO$_2$/HR) 9.2 ml/beat, 125% predicted in the first test vs. 9.3 ml/beat, 92% of predicted respectively and for VO$_2$/HR slope; 14.1 ml/beat vs. 14.9 ml/beat).
Conclusions: In this case of uncorrected pulmonary sling a deterioration in exercise capacity and cardiovascular exercise parameters was observed over puberty inspite of improvement in pulmonary parameters. Possible mechanisms are maturation dependent abnormal pulmonary sling flow, deconditioning and increased % body fat. To the best of our knowledge this is the first report of exercise evaluation in this unique population. More studies are needed with larger number of patients, including accurate measurement of body composition and characterizing exercise capacity evaluation following surgical repair.

Pulse Wave Analysis of HbA1C Categorized Prediabetes, Type 2 Diabetes and Normo-Glycemic Populations: A Pilot Study

Jennifer J. Brown[1], Kimberly G. Baskette[2], Corey A. Rynders[3], Aaron I. Vinik[4], Sheri R. Colberg-Ochs, FACSM[2]. [1]Elizabeth City State University, Elizabeth City, NC. [2]Old Dominion University, Norfolk, VA. [3]University of Colorado Denver-Anshutz Medical Campus, Denver, CO. [4]Eastern Virginia Medical School, Noroflk, VA.

(No relevant relationships reported)

Arterial stiffness is a significant risk factor for cardiovascular events and early detection is key for intervention and monitoring. This pathophysiological process is accelerated in type 2 diabetes (T2D), yet the onset of this condition has a limited body of research.
PURPOSE: To evaluate (1) arterial stiffness properties via pulse wave analysis (PWA) across a 4-group spectrum, and (2) determine whether waist-to-height-ratio (WHtR), waist circumference (WC) or body mass index (BMI) serves as the best predictor of early changes in PWA pathophysiology.
METHODS: PWA was measured in 52 participants across four groups separated by HbA1c values: 13 normo-glycemic (N, 4.0-5.1), 14 high normal (HN, 5.2-5.6), 10 prediabetes (PD, 5.7-6.4) and 13 with T2D (T2D, ≥ 6.5). Brachial, central and peripheral pressures, central and peripheral augmentation index (AIx) data were collected via Sphygmocor using validated methods after overnight caffeine abstinence and a minimum 4-hr fast. Group differences were evaluated via MANCOVAs. Hb$_{A1C}$, WHtR, WC and BMI data were assessed through regression to determine the best predictor.
RESULTS: Significant differences were found between N to T2D and HN to T2D for brachial systolic blood pressure (SBP) [$F(3,46)$=2.743, p<.05], brachial diastolic blood pressure (DBP) [$F(3,46)$=3.329, p<.028] and brachial mean pressures (MP) [$F(3,46)$=4.321, p<.009]. Central DBP and MP differed between N to T2D, and HN to PD and T2D groups [DBP:$F(3,44)$=3.874, p<.015; MP:$F(3,44)$=3.303, p<.029]. Central pulse pressure (PP) and CAIx showed no differences between groups. Peripheral pressures significantly differed between N and both PD and T2D; HN and both PD and T2D groups for peripheral SBP [$F(3,44)$=3.007, p<.040], peripheral DBP [$F(3,44)$=4.316, p<.009] and peripheral MP [$F(3,44)$=3.487, p<.023], but not PP or

FRIDAY, JUNE 1, 2018

PAIx. WHtR and WC were identified as the best predictors of CAIx after adjusting for age and height [R^2=.800, $F(5,45)$=16.023, $p<$.0005; adj. R^2=.640], while PAIx had no significant predictor.
CONCLUSIONS: PWA may be effective for identifying differences in multiple brachial, central and peripheral pressure measures across a novel, pre-defined HbA1C spectrum; however, more research needs to be executed to validate these findings. WHtR and WC, but not BMI, effectively predicts CAIx.

Insulin Potentiates Neuronal Responses to Chemical Stimulation in Thin Muscle Afferents and Dorsal Root Ganglia

Norio Hotta[1], Kimiaki Katanosaka[1], Kazue Mizumura[1], Jere H. Mitchell, FACSM[2], Scott A. Smith[2], Masaki Mizuno[2]. *[1]Chubu University, Kasugai, Japan. [2]University of Texas Southwestern Medical Center, Dallas, TX.* (Sponsor: Jere H. Mitchell, FACSM)
(No relevant relationships reported)

The cardiovascular response to physical activity is abnormally exaggerated in patients with type 2 diabetes mellitus (T2D). Recent studies in patients with T2D have suggested that this exaggerated responsiveness is mediated, in part, by the skeletal muscle metaboreflex. However, the mechanisms causing augmentations in muscle metaboreflex function in this disease remain to be elucidated. Chronic hyperinsulinemia associated with peripheral insulin resistance is one of the pathophysiological characteristics of T2D. Evidence suggests that transient receptor potential vanilloid receptors, which contribute to metaboreflex activation, are more responsive to stimuli in the presence of insulin. Given that metaboreflex afferent fibers reside in skeletal muscle, it is suggested that hyperinsulinemia may underlie the skeletal muscle metaboreflex overactivity manifest in T2D. **PURPOSE**: To examine the impact of insulin on neuronal responses to chemical stimulation in thin muscle afferents and dorsal root ganglia (DRG) of normal healthy rodents. It was hypothesized that insulin potentiates the activity of metabolically sensitive afferent neurons. **METHODS**: Chemically activated neurons were assessed by single-fiber recordings from rat muscle-nerve preparations in vitro and by whole cell patch-clamp recordings from cultured mice DRG neurons. The magnitude of responses to capsaicin stimulation and the capsaicin activated current were recorded, respectively. **RESULTS:** Compared to control conditions, thin muscle afferent response magnitude was significantly increased by insulin exposure (0.03±0.03 vs. 0.25±0.02 imp, n=3, P<0.05). In DRG cell culture, total charge transfer by capsaicin activated current was largely augmented by insulin administration (403±159 % changes from control conditions, n=3, P=0.11). **CONCLUSIONS**: These data demonstrate that thin muscle afferent as well as DRG neuronal responses to capsaicin are augmented by insulin exposure in normal healthy animals. The data support the concept that chronic hyperinsulinemia may potentiate skeletal muscle metaboreflex function in T2D contributing to the abnormal cardiovascular response to exercise characteristic of this disease. *Supported by the Lawson & Rogers Lacy Research Fund in Cardiovascular Disease and JSPS KAKENHI JP17K01769*

High Intensity Treadmill Running Reduces Tumour Hypoxia in Mice.

Simon Lønbro, Pernille Byrialsen Elming, Thomas R. Wittenborn, Michael R. Horsman. *Aarhus University Hospital, Aarhus C, Denmark.*
(No relevant relationships reported)

PURPOSE: Low blood perfusion and hypoxia are characteristic features of tumours and are factors of resistance to radiation and chemotherapy. A few rodent studies have shown that aerobic exercise, that has no severe side-effects, may improve perfusion and reduce hypoxia, however the optimal exercise intensity and timing of the effect on the tumour response during radiation and chemotherapy remain uninvestigated. The aim of our study was to investigate the acute effect of one exercise bout of either low, moderate, or high intensity aerobic exercise on tumour perfusion and hypoxia.
METHODS: Two weeks after injection of the C3H mammary carcinoma in the mammary fat pad, 24 female CDF1 mice were allocated to either a control group (no exercise) or three groups performing low (6 m/min), moderate (12 m/min) or high intensity (18 m/min) treadmill running for 30 minutes (n=6 for each group). Just prior to running all mice were injected (i.p.) with Pimonidazole (60 mg/kg) and immediately after exercise they were injected (i.v.) with Hoechst 33342 (10 mg/kg). Exactly 1 minute later the mice were sacrificed, tumours excised, and histological sections prepared. Hypoxia could be determined from the degree of Pimonidazole binding, while analysis of the Hoechst 33342 staining enabled us to analyses perfused vessels in the tumour. The results were statistically compared to similar measurements in the control tumours using a Student's T-test (p<0.05). **RESULTS**: Pimonidazole binding revealed a hypoxic fraction (HF) of 8.7±3.7% in tumours from control animals. This was not significantly changed by low intensity (HF = 8.5±3.2%) or moderate

intensity (HF = 10.3±3.7%) running. However, for those mice exposed to the high intensity running schedule, the tumour hypoxic fraction was significantly reduced to 4.3±2.2% (p=0.03). The Hoechst 33342 analyses on tumour perfusion are currently pending. **CONCLUSIONS**: Our data show that mice running at high intensity for 30 minutes elicit an acute reduction in the hypoxic fraction in the tumour when compared to sedentary mice or mice running at both moderate and low intensities. Our future studies will focus on how long the reduction in hypoxia is maintained after running stops and how that exercise regime can be used to improve tumor treatment-response, especially to radiation.

Preliminary Results of Vascular Function and Aerobic Capacity Profile of Breast Cancer Survivors

Jordan T. Lee, Chad W. Wagoner, Lee Stoner, Kirsten A. Nyrop, Hyman B. Muss, Erik D. Hanson, Aaron Piepmeier, Claudio L. Battaglini, FACSM. *University of North Carolina at Chapel Hill, Chapel Hill, NC.* (Sponsor: Claudio L. Battaglini, FACSM)
(No relevant relationships reported)

PURPOSE: To describe vascular function and aerobic capacity in breast cancer survivors (BCS) who are within one year of completing primary anti-cancer therapy pre and post a 16-week exercise intervention.
METHODS: Applanation tonometry was used to evaluate vascular function (pulse wave velocity, PWV) and cardiopulmonary exercise testing to evaluate aerobic capacity (VO_{2peak}) pre and post 16 weeks of progressive aerobic and strength training exercise at a community based exercise program. Descriptive statistics were used to characterize the sample, paired t-tests to assess pre-post change, and Pearson correlations to evaluate associations between PWV and VO_{2peak}.
RESULTS: Eight BCS, mean age=60 (±8y), BMI=29.5 (±7.4) have been evaluated at baseline. Baseline mean PWV=7.2 (±1.65 m/s) and mean VO_{2peak}=17.3 (±3.24 mL/kg/min). Baseline correlation between PWV and VO_{2peak} was moderate (r^2=0.42, p=0.083). Mean VO_{2peak} improved (+4.04±1.43, p=0.049) in 3 subjects who have completed the exercise intervention to date. Post-intervention PWV was not evaluable at follow-up.
CONCLUSIONS: It has been previously established that aerobic capacity is impaired in BCS compared to age-matched, non-cancer populations. Our findings support this notion (17.3 vs. ~26mL/kg/min healthy; Jones *et al.*, 2012). Vascular function in our sample is similar to previously reported values in BCS (Grover *et al.*, 2015) but reference literature is limited. Our approach exploring correlations between vascular function and aerobic capacity following primary cancer therapy is novel and important as it relates to the potential for designing future preventative interventions. Exercise appears beneficial to aerobic capacity. More follow-up data is needed, and is underway, to assess impact of exercise on vascular function. Supported by funding from Breast Cancer Research Foundation of New York.

Seven Days Of Remote Ischemic Preconditioning Augmented Local-heating Induced Vasodilation In Human Skin

Jahyun Kim, Warren Franke, FACSM, James Lang. *Iowa State University, Ames, IA.* (Sponsor: Warren Franke, FACSM)
(No relevant relationships reported)

PURPOSE: Remote ischemic preconditioning (RIPC), induced by intermittent periods of sublethal ischemia and reperfusion, is a powerful stimulus for adaptations that increase cardioprotection from ischemic-reperfusion (IR) injury. Although RIPC-induced cardioprotection has consistently been demonstrated using animal models, two major clinical trials in humans undergoing cardiac surgery has yielded conflicting results. These different results may be explained by coexisting conditions (e.g., diabetes, obesity, and hypertension) and other factors (e.g., dose of ischemia used to 'precondition' vessels, preexisting ischemia, medications, age, fitness level, etc). Using skin as an alternative human model to study RIPC, we tested cutaneous microvascular responsivity to local heating (Tsk=42oC) before and after repeated RIPC. We hypothesized that seven consecutive days of RIPC will improve the vasodilation response to local heating.
METHODS: Nine young participants (26 ± 1 years, 4 male and 5 female) performed RIPC for seven days. Each daily RIPC session consisted of 4 repetitions of upper arm blood flow occlusion by inflating an arm cuff to 220mmHg for 5 minutes followed by deflation for 5 minutes. Before and after the 7-day RIPC training period, laser

Abstracts were prepared by the authors and printed as submitted.

FRIDAY, JUNE 1, 2018

speckle contrast imaging (LSCI) was used to measure the speed and number of blood cells moving through the forearm cutaneous microvasculature and reflected as a flux value, thereby providing an index of skin blood flow changes during local heating. Flux and blood pressure measurements were collected during baseline (Tsk=33oC) and local heating of forearm skin (Tsk=42oC). Data are represented as cutaneous vascular conductance (CVC), which was calculated as flux / mean arterial pressure.
RESULTS: After seven days of RIPC, the cutaneous vasodilation response to local heating was increased (Pre: 1.17 ± 0.10 vs. Post: 1.51 ± 0.20 CVC, p<0.05). But, baseline values were not different following RIPC (Pre: 0.22 ± 0.03 vs. Post: 0.29 ± 0.40 CVC).
CONCLUSIONS: Seven days of RIPC augmented the local heating response in young forearm skin blood flow. These data suggest that endothelial factors contributing to the local heating response in skin may be affected with repeated RIPC.

The Role of Melatonin In Exercise Enhanced Endothelium-dependent Vasorelaxation In Mesenteric Arteries of SHR

WU Ying, Shi Lijun. *Beijing Sport University, Beijing, China.*
(No relevant relationships reported)

PURPOSE: To determine if melatonin plays an important role in the hypotensive effects of exercise training. Further, to study the role of melatonin binding to melatonergic receptors in the vasorelaxation of small MAs in SHR.
METHODS:Twelve-week-old male normotensive Wistar-Kyoto rats (WKY, n=18) and SHRs (n = 48) were used. SHRs were randomly divided into four groups: SHR sedentary group (SHR-SED, n = 18), SHR sedentary with melatonin receptor antagonist luzindole (Luz) injection group (SHR-SED + Luz, n = 6), SHR exercise group (SHR-EX, n = 18) , and SHR exercise with luzindole injection group (SHR-EX + Luz, n = 6). Luzindole injection groups were injected intraperitoneally (i.p.) with luzindole (1 mg/kg/day in sterile saline) each day. Rats in the exercise groups were subjected to aerobic exercise. Blood pressure and heart rate were measured after exercise. Serum melatonin levels were examined by ELISA. The mechanical properties of small mesenteric arteries were studied with myograph. Western blot and immunofluorescence colocalization were performed to examine the protein expression and distribution of MT1, MT2 receptors and eNOS.
RESULTS: Exercise training produced a significant reduction in blood pressure and heart rate in SHR, which was significantly attenuated by intraperitoneal administration of luzindole, a nonselective melatonin receptor (MT1/MT2) antagonist. Serum melatonin levels in the SHR group were significantly lower than those in the WKY group at 8:00-9:00 and 21:00-22:00, and exercise training reduced this difference. Endothelium-dependent vessel relaxation induced by acetylcholine was significantly blunted in SHR compared with age-matched WKY. Both exercise training and luzindole ameliorated this endothelium-dependent impairment of relaxation in hypertension. Immunohistochemistry and Western blotting showed that protein expression of the MT2 receptor and eNOS, as well as their colocalization in the endothelial cell layer in SHR, was significantly decreased; exercise training suppressed this reduction.
CONCLUSIONS:These results provide evidence that regular exercise has a beneficial effect on improving endothelium-dependent vasorelaxation in MAs, in which melatonin plays a critical role by acting on MT2 receptor to increase NO production and/or NO bioavailability.

The Effects Of Acute Bouts Of Whole Body Vibrate On Central Hemodynamics In The Frail Elderly: A Pilot Study.

Katie Burnet. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*
(No relevant relationships reported)

PURPOSE: Whole body vibration training (WBV) is a promising alternative to conventional exercise therapy in the frail elderly. However, little is known about its effect on the cardiovascular system. The aims of this study were to determine whether an acute bout of WBV: (i) improves measures of central hemodynamics [central systolic blood pressure (cSBP), Augmentation Index (AIx), and Double Product (DP)]; and (ii) can be completed without inducing orthostatic intolerance - a sustained drop in systolic blood pressure (SBP) >20 mmHg or diastolic pressure (DBP) >10 mmHg.
METHODS: Nine elderly rest home residents [81.1 years (SD 7.1), 88% F] participated in a randomized cross-over design incorporating WBV and non-vibrational control experimental conditions (CON) on two separate testing day. On each occasion, participants laid supine for their basement measurement, completed their CON or WBV training, then returned to supine for 90-minute post-exercise evaluation.
RESULTS: There was no between-day difference at baseline. During training, no interaction or between-condition effects were observed for any variable, but there were moderate-large time effects for cSBP (P=0.001), and DP (P<0.001). Following training, no interaction or between-condition effects were observed for cSBP or DP,

---

but an interaction effect was reported for AIx (P<0.019). Post-hoc analysis revealed a non-significant time effect for CON (P=0.0167, Eta 0.0151) and a significant large increase in AIx for WBV (P=0.020, Eta=0.202). None of the participants exhibited orthostatic tolerance.
CONCLUSIONS:WBV is a safe training method for the frail. Future research is warranted to determine the chronic effects on cardiovascular health.

Effects Of Habitual Isometric Handgrip Exercise On Central Blood Pressure In Older Adults

Takanobu Okamoto[1], Ryota Kobayashi[2], Yuto Hashimoto[1], Hiroyuki Hatakeyama[1]. *[1]Nippon Sport Science University, Setagaya-ku, Tokyo, Japan. [2]Teikyo University of Science, Adachi-ku, Tokyo, Japan.*
(No relevant relationships reported)

Central (aortic) blood pressure (BP) is a more important predictor of cardiovascular diseases than peripheral (brachial) BP. Isometric handgrip exercise can effectively decrease peripheral BP. However, effects of isometric handgrip exercise on central BP remain unknown. **PURPOSE:** The present study aimed to determine whether habitual isometric handgrip exercise decreases central BP in older adults with stage 1 and 2 hypertension. **METHODS:** Twenty-four males and females (mean age 63 ± 2 y; $\pm$ SEM) with stage 1 and 2 hypertension (brachial systolic or diastolic BP of 140-179 or 90-109 mmHg, respectively) who were not actively involved in regular resistance or endurance training were randomly assigned to a group that did isometric handgrip exercise (IHG) or a control (CON) group. The isometric handgrip exercise comprised four unilateral 2-min isometric contractions at 30% of maximal voluntary contraction using a programmed handgrip dynamometer with 1-min rest periods for five days per week for four weeks. Central systolic BP (cSBP), brachial systolic BP (bSBP), brachial diastolic BP (bDBP), and the augmentation index at a heart rate of 75 beats per minute (AIx75) were non-invasively measured after resting in the supine position for at least five minutes in both groups before (baseline) and after four weeks of training using an automated applanation tonometric system. **RESULTS:** Baseline cSBP, bSBP, bDBP, and AIx75 did not significantly differ between the groups. Consistent with previous studies, bSBP and bDBP after training significantly decreased from baseline from 155 ± 3 to 142 ± 3 mmHg and from 94 ± 3 to 88 ± 2 mmHg, respectively (p<0.05 for both). The cSBP and AIx75 did not change in the CON group, but significantly decreased from baseline after training in the IHG group from 165 ± 4 to 148 ± 4 mmHg and from $88\pm4\%$ to $82\pm4\%$, respectively (p<0.05 for both). The cSBP was significantly lower after training in the IHG than in the CON group (148 ± 4 vs. 159 ± 3 mmHg, p<0.05). **CONCLUSIONS:** These results suggest that isometric handgrip exercise could reduce central BP in older adults with stage 1 and 2 hypertension. Therefore, isometric handgrip exercise might be an effective non-pharmacological therapy for prevention and treatment of cardiovascular disease.

Arterial Stiffness and Mitochondrial Oxidative Capacity in Obese African Americans
Joshua E. McGee, Terence E. Ryan, Gabriel S. Dubis, Savanna G. Barefoot, Patricia M. Brophy, Damon L. Swift.
East Carolina University, Greenville, NC
PURPOSE: African Americans are at greater risk for arterial stiffness and mitochondrial dysfunction compared to Caucasian Americans. Prior studies report a relationship between arterial stiffness and mitochondrial function in individuals with hypertension or gestational diabetes, but it has not been evaluated in healthier populations or African Americans. This study assessed arterial stiffness and in vivo skeletal muscle mitochondrial capacity in obese African Americans. **METHODS**: Fifteen (47.7 ± 6.9 yrs; 34.6 ± 4.2 kg/m²; 86.7% female) obese African Americans from an on-going exercise training study were analyzed. Mitochondrial capacity was determined via near-infrared spectroscopy (NIRS) and quantified as recovery kinetics of muscle O_2 consumption (rate constant) after a short bout of exercise (vastus lateralis), followed by short bouts (5-10 s) of ischemia. Arterial stiffness was assessed as carotid-femoral pulse wave velocity (cfPWV) and aortic augmentation index (AIx). **RESULTS**: No significant correlation was observed between rate constant and cfPWV (r=0.17, p=0.55) or AIx (r=-0.01, p=0.97), but approached significance with mean arterial pressure (r=0.50, p=0.057). Adjusting for age and gender revealed no significant findings between arterial stiffness and mitochondrial capacity parameters. **CONCLUSIONS**: Arterial stiffness was not associated with mitochondrial oxidative capacity. Future studies should consider a larger sample size or greater variance in African American participant demographics (e.g. sedentary status, BMI, gender).

Skeletal Muscle Oxygenation During Plantarflexion Exercise In Young-old And Older-old Adults

Arun Maharaj[1], Salvador J. Jaime[2], Justin Mason[3], Patrick Saracino[3], Arturo Figueroa-Galvez, FACSM[1]. *[1]Texas Tech University, Lubbock, TX. [2]University of Wisconsin - La Crosse, La Crosse, WI. [3]Florida State University, Tallahassee, FL.* (Sponsor: Arturo Figueroa, FACSM)
(No relevant relationships reported)

The aging process is associated with a gradual decrease in exercise performance, leg muscle blood flow and oxygenation, and endothelial vascular function. **PURPOSE**: To examine potential differences in femoral artery flow-mediated dilation (fa-FMD) and calf muscle oxygenation (HbO_2) during low-intensity plantarflexion exercise in older adults. **METHODS**: 43 young-old (YO; n=24, 67 ± 1 years) and older-old (OO: n=19, 70 ± 1 years) individuals were included in this study. We measured body fat % and leg lean mass (LLM) by DEXA and handgrip maximal voluntary contraction (MVC) using a dynamometer. VO_{2max} was estimated using a submaximal treadmill test. fa-FMD was assessed by Doppler ultrasound, measuring the relative change in diameter from baseline to peak hyperemic response following 5 min of muscle ischemia. After a 10-min semi-recumbent rest, participants performed three sets (3-min each) of rhythmic plantar-flexion exercise at increasing intensity (20, 30 and 40 pounds) separated by 1-min of rest. Percent changes (%Δ) in muscle HbO_2 from baseline to the 3rd min of each set was monitored by near-infrared spectroscopy (NIRS) on the medial gastrocnemius muscle. **RESULTS**: There were no between-group differences in VO_{2max}, MVC, LLM, body fat %, and fa-BF (*P*= .07). The OO group had significantly lower fa-FMD compared to the YO group (5.7 ± 1.4 vs 6.7 ± 1.6%, *p* < .05). During exercise, the OO group exhibited a higher %Δ in HbO_2 compared to the YO in sets 2 (-60.0 ± 21.2 vs. -44.7 ± 17.2%, *p* < .05) and 3 (-66.7 ± 18.8 vs. -52.6 ± 18.2%, *p* < .05). **CONCLUSIONS**: There was a lower calf muscle oxygenation during low-intensity plantar-flexion exercise performed at the same absolute intensity in OO compared to YO adults. Exercising at a greater relative intensity may explain the lower calf muscle oxygenation in OO adults.

Assessment of Vascular Function throughout the Menstrual Cycle

Alexandra E. Hirt, Elissa K. Katulka, Megan M. Wenner, Melissa A.H. Witman. *University of Delaware, Newark, DE.*
(No relevant relationships reported)

BACKGROUND: Fluctuating sex hormones throughout the menstrual cycle, particularly endogenous estrogen, have been documented to correspond with nitric oxide (NO) bioavailability and likely have a cardioprotective effect in premenopausal women. However, the corresponding temporal changes in vascular function are not entirely understood. **METHODS:** Passive leg movement (PLM) is a relatively novel technique assessing NO-mediated vascular function, with a higher degree of NO-dependence than the traditionally used flow-mediated dilation (FMD) technique that could provide additional insight. **PURPOSE:** To assess vascular function throughout the menstrual cycle in premenopausal women using PLM, in addition to FMD. **RESULTS:** Brachial artery FMD tended to be increased during the OV phase (8.8±1%) compared to the EF (7.8±1%) and ML (7.6±1%) phases. The femoral artery PLM AUC response during the ML phase was significantly lower than the EF response (leg blood flow AUC EF: 154±41 mL, OV: 79±24 mL, and ML: 44±15 mL). **CONCLUSION:** These findings support the importance of menstrual cycle when interpreting vascular function data as measured by FMD and PLM.

Different Restrictive Devices to Achieve Blood Flow Restriction on Pulse Wave Reflection

Erica M. Marshall, Jason C. Parks, Yu Lun Tai, Alaina Glasgow, Leslie Sensibello, Kathryn Geither, J. Derek Kingsley, FACSM. *Kent State University, Kent, OH.*
(No relevant relationships reported)

Blood flow restriction (BFR) has mainly been achieved with an automated blood pressure cuff. However, knee wraps to restrict flow are used as a form of practical BFR (pBFR). The effects of resistance exercise with BFR and pBFR on pulse wave reflection is unclear. **PURPOSE**: To examine the effects of BFR, pBFR, and traditional high-intensity (HI) bench press resistance exercise on pulse wave reflection in resistance-trained individuals. **METHODS**: Twenty-three (Age: 23±3yrs) resistance-trained men underwent either bench press with BFR, pBFR [30% 1-repetition maximum (1RM), 4 sets, 30-15-15-15 repetitions, 30sec of rest], HI [70% 1RM, 4

sets, 8 repetitions, 60sec of rest] or a control. Measurements were taken at rest and 10mins postexercise. A 4x2 ANOVA was used to evaluate condition (BFR, pBFR, HI, Control) across time (rest, recovery) on pulse wave reflection. **RESULTS:** There were significant (p=0.0001) increases in heart rate [(BFR: rest: 60±7bpm; recovery: 69±7bpm), (pBFR: rest: 58±10bpm; recovery: 64±11bpm), (HI: rest: 58±12; recovery: 72±13bpm)] such that all three conditions were different compared to rest and the control. There was a significant interaction (p=0.0001) for the augmentation index (AIx) in that during recovery from BFR (rest: 117.9±8.2%; recovery: 126.2±9.0ms), pBFR (rest: 114.9±4.9ms; recovery: 127.9±9.8ms) and HI (rest: 115.6±6.2ms; 122.8±6.4ms) it was elevated compared to rest, and the control. There was also a significant (p=0.0001) interaction for the AIx normalized at 75bpm (AIx@75) [BFR: rest: 8.8±13.3%; recovery: 25.9±9.5%; pBFR: rest: 2.7±8.5%; recovery: 23.3±14.2%; HI: 4.4±12.1%; recovery: 21.2±9.9%)] in that it was augmented during recovery to rest and the control. The subendocardial viability ratio (SEVR) for BFR (rest: 138.4±19.5; recovery: 111.2±11.3), pBFR (152.2±27.5; recovery: 125.5±33.5), and HI (rest: 152.9±37.9; recovery: 111.9±28.7) also demonstrated a significant (p=0.0001) condition by time interaction such that they were elevated above rest in all three resistance exercise conditions, which were different than the control. **CONCLUSION:** These data demonstrate that BFR using an automated cuff or knee wraps has similar effects as traditional high-intensity resistance exercise on pulse wave reflection in resistance-trained men after the bench press.

Effect of a High Fat Meal on Microvascular Responsiveness Measured using Near Infrared Spectroscopy

Britton C. Scheuermann, Erin C. Garmyn, Morgan M. Monahan, Timothy R. Rotarius, Christopher R. Silette, Barry W. Scheuermann. *The University of Toledo, Toledo, OH.*
(No relevant relationships reported)

Studies indicate that the rate of tissue oxygen reperfusion following brief periods of occlusion can detect differences in vascular responsiveness. Consumption of a high fat meal (HFM) has been shown to reduce vascular function in conduit arteries. The extent that consumption of a HFM effects microvascular reactivity has not been examined. **PURPOSE:** To examine the effect of a HFM on microvascular responsiveness in the brachial artery (BA). It was hypothesized that a HFM would slow tissue reperfusion consistent with impaired microvascular function. **METHODS:** Eleven healthy (27.8 ± 3.2 yrs, (± SEM)) men (n=7) and women (n=4) reported to the laboratory following a 12 h fast and no prior exercise. Vascular function in the left BA was assessed using the flow-mediated dilation (FMD). BA images were obtained in B-mode using a linear array probe (operating frequency of 7.0 MHz). Images were captured (10 fps) and analyzed using software that incorporates automated wall detection. %FMD was calculated as the difference between baseline diameter and the maximal diameter measured following cuff release. Near infrared spectroscopy was used to measure changes in oxy- (HbO_2) and deoxy-hemoglobin (HHb) in the right forearm. Tissue oxygenation saturation (StO_2) was calculated ($[HbO_2]/[HbO_2 + HHb]$). The slope of StO_2 reperfusion (S2) following cuff release was measured using linear regression. After Pre-HFM measures were obtained, subjects consumed a HFM consisting of 90 g total fat (63 g saturated fat), 364 mg cholesterol, 17 g carbohydrate, and 139 mg sodium. Measures of %FMD and S2-StO_2 were repeated after 2 hours. **RESULTS:** The HFM resulted in a decrease in BA reactivity (Pre-HFM, 6.80 ± 0.79 %FMD; Post-HFM, 4.12 ± 0.55 %FMD; p>0.05). Compared to baseline, the HFM resulted in a lower S2-StO_2 slope (Pre-HFM, 3.32 ± 0.18 % a.u./s; Post-HFM, 2.96 ± 0.16 % a.u./s; p<0.05). **CONCLUSION:** This study provides evidence that a HFM reduces the reperfusion rate in the microcirculation, consistent with an impaired vasodilatory response. While there was no correlation between the slowed reperfusion and impaired FMD following the HFM, it may be speculated that differences in measurement site may have contributed, at least in part, to this discrepancy. The mechanism responsible for the slowed reperfusion requires further investigation.

Different Responses Of Arterial Stiffness And Nitric Oxide Bioavailability To Different Exercise Training Programs

Natsuki Hasegawa[1], Shumpei Fujie[1], Naoki Horii[1], Eri Miyamoto-Mikami[2], Katsunori Tsuji[1], Masataka Uchida[1], Takafumi Hamaoka, FACSM[1], Izumi Tabata, FACSM[1], Motoyuki Iemitsu[1]. *[1]Ritsumeikan University, Kusatsu, Japan. [2]National Institute of Fitness and Sports in Kanoya, Kanoya, Japan.*
(No relevant relationships reported)

Aerobic training (AT) and high-intensity intermittent training (HIIT) reduce arterial stiffness, whereas resistance training (RT) induces no change or deterioration of arterial stiffness. Nitric oxide (NO) is produced from L-arginine by endothelial NO synthase (eNOS) in endothelial cells. AT enhances arterial NO-derived vasodilation,

resulting in the reduction in arterial stiffness. However, the underlying molecular mechanism related to different effects of different exercise training on arterial stiffness remains unclear. **PURPOSE**: This study aimed to clarify the different responses of arterial stiffness and NO production to different exercise training in rats and humans. **METHODS**: Animal study; Forty 10-week-old male Sprague-Dawley rats were randomly divided into 4groups; sedentary control (CON), AT (treadmill running for 60min at 30m/min, 5days/wk for 8weeks), RT (ladder climbing, 8-10sets/day, 3days/wk for 8weeks), and HIIT (fourteen 20sec swimming sessions with a weight equivalent to 14-16% of each body weight and 10 sec pause was allowed between exercise sessions, 4days/wk for 6weeks from 12-week-old). Human study; 21 healthy young subjects were randomly divided into 3groups; CON, AT (45min of cycling at 60-70% maximal oxygen uptake [VO2max] intensity, 3days/week for 8-week), and HIIT (6-7×20sec exhaustive cycling at 170%VO2max with 10 sec rest between each sessions, 4days/week for 6-week). **RESULTS**: Animal study; aortic pulse wave velocity (PWV), as an index of arterial stiffness, was significantly reduced in both AT and HIIT as compared to CON and RT (P<0.05), whereas there was no difference between RT and CON. Arterial eNOS and Akt phosphorylation and plasma NOx level were significantly elevated in AT and HIIT as compared to CON and RT (P<0.05), but did not change in the RT. Arterial eNOS phosphorylation was negatively correlated with aortic PWV (r=-0.38, P<0.05). Human study; carotid-femoral PWV was decreased and plasma NOx level was elevated by AT and HIIT (P<0.05). HIIT-induced reduction of carotid-femoral PWV and elevation of plasma NOx level were equal to that caused by AT. **CONCLUSIONS**: HIIT-induced increase in aortic NO bioavailability may improve central arterial stiffness, as same degree of AT. Estrous Cycle-Mediated Regional Diversity in BK Channel Expression and Function in Arterial Myocytes

Jacob A. Goldsmith, Kirk W. Evanson. *Florida State University, Tallahassee, FL.* (Sponsor: Heidi Kluess, FACSM)

(No relevant relationships reported)

Large-conductance calcium (Ca^{2+})-activated potassium (BK) channels are significant regulators of arterial smooth muscle cell (myocyte) membrane potential and arterial contractility. The expression and function of BK channels in ovary-intact female resistance arteries are poorly understood. Moreover, the effects of endogenous steroid levels associated with the estrous cycle on arterial BK channels are unclear. **PURPOSE:** To investigate estrous cycle effects on BK channel expression and function in uterine and cerebral arterial smooth muscle. **RESULTS:** Western blotting and biotinylation of whole uterine arteries revealed an increase in total (~ 39%, n=7) and plasma membrane-localized (~ 64%, n=4-5) β1 subunits during proestrus as compared to diestrus. Patch-clamp electrophysiology demonstrated that BK channel activation (open probability $[P_O]$) was enhanced ~ 5-fold during proestrus in uterine arterial myocytes (diestrus: P_O=0.09±0.05 (n=4), proestrus: P_O =0.55±0.10 (n=5); 10μM free Ca^{2+}). In contrast, BK channel expression and activation were unchanged during proestrus in cerebral arterial myocytes (diestrus: P_O=0.48±0.08 (n=11), proestrus: P_O =0.56±0.09 (n=4); 10μM free Ca^{2+}). **CONCLUSION:** These data suggest that endogenous steroids associated with the estrous cycle can alter BK channel expression and function in female resistance arteries. However, the estrous cycle effects on arterial BK channels are region-specific.

Comparison of Vascular Structure and Function in Obese Children and Youth: A Pilot Study

Nicola R. Hurley[1], Sarah M. Kelly[1], Sinead Murphy[2], Clare McDermott[1], Niall M. Moyna[1]. *[1]Dublin City University, Dublin, Ireland. [2]Temple Street Children's University Hospital, Dublin, Ireland.*

(No relevant relationships reported)

Comparison of Vascular Structure and Function in Obese Children and Youth – A Pilot Study

Hurley NR[1], Kelly SM[1], Murphy S[2], McDermott C[1], Moyna NM[1]

[1]Vascular Research Unit, School of Health and Human Performance, Dublin City University, Dublin 9, [2]Temple Street Children's University Hospital, Dublin

Introduction: Atherosclerotic cardiovascular disease is accelerated by early exposure to established risk factors and their persistence over time. The purpose of this pilot study was to compare vascular structure and function between obese (OB) and normal weight (NW) children and youth. **Methods:** Five OB (mean ±SD; age 12.2 ± 2.0 yr) and six NW controls (13.5 ± 1.3 yr) made a single visit to DCU following an overnight fast. A blood sample was taken and left far wall (LFW) carotid intima-media thickness (cIMT), changes in brachial artery diameter (BAD) in response to shear stress and glyceryl-trinitrate, and VO_2max were measured. Values are mean ±SD. **Results:** Compared to NW participants, OB participants had a significantly higher BMI (20.85 ± 2.69 vs. 36.62 ± 3.74 kg×m²), waist-hip ratio (0.85 ± 0.06 vs. 0.94 ±

0.08), systolic blood pressure (SBP) (110.33 ± 8.33 vs 129.60 ± 2.60 mmHg) and significantly lower VO_2max scores (41.08 ± 13.69 vs. 24.72 ± 3.00 mL×kg×min^{-1}×). LFW-cIMT was significantly higher in OB than NW (0.06 ± 0.00 vs. 0.05 ± 0.00 mm) and there was no significant group difference in BAD in response to shear stress (OB vs NW; 11.27 ± 7.94 vs. 11.79 ± 4.94 mm) or glyceryl-trinitrate (30.63 ± 10.84 vs. 29.20 ± 12.67 mm). LFW-cIMT was positively related to fasting insulin (p<0.05), BMI (p<0.001), SBP (p<0.001) and inversely related to VO_2max (p<0.003). **Conclusion:** cIMT is i) higher in OB than NW children and youth, ii) positively related to SBP and BMI, and iii) inversely related to VO_2max.

The Comparison Of High-intensity Interval Exercise Vs. Continuous Moderate-intensity Exercise On C1q/tnf-related Protein-9 Expression And Flow-mediated Vasodilation In Obese Individuals

Brandon G. Fico[1], Ryan S. Garten[2], Michael C. Zourdos[1], Michael Whitehurst, FACSM[1], Peter J. Ferrandi[1], Katelyn M. Dodge[1], Gabriel Pena[1], Alexandra A. Rodriguez[1], Chun-Jung Huang, FACSM[1]. *[1]Florida Atlantic University, Boca Raton, FL. [2]Virginia Commonwealth University, Richmond, VA.* (Sponsor: Dr. Chun-Jung Huang, FACSM)

(No relevant relationships reported)

PURPOSE: A recent novel adipocytokine, C1q-TNF-related protein-9 (CTRP9), has been shown to increase activation of endothelial nitric oxide synthase and reduce vasoconstrictors (e.g., endothelin-1). In addition, CTRP9 may play a compensatory role in obesity-related endothelial dysfunction. Although there is limited information regarding exercise-mediated CTRP9, high-intensity interval exercise (HIIE) has been shown to be as or more effective than continuous moderate-intensity exercise (CME) in improving indicators of endothelial function (e.g., brachial artery flow-mediated dilation [BAFMD]). Therefore, the purpose of this study was to investigate the effect of acute HIIE vs. CME on serum CTRP9 and BAFMD responses in obese individuals. **METHODS**: Sixteen young male subjects (9 obese and 7 normal-weight) participated in a counterbalanced and caloric equated experiment: HIIE (30 minutes, 4 intervals of 4 minutes at 80-90% of VO_{2max} with 3 minutes rest between intervals) and CME (38 minutes at 50-60% VO_{2max}). Serum CTRP9 and BAFMD, were measured prior to, immediately following exercise, and 1 hour and 2 hours into recovery. **RESULTS**: The concentration of serum CTRP9 was significantly increased immediately following acute HIIE and CME in both obese and normal-weight groups (p = 0.003). Furthermore, both significant treatment by time and group by time interactions for BAFMD were observed following both exercise protocols (p = 0.018; p = 0.009; respectively), with a greater CME-induced BAFMD response at 2 hours into recovery in obese compared to normal-weight subjects. Additionally, a positive correlation in percent change (baseline to peak value) between CTRP9 and BAFMD was found following acute CME (r = 0.589, p = 0.016). **CONCLUSIONS**: Acute HIIE is as effective as CME to upregulate CTRP9 expression in both obese and normal-weight individuals, although CTRP9 may potentially improve CME-mediated BAFMD. The novel results from this study provide a foundation for additional examination of the mechanisms of exercise-mediated CTRP9 on endothelial function.

The Effect Of Aquatic Exercise On Arterial Stiffness And Central Blood Pressure

Marina Fukuie[1], Takayuki Yamabe[1], Yosuke Nomura[2], Tatsuya Hashitomi[2], Seiji Maeda[1], Jun Sugawara[3]. *[1]University of Tsukuba, Tsukuba, Japan. [2]Tsukuba Aqualife Laboratory, Tsukuba, Japan. [3]National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.* (Sponsor: Shigehiko Ogoh, FACSM)

(No relevant relationships reported)

Purposes: Aquatic exercise is ideal for older adults because it mitigates weight-bearing stress. However, the effect of aquatic exercise on arterial stiffness and central (e.g., aortic) blood pressure (BP), strong determinants of future cardiovascular disease, remains unclear. We determined if aquatic exercise would decrease arterial stiffness and central blood pressure. **Method:** Twelve normotensives middle-aged and older peoples (mean age = 66±9 yrs, 5 men) participated a supervised aquatic exercise training program (90 min, 1 day/week, 3 months) which mainly consisted of walking, stretching, and muscle strengthening in water. Brachial and aortic BP (estimated from brachial BP waveform via general transfer function), and brachial-ankle pulse wave velocity (baPWV; an index of arterial stiffness) were measured before and after the training period. **Results:** Following the training intervention, body mass did not change significantly, whereas brachial and aortic systolic BP significantly decreased (from 116 ± 10 to 109 ± 12mmHg, P = 0.04 and from 111 ± 9 to 104 ± 11mmHg, P = 0.03, respectively). In addition, baPWV lowered significantly after the training

intervention (from 1355 ± 154 to 1274 ± 168 m/s, P = 0.004). **Conclusion:** The current study firstly demonstrates that regular aquatic exercise, even at a low frequency, could mitigate cardiovascular disease risk in normotensive middle-aged and older people. In the future, we should compare effectiveness of aquatic exercise with that of exercise on land, and study on other populations (e.g., hypertensive patients).

Oxidant-Antioxidant Balance And Peripheral Vascular Function: The Impact Of Chronic Antioxidant Supplementation

Austin C. Hogwood, Jennifer Weggen, Carson Fralin, David Lee, Matthew Scott, Ryan S. Garten. *Virginia Commonwealth University, Richmond, VA.*

(No relevant relationships reported)

Reactive oxygen and nitrogen species (RONS) have been revealed to incur both positive and negative changes to physiological function and adaptation. Specific to the peripheral vasculature, RONS can act to reduce important vasoactive components, such as nitric oxide (NO), or, in some instances, act in vasodilatory capacity as an endothelial-derived hyperpolarizing factor. **Purpose:** This study sought to determine the effects of altering the oxidant-antioxidant balance, via a chronic antioxidant supplementation, on leg vascular function. **Methods:** Five healthy, young male subjects ingested an antioxidant cocktail (500mg vitamin C, 400mg vitamin E, and 200 mg of alpha lipoic acid) twice a day for 28 days. Leg vascular function, measured via passive leg movement (PLM), was performed prior to supplementation (Day 0) and on days 1, 7, 14, 21, 28 after the start of supplementation. An additional testing day was performed 7 days after cessation of the supplementation (Day 35). **Results:** Leg vascular function, measured via PLM-induced leg blood flow (LBF) and AUC, was significantly decreased over time with a 50% reduction in the PLM-induced LBF and 60% reduction in LBF AUC. After a 7-day cessation of supplementation, PLM-induced LBF and LBF AUC returned to baseline. **Conlusion:** This study revealed that 28 days of chronic antioxidant supplementation resulted in a reduction in peripheral vascular function in young healthy individuals that was completely restored after cessation of supplementation. As PLM has been revealed to be highly NO-mediated, this study identifies antioxidant supplementation as a modulator of NO bioavailability potentially through the inhibition of RONS-induced vasodilatory capacity or a reductive stress-like mechanism.

Racial Differences in Vascular Function in Response to Mental Stress

Bryon M. Curtis, John D. Akins, Jordan C. Patik, Guillermo X. Olvera, Aida Nasirian, Jeremiah C. Campbell, R. Matthew Brothers. *University of Texas at Arlington, Arlington, TX.*

(No relevant relationships reported)

African Americans (AA) have a higher prevalence of hypertension and other cardiovascular (CV) complications compared to other populations. While the reasons for this elevated CV disease risk are multifactorial, vascular dysfunction is a key contributing factor. It has been previously shown that mental stress, induced by mental arithmetic, results in a significant increase in forearm blood flow (FBF). This response has been predominantly attributed to a mental stress-induced release and subsequent vasodilatory effect of Nitric Oxide (NO). In this regard, a previous study has reported that AA have an attenuated increase in FBF as compared to Caucasians (CA) in response to mental stress, which may be related to impaired vascular function and thus elevated CV disease risk in AA. However, this study was conducted in a middle-age cohort (mid to late 40's). Whether this attenuation is present in a relatively young and healthy population is unknown. **PURPOSE:** The purpose of this study was to test the hypothesis that the vasodilatory response to mental stress is blunted in a relatively young and healthy AA population. **METHODS:** 6 AA and 6 CA males (AA age: 22 ± 2.6, CA age: 23 ± 4.6) participated in this study. All measurements were obtained in the morning following an overnight fast. Brachial artery diameter and blood velocity were assessed using high resolution duplex ultrasound. Mental stress was induced by asking subjects to subtract 7 continuously from a 3-digit number while attempting to report answers at a pace set by a 60 bpm metronome. The 3-digit number was changed at 20 second intervals. FBF was measured during a two minute baseline followed by 3 minutes of mental stress. Vascular function was assessed as the absolute peak blood flow response (ml/min) as well as peak conductance (ml/min/mmHg) during the mental stress. **RESULTS:** The absolute peak flow (AA: 183 ± 39 ml/min, CA: 307 ± 127 ml/min; P = 0.05) were significantly greater in CA compared to AA. The maximum increase in conductance (AA: 2.03 ± 0.32 ml/min/mmHg, CA: 3.69 ± 1.39 ml/min/mmHg; P = 0.02) was also significantly higher in CA as compared to AA. **CONCLUSION:** This preliminary data support our hypothesis that vascular function in response to mental stress is attenuated in young healthy AA as compared to their CA counterparts.

The Effect Of Exercise On Endothelial Function And Glycemic Control In Type 2 Diabetes: Meta-analysis

Yoonjung Park[1], Junghoon Lee[2], Ruda Lee[3], Moon-Hyon Hwang[3], Marc T. Hamilton[1]. *[1]University of Houston, Houston, TX. [2]Korea National Sport University, Seoul, Korea, Republic of. [3]Incheon National University, Incheon, Korea, Republic of.*

(No relevant relationships reported)

PURPOSE: Vascular endothelial dysfunction induced by hyperglycemia and elevated insulin resistance is a potent risk factor for cardiovascular disease (CVD) and likely contributes to multiple chronic disease complications associated with aging like dementia. The aim of this study was to systematically review and quantify the effects of exercise on endothelial function (EF) in type 2 diabetes (T2D). **METHODS**: Five electronic databases were searched (until June 2017) for studies that met the following criteria: (i) randomized controlled trials; (ii) T2D aged ≥18 years; (iii) measured EF by brachial artery flow-mediated dilation (FMD); (iv) structured and supervised exercise intervention for ≥8 weeks. **RESULTS**: Thirteen cohorts of eight studies (306 patients, average age 59 years) met the inclusion criteria. Exercise training significantly increased FMD (mean ES = 0.41, 95% CI = 0.21 to 0.62, P < 0.001). Low to moderate intensity subgroups and aerobic exercise (AE) subgroups significantly increased FMD more than moderate to high intensity subgroups and combined AE and resistance exercise (RE) subgroups respectively (P < 0.01, P < 0.05). Exercise training significantly decreased glycated hemoglobin (HbA1c) (mean ES = -0.40, 95% CI = -0.61 to -0.19, P < 0.001). Low to moderate intensity subgroups significantly decreased HbA1c more than moderate to high intensity subgroups (P < 0.05). **CONCLUSIONS**: Our results suggest that in patients with T2D, lower intensity exercise has physiological meaningful effects on EF, in support of the emerging concept that the lower efforts of exercise are not necessarily less cardioprotective than higher intensity training.

High Aerobic Fitness And Muscular Strength Offset Aging-induced Deterioration Of Male Sexual Function

Hiroshi Kumagai[1], Toru Yoshikawa[2], Kanae Myoenzono[2], Nobuhiko Akazawa[3], Seiji Maeda[2]. *[1]Juntendo University, Inzai, Japan. [2]University of Tsukuba, Tsukuba, Japan. [3]Japan Institute of Sport Sciences, Kita-ku, Japan.*

(No relevant relationships reported)

PURPOSE: Erectile dysfunction (ED) is an impaired male sexual function and associated with depressive symptoms, quality of life and cardiovascular disease in men. The main causes of ED are aging and impaired vascular functions. Vascular functions are positively influenced by physical fitness, such as aerobic capacity, muscle strength and flexibility. However, the relationship between physical fitness and erectile function remains poorly understood. The aim of this study was to investigate the association between physical fitness parameters and erectile function. **METHODS**: In 177 adult males (age; 57 ± 15 [range: 23−82] years, BMI; 22.6 ± 2.6 [range: 17.3−33.6] kg/m²; mean ± SD [range]), we measured peak oxygen consumption (VO_{2peak}) as an index of aerobic fitness, handgrip strength (HGS) as an index of muscular strength, and sit and reach as an index of flexibility. Also, we measured serum testosterone levels. Erectile function was assessed by using International Index of Erectile Function-5 questionnaire (IIEF5: descending score indicates worsening of erectile function). **RESULTS**: IIEF5 score was significantly correlated to age (r_s = −0.56, P < 0.01), height (r_s = 0.35, P < 0.01), glucose (r_s = −0.26, P < 0.01), HbA1c (r_s = −0.43, P < 0.01), testosterone (r_s = 0.18, P < 0.05), VO_{2peak} (r_s = 0.52, P < 0.01) and HGS (r_s = 0.37, P < 0.01), but not sit and reach (r_s = 0.08, n.s.). Multivariate linear regression analysis revealed that IIEF5 score was significantly and independently associated only with VO_{2peak} and HGS, although age and other factors were included in the regression model as confounders. Furthermore, when the subjects were divided into four groups according to median value of HGS value and VO_{2peak} value, IIEF5 score exhibited the highest value in the group with high-HGS and high-VO_{2peak}, and the lowest value in the group with low-HGS and low-VO_{2peak}. **CONCLUSION**: These results suggest that the maintenance of high aerobic fitness and muscular strength may offset aging-induced deterioration of male sexual function. Our present findings may provide a novel insight into the role of physical fitness in reducing the risk of ED and contribute to establish a new approach for ED treatment.

Abstracts were prepared by the authors and printed as submitted.

Reproducibility of a Ramping Protocol to Measure Cerebral Vascular Reactivity Using Functional Magnetic Resonance Imaging

Nicholas G. Evanoff[1], Kara L. Marlatt[2], Justin R. Geijer[3], Bryon A. Mueller[1], Kelvin O. Lim[1], Donald R. Dengel, FACSM[1]. [1]University of Minnesota, Minneapolis, MN. [2]Pennington Biomedical Research Center, Baton Rouge, LA. [3]Winona State University, Winona, MN. (Sponsor: Donald Dengel, FACSM)
(No relevant relationships reported)

PURPOSE: Though individual differences in arterial carbon dioxide and oxygen levels inherently exist, the degree of their influence on cerebral vascular reactivity (CVR) is less clear at the micro-vessel level. The introduction of a partial re-breathing method that independently controls end-tidal carbon dioxide ($P_{et}CO_2$) and end-tidal oxygen ($P_{et}O_2$) has enabled examination of hypercapnic effects on blood oxygen level-dependent (BOLD) magnetic resonance imaging (MRI) signal changes. The purpose of this study was to examine the within- and between-visit reproducibility of BOLD signal changes to an iso-oxic ramping protocol in $P_{et}CO_2$.
METHODS: To stimulate changes in CVR, PetCO2 was altered while $P_{et}O_2$ was held constant using a computer controlled prospective gas-blending device. Two fMRI scans, each including a linear change in $P_{et}CO_2$ were performed on the same visit using a 3-Tesla (3T) scanner. This ramp sequence consisted of decreasing $P_{et}CO_2$ to 30 mmHg and then increasing $P_{et}CO_2$ linearly to 50 mmHg over a 7 min period. The protocol was repeated on a separate visit with minimum of 3 days between scanning sessions. Intraclass correlation coefficients (ICC) and coefficients of variation (CV) were calculated to quantify reproducibility.
RESULTS: Eleven subjects (6 females; mean age 26.5±5.7 years) completed the full testing protocol. Very good reproducibility was observed for the within-visit ramp wave (Visit 1: ICC = 0.82, CV = 6.5%; Visit 2: ICC = 0.74, CV = 6.36%). Similarly, ramp waves were reproducible between scanning sessions (Scan 1: ICC = 0.74, CV = 6.5%; Scan 2: ICC = 0.66, CV = 6.13%).
CONCLUSION: This study demonstrates BOLD signal changes in response to ramp alterations in $P_{et}CO_2$ are reproducible both within- and between-visit MRI scans. Establishment of reproducible methodologies for measuring BOLD signal changes while altering $P_{et}CO_2$ using a ramp protocol will allow researchers to study CVR functionality. Finally, adding a ramping protocol to CVR studies could provide information about linear changes in CVR over a broad range of $P_{et}CO_2$.

Impact of Acute Aerobic and Resistance Exercise on Postprandial Flow-Mediated Dilation in Overweight and Obese Adults

Conlan J. Varty, Craig W. Berry, Kristina B. Arslain, Kevin D. Ballard. *Miami University, Oxford, OH.* (Sponsor: Helaine Alessio, FACSM)
(No relevant relationships reported)

Postprandial hyperglycemia (PPH) transiently impairs brachial artery flow-mediated dilation (FMD) and increases future cardiovascular disease risk. A single bout of aerobic exercise (AE) has been shown to attenuate PPH-induced impairments in FMD in healthy adults for up to 17 hours post-exercise. Studies examining the effects of acute resistance exercise (RE) on postprandial FMD responses are lacking. **PURPOSE:** The purpose of this ongoing investigation is to determine the effects of different exercise modalities on postprandial glucose and FMD responses to an oral glucose tolerance test (OGTT) in overweight and obese adults. We hypothesize that a single bout of exercise performed the prior evening will attenuate PPH-mediated impairments in FMD, independent of exercise modality. **METHODS:** Recruitment for the current study is ongoing. In a randomized, cross-over design, overweight and obese adults [n=4 (3 women); age=21.3±2.1 y; BMI=30.6±4.2 kg/m², VO_2max=31.6±4.5 ml/kg/min; mean±SD] completed three separate trials. Seated rest (control), a single bout of AE (30 min at ~60% VO_2max), or a single bout of whole-body RE (6 exercises, 3 x 10-repetition maximum) preceded an OGTT (1 g/kg body weight) by 14-17 hours. Blood glucose and brachial artery FMD were measured prior to and at 30 min intervals for 2 hours following the OGTT. Repeated-measures ANOVA and LSD post-hoc tests were used to evaluate differences within and between trials. **RESULTS**: Brachial artery FMD (8.3%, 9.1%, and 9.4% for control, AE, and RE trials, respectively) and blood glucose did not differ between trials at baseline. A main effect due to time (P<0.05) was observed for FMD. Brachial FMD transiently decreased (P<0.05) at 30 min post-ingestion in the control (6.1%), AE (6.8%), and RE (6.0%) trials, respectively. A main effect due to time (P<0.001) was observed for blood glucose. Relative to baseline, blood glucose increased (P<0.05) at 30-120 min post-ingestion in the control (%Δ from baseline = 32-57%), AE (20-53%), and RE (28-45%) trials, respectively. **CONCLUSIONS:** Preliminary findings from our ongoing study in overweight and obese adults suggest that acute AE or RE performed the evening prior to an OGTT does not attenuate postprandial decreases in FMD. **Supported by Miami University Seed Grant and Committee on Faculty Research Grant.**

Effects of Obese Skeletal Muscle Cells on Endothelial Cell Angiogenesis

Christopher K. Kargl[1], Yaohui Nie[2], Ron T. Garner[1], Sheelagh Evans[1], Zach R. Hettinger[1], Brian Sullivan[1], Tim P. Gavin, FACSM[1]. [1]Purdue University, WEST LAFAYETTE, IN. [2]Harvard University, Cambridge, MA. (Sponsor: TP Gavin, FACSM)
(No relevant relationships reported)

Vascular disease is a leading cause of morbidity and mortality in obesity. Obesity is associated with impaired endothelial cell (EC) angiogenesis. Skeletal myocytes are important regulators of angiogenesis - EC proliferation, migration, and tube formation. **Purpose**: Determine the effects of obesity on skeletal muscle regulation of EC angiogenesis. **Methods**: Primary human skeletal muscle satellite cells were isolated from the vastus lateralis from lean (LN) and obese (OB) subjects and differentiated into myotubes (HSkMC). Conditioned medium (CM) from HSkMC was collected after a two-day incubation period and used to treat Human Umbilical Vascular Endothelial Cells (HUVECs). HUVEC proliferation was assessed via cell counting, cell viability was determined using an MTT assay, and EC tube formation (tube length and branches) was measured in matrigel after a 4-hour incubation. **Results**: After 24-hour treatment, there was no difference in HUVEC proliferation (LN: 23,333 vs. OB: 22,750, cells) or viability (LN: 181.62 vs. OB: 183.52, AU) between LN and OB HSkMC CM. Also, there was no difference in HUVEC tube length (LN: 23,726 vs. OB: 24,046, AU) or branches (LN: 452 vs. OB: 465, AU) between LN and OB HSkMC CM. **Conclusion**: In cell culture, there is no apparent effect of obesity on skeletal muscle regulation of endothelial cell angiogenesis. However, incubating cells (SkM and EC) with high glucose or high fatty acid, metabolic challenges that are present in vivo, may reveal insights into obesity impaired angiogenesis.

Perfusive and Diffusive Microvascular Oxygen Delivery During Simulated Hypovolemia and Dynamic Forearm Exercise

Shane M. Hammer, Jacob T. Caldwell, Kaylin D. Didier, Andrew M. Alexander, Carl J. Ade, Thomas J. Barstow, FACSM. *Kansas State University, Manhattan, KS.*
(No relevant relationships reported)

The maintenance of brachial artery blood flow during dynamic forearm exercise in the face of simulated hypovolemia (via lower-body negative pressure (LBNP)), has been previously demonstrated. The distinct facets of microvascular oxygen delivery (i.e. perfusive and diffusive) during such an event, however, have not been described. **PURPOSE:** We tested the hypothesis that, during dynamic handgrip exercise, the initiation of LBNP would result in no significant changes in the indices of microvascular perfusive or diffusive oxygen delivery (deoxy-[heme] and total-[heme], respectively) in the exercising muscle. **METHODS:** Six men (26.2 ± 1.7 yrs, 85.5 ± 6.2 kg, 177 ± 1 cm) participated in this study. To determine the effects of LBNP in the absence of exercise, LBNP (~30 mmHg) was applied for two minutes following a resting baseline. After recovery to a second resting baseline, subjects performed seven minutes of dynamic handgrip exercise at 20% MVC. During the final two minutes of exercise, LBNP was initiated. Mean arterial pressure (MAP) was measured continuously via calibrated finger photoplethysmography (Finometer Pro, FMS). Absolute concentrations of deoxy-[heme] and total-[heme] of the flexor digitorum superficialis muscle were measured continuously via frequency-domain multi-distance near-infrared spectroscopy (OxiplexTS, ISS). **RESULTS:** MAP (92.4 ± 12.8 mmHg), deoxy-[heme] (83.7 ± 14.5 μM) and total-[heme] (343 ± 48 μM) were not different between resting baselines (p > 0.05). While all subjects demonstrated an increase in deoxy-[heme] (99.1 ± 8.6 μM) following the application of LBNP at rest, intersubject variability precluded statistical significance (p > 0.05). No significant changes were detected in MAP or total-[heme] (p > 0.05). Dynamic handgrip exercise resulted in significant increases in MAP (104 ± 14 mmHg), deoxy-[heme] (121 ± 29 μM) and total-[heme] (367 ± 52 μM) (p < 0.05); however, the initiation of LBNP during exercise resulted in no significant further changes in MAP, deoxy-[heme] or total-[heme] (p > 0.05). **CONCLUSION:** The absence of any significant changes in deoxy-[heme] or total-[heme] during simulated hypovolemia (i.e. LBNP) suggests that perfusive and diffusive microvascular oxygen delivery to skeletal muscle was preserved at rest and during dynamic handgrip exercise.

Influence of Short, Disrupted Sleep and High-Intensity Interval Exercise on Brachial Artery Vascular Responses

Zacharias Papadakis[1], Jeffrey S. Forsse[1], Matthew N. Peterson[1], Fernando Gutierrez[1], J. Kyle Taylor[2], Peter W. Grandjean, FACSM[1]. [1]Baylor University, Waco, TX. [2]Auburn University, Montgomery, AL. (Sponsor: Peter W. Grandjean, FACSM)
(No relevant relationships reported)

Brachial artery flow-mediated dilation (FMD) is a nitric oxide-dependent measure of conduit artery endothelial function that is transiently potentiated by exercise; yet, it is unclear how short, disrupted sleep (SDS) modifies post-exercise FMD responses to a single episode of high-intensity interval exercise (HIIE). **PURPOSE:** To determine the influence of a single night of SDS on brachial artery FMD responses after HIIE. **METHODS:** Fifteen male participants (age 31.1 ± 5.3 yr; weight 83.5 ± 11.4 kg; BMI 25.8 ± 2.7 kg/m^2; VO$_2$max 49.1 ± 8.5 ml/kg/min) completed a non-exercise control trial after 9 to 9.5 hrs of reference sleep (REF), HIIE by treadmill running (90% and 40% of VO$_2$reserve in 3:2 min ratio) to expend 500 kcals after reference sleep (REF+EX) and HIIE after 3 to 3.5 hrs of short and disrupted sleep (SDS+EX) in a randomized crossover design. Ultrasound measurements of brachial artery FMD were obtained by the same technician under standardized conditions just before, 1 hr and 4 hrs after exercise. FMD responses were analyzed using 3 (condition) by 3 (sample point) repeated measures ANOVAs. **RESULTS:** FMD was augmented 1 hr after exercise in REF+EX (pre-exercise = 12.5 ± 0.9; 1 hr = $17.2^* \pm 1.5$; 4 hr = $12.5 \pm 0.9\%$) and SDS+EX (pre-exercise = 14.9 ± 1.7; 1 hr = $19.3^* \pm 2.2$; 4 hr = $16.2 \pm 2.4\%$) versus no change in REF (pre-exercise = 12.6 ± 1.4; 1 hr = 11.3 ± 1.0; 4 hr = $13.5 \pm 2.1\%$) (p < 0.0494 condition by time interaction). **SUMMARY:** HIIE transiently augments brachial artery FMD and this response is not modified by a single night of short, disrupted sleep.

Obesity Associated Hypertension in Admitted Patients: Treating Isolated Systolic Hypertension May Be Short Sighted

Kelly L. McKinnie[1], J. Mark VanNess[1], Michelle M. Amaral[1], Greg Roberts[2], Jonathan M. Saxe[2], Lewis E. Jacobson[2], Courtney D. Jensen[1]. [1]University of the Pacific, Stockton, CA. [2]St. Vincent Hospital, Indianapolis, IN.
(No relevant relationships reported)

The close association of excess adiposity and elevated blood pressure is well documented. The role of obesity as a contributing factor for resistant hypertension, cardiovascular disease, and cerebrovascular disease is recognized. Given that exercise training could be used to treat both obesity and elevated blood pressure when patients are admitted for trauma care, identifying obesity-associated systolic hypertension may help with long-term control of the root causes for these illnesses. **PURPOSE:** To examine the relationship between body composition, blood pressure, and other measures collected on patient admittance. **METHODS:** Data were collected from 2,306 consecutive patients admitted to a Level 1 trauma center between July, 2012 and June 2015. Patients with head trauma or traumatic brain injury were not analyzed. Patients were considered obese if their BMI was ≥ 30. Multiple linear regression was used to examine the effect of obesity on blood pressure. Other significant variables were examined from the database that contributed to the prediction model. **RESULTS:** Significant predictors of systolic hypertension included blood lactate, age, obesity, pulse pressure, pH, %O2 saturation and hemoglobin levels (R=0.464; p<0.001). Holding all other variables constant, obesity was associated with a 9.7 mmHg increase in systolic blood pressure (p=0.009). A mild (3 mmHg) increase in diastolic blood pressure was noted, but was not found to be statistically significant (p=0.172). **CONCLUSIONS:** The demonstrated relationship between obesity and systolic blood pressure illustrates the need for integrated blood pressure and obesity treatment with exercise training. Therapeutic exercise focused on weight loss goals will likely ameliorate elevated systolic blood pressure. Weight management discussions are challenging, and often avoided by health professionals, but these data show that concomitant antihypertensive medication with therapeutic exercise training may be warranted for prevention of subsequent cardiovascular and cerebrovascular diseases.

2233   Board #69   June 1 11:00 AM - 12:30 PM

Changes in Scattering, Absorption, and Resulting Differential Pathlength Factor During Arterial Occlusion and Reperfusion

Lillie M. Huckaby[1], Shane M. Hammer[1], Dana K. Townsend[2], Thomas J. Barstow, FACSM[1]. [1]Kansas State Universtiy, Manhattan, KS. [2]Wheaton College, Wheaton, IL.
(No relevant relationships reported)

Continuous wave near-infrared spectroscopy (CW-NIRS) has been used to assess microvascular function and the balance between muscle oxygen delivery and oxygen consumption via post-occlusion reactive hyperemia (PORH) tests. However, CW-NIRS relies on the assumption that the scattering and absorption characteristics of the investigated tissue remain unchanged via a constant differential pathlength factor (DPF). **PURPOSE:** We tested the hypothesis that the DFP of forearm tissue would be significantly different among the phases of a PORH test (i.e. baseline, arterial occlusion, and arterial reperfusion). **METHODS:** 5 subjects (22.6 ± 1.8 yrs, 170 ± 5 cm, 66.0 ± 10.8 kg) completed three PORH tests consisting of 1 min of baseline, 5 min of brachial arterial cuff occlusion, and 3 min of recovery following arterial reperfusion. Reduced scattering (μ_s') and absorption (μ_a) coefficients were continuously measured, and later used to calculate a DPF, at wavelengths of 692 and 834 nm (DPF$_{692}$ and DPF$_{834}$, respectively) via frequency domain near-infrared spectroscopy (FD-NIRS) during the entire duration of the PORH tests. The minute averaged DPF response was averaged among the three PORH tests. **RESULTS:** DPF$_{692}$ was significantly greater that DPF$_{834}$ during each minute of the PORH tests (p < 0.05). DPF$_{834}$ did not significantly change during any phase of the PORH test from baseline (3.83 ± 0.79; p > 0.05). DPF$_{692}$ was significantly less during the final minute of arterial occlusion (4.07 ± 0.69) when compared to baseline (4.67 ± 0.78; p < 0.001). Further, following arterial reperfusion, DPF$_{692}$ was significantly greater (4.91 ± 0.78) when compared to the final minute of arterial occlusion (p < 0.001), but not different when compared to baseline. **CONCLUSION:** These data demonstrate that the DPF$_{692}$ of forearm tissue does not remain constant across the phases of a PORH test. The assumption of a constant DPF may alter interpretations of data related to microvascular function and the balance between muscle oxygen delivery and oxygen consumption obtained via PORH tests.

Exercise-levels Of Laminar Shear Stress In Combination Of Aspirin And Celecoxib Normalize An Atherognic Environment

Jan Kretzschmar[1], Heather Grimm[1], Micheal D. Brown, FACSM[2]. [1]King's College, Wilkes Barre, PA. [2]Auburn University, Auburn, AL.
(No relevant relationships reported)

Optimal vascular function is a hallmark of cardiovascular health. Specifically, the balance of vasoconstricting and vasodilating substances in the vascular bed is recognized as a surrogate measure of the health of resistance vessels. Endothelial Nitrix Oxide Synthase (eNOS) is considered to be one of the best indicators of vasokine balance in these vessels, with high levels of expression being considered to be favorable. Further, the balance of the vasodilating/anti-thrombotic substance prostacyclin and vasoconstricing/pro-thrombotic substance thromboxane in the endothelial cell layer is a further indicator of the overall health of the cardiovascular system. One of the greatest challenges to vascular health and vasodilatory balance is TNFα-mediated inflammation. Uncovering effective strategies that maintain a vascular environment that is more vasodilatory and anti-thrombotic in the face of an inflammatory challenge is favorable. **Purpose:** To test the ability of various anti-thrombotic and pro-vasodilatory treatments, as well as combinations thereof, to prevent disruptions of vascular health of endothelial cells when faced with an inflammatory challenge in the form of TNFα. **Methods:** Human Umbilical Vein Endothelial Cells HUVECs were pre-treated exercise-like levels of laminar shear stress (LSS), aspirin, celecoxib, and their combination prior to a TNFα challenge. Western blot analysis, as well as calorimetric assays were used to determine levels of eNOS and prostacyclin (6-keto PGF$_{1\alpha}$)/thromboxane (TXB$_2$) metabolite ratio, respectively. **Results:** Neither aspirin, nor celecoxib was effective in preventing TNFα-induced reduction in eNOS. Further, aspirin was unable to maintain baseline levels of prostacyclin/thromboxane ratio in the face of the inflammatory challenge. LSS, aspirin/LSS combination, and celecoxib/LSS combination were all able to prevent TNFα-induced reductions in eNOS levels and prostacyclin/thromboxane ratio. **Conclusion:** Effective strategies to maintain a healthy endothelium and therefore resistance vessel health, need to include exercise-levels of shear stress to be effective.

Abdominal Aorta Compliance and Distensibility Among Youth Ranging from Normal Weight to Severe Obesity

Michelle M. Harbin, Nicholas G. Evanoff, Aaron S. Kelly, Justin R. Ryder, Donald R. Dengel, FACSM. *University of Minnesota, Twin Cities, Minneapolis, MN.* (Sponsor: Donald R. Dengel, FACSM)
(No relevant relationships reported)

PURPOSE: This study evaluated abdominal aorta stiffness and diameter among youth throughout a range of body mass index (BMI) values. **METHODS:** Non-invasive ultrasonographic measurements of the abdominal aorta were obtained from 190 youth (92 males; mean±SE: age=12.9±0.2 years). Body composition was assessed by dual-energy X-ray absorptiometry. Obesity status was defined using age- and sex-based BMI percentiles: normal-weight (NW) (≥5th to <85th percentile); overweight (OW) and obese (OB) (≥85th to <1.2 X 95th percentile); and severe obese (SO) (≥1.2 X 95th percentile). Analysis of covariance compared differences by obesity status with adjustments made for race, sex, and Tanner stage. Multiple linear regression evaluated the association of sex, age, and percent body fat (%BF) on abdominal aorta elasticity. **RESULTS:** Prior to adjustment, abdominal aorta diameter (aBD) was significantly larger among SO (mean±SE: 11.1±0.4 mm) compared to both OW/OB (9.6±0.3 mm, $p=0.006$) and NW (8.9±0.3 mm, $p=0.001$). Abdominal aorta incremental elastic modulus (aIEM) was higher among SO (1153.0±70.8 mmHg) compared to OW/OB (960.4±48.6 mmHg, $p=0.044$) and NW (846.0±40.9 mmHg, $p<0.0001$). Abdominal aorta diameter distensibility (aDD%) was lower among SO (14.2±0.6%) compared to NW (16.6±0.6%, $p=0.029$). Abdominal aorta cross-sectional distensibility (aCSD) was lower among SO (30.6±1.5%) compared to NW (36.4±1.5%, $p=0.03$). After adjusting for covariates, aBD remained significantly larger among SO compared to OW/OB ($p=0.018$) and NW ($p=0.001$); aIEM was significantly higher among SO compared to NW ($p=0.002$). Adjusted aDD% and aCSD were not significantly different among groups. Age was associated with higher aBD (β=0.41, $p<0.001$), higher aIEM (β=42.92, $p<0.001$), decreased aDD% (β=-0.38, $p=0.007$), and decreased aCSD (β=-0.96, $p=0.004$). Percent body fat was associated with both higher aBD (β=0.06, $p=0.001$) and aIEM (β=7.44, $p=0.007$), while sex was not associated with measures abdominal aorta elasticity and stiffness. **CONCLUSION**: The deleterious effect of obesity on arterial stiffness extends to the abdominal aorta. Higher age and BF%, but not sex, was associated with greater abdominal aorta stiffness.

2236   Board #72   June 1 11:00 AM - 12:30 PM

Effects Of Different Frequencies Of Electric Muscle Stimulation Of The Lower Limbs On The Vascular Endothelial Function

Hajime Miura, Miduki Ishikawa, Ayako Azuma, Yasuaki Tamura. *Tokushima University, Tokushima, Japan.*
(No relevant relationships reported)

The use of electrical muscle stimulation (EMS) has been shown to potentially improve the arterial function as well as the muscle strength. However, few attempts have been made to identify the effects of different frequencies of EMS on the vascular endothelial function. **PURPOSE**: The aim of this study was to evaluate the effects of different frequencies of EMS on the vascular endothelial function in the lower extremities as determined by flow-mediated vasodilation (FMD). **METHODS**: Nine healthy adult men underwent 2 experimental trials (4 and 20 Hz of EMS) in the face-down posture. EMS was applied for 20 min to both lower leg and thigh muscles at 4 Hz sequentially or 20 Hz with duty cycle of 3 sec stimulation/2 sec relaxation. To measure the FMD, a lower limb cuff was inflated to 300 mmHg for 5 min with subsequent deflation. The right popliteal artery diameter was measured using a high-resolution ultrasound device. The FMD was then estimated as the percent change in the arterial diameter over the baseline value at maximum dilation during reactive hyperemia. The blood flow (BF) at the left popliteal artery was also measured using an ultrasound Doppler device. **RESULTS**: In both trials, the FMD and BF were significantly elevated immediately after and at 30 min after EMS compared with at rest ($p<0.05$). Immediately after each trial, significant differences in the FMD were found between the 4- and 20-Hz trials (7.8±0.6% vs. 6.3±0.8%, $p<0.05$). There was also significant differences in the BF between the two trials (125.4±20.1ml/min vs. 87.9±17.9ml/min, $p<0.05$). **CONCLUSIONS**: Acute EMS at 4 Hz resulted in a larger improvement in the vascular endothelial function than EMS at 20 Hz due to a greater BF. These findings suggest that chronic low-frequency EMS might be useful for reducing the risk of cardiovascular disease.

Exercise-levels Of Laminar Shear Stress In Combination With Aspirin And Celecoxib On Tnf-α Induced Emp Formation

Heather Grimm[1], Jan Kretzschmar[1], Micheal D. Brown, FACSM[2]. *[1]King's College, Wilkes Barre, PA. [2]Auburn University, Auburn, AL.*
(No relevant relationships reported)

Endothelial Microparticles (EMPs) are increasingly being accepted as an important marker and regulator of vascular homeostasis and atherosclerotic disease state. TNFα is key regulator of the athero-genic process and thereby heart disease. Exercise-mimetic levels of laminar shear stress (LSS), aspirin, and celecoxib have long since been implicated in the prevention and treatment of the athero-genic process. **Purpose:** To determine the effect of combination treatment of exercise-mimetic levels of LSS with aspirin or celecoxib on the prevention of TNFα-induced EMP formation in Human Umbilical Vein Endothelial Cells (HUVECs). **Methods:** HUVECs were challenged with athero-genic levels of TNFα after various athero-protective pre-treatments and combinations thereof. EMPs were analyszed using flow cytometry. Both EMPs indicative of cellular apoptosis (CD31+) and cellular activation (CD62E+) were measured. **Results:** Neither aspirin, nor celecoxib pre-treatment of HUVECs were able to blunt TNFα-mediated production of EMPs indicative of cellular apoptosis and activation. However, exercise-mimetic levels of LSS blunted TNFα-mediated production of EMPs when given in isolation and in combination with aspirin and celecoxib. **Conclusion:** When given in isolation, neither aspirin, nor celecoxib seem effective enough to prevent TNFα-mediated EMP production. Only when HUVECs were treated with combinations of LSS and aspirin or celecoxib could EMP production be blunted. This implicates the powerful potential of exercise to prevent the athero-genic process, especially when compared to commonly prescribed preventative treatments in the form of aspirin and celecoxib.

Aerobic Fitness is not Protective of Endothelial Function with Menopause

Corinna Serviente[1], Sarah Witkowski[2]. *[1]University of Massachusetts Amherst, Amherst, MA. [2]Smith College, Northampton, MA.* (Sponsor: Jane Kent, FACSM)
(No relevant relationships reported)

Endothelial dysfunction is a pre-clinical marker for cardiovascular disease (CVD). In most populations, aerobic fitness is protective of endothelial function. Whether this protection remains during and after menopause is unclear. **PURPOSE:** To evaluate differences in endothelial function before and after acute exercise in women at different menopausal stages with disparate levels of aerobic fitness. **METHODS:** Brachial artery flow-mediated dilation (FMD) was evaluated before and after 30min of treadmill exercise (60-64% VO_{2peak}) in healthy high (HIGH) and low (LOW) fit perimenopausal (PERI: HIGH, n=12, 50.8±1.0 yr, 49.1±2.5 ml/kg/min; LOW, n=7, 47.3±1.5 yr, 30.1±1.6 ml/kg/min) and postmenopausal (POST: HIGH, n=13, 60.5±1.0 yr, 43.8±1.8 ml/kg/min; LOW, n=8, 58.9±1.4 yr, 28.3± 1.1 ml/kg/min) women. High fit premenopausal (PRE: n=6, 44.6±1.3 yr, 50.5±3.6 ml/kg/min) women were included as a reference group. Data were evaluated with repeated measure ANOVAs and post hoc testing, where appropriate, and are presented as mean±SEM. FMD data in LOW were previously published (Serviente et al., 2016). **RESULTS:** Overall, there was a main effect of menopause on FMD (p=0.024), with lower FMD in POST compared to PERI (p=0.007). There was a main effect of fitness (p=0.031) with lower FMD in HIGH compared to LOW. Within HIGH, PRE had higher FMD than POST (p=0.018), but not PERI (p=0.737). FMD was lower in HIGH vs. LOW POST (4.2±0.8% vs. 6.51±0.5%, p=0.047) before, but not after acute exercise (4.31±0.6% vs. 6.2±1.0%, p=0.103). After acute exercise, FMD was lower in HIGH POST compared to PRE (6.2±1.0% vs. 7.7±1.1%, p=0.011). There was no difference in FMD in HIGH vs. LOW PERI before exercise (7.1±1.5% vs. 6.5±0.5%, p=0.73); however, FMD was higher in LOW after exercise (5.7±0.6 % vs. 8.5±1.1%, p=0.029). **CONCLUSIONS:** While endothelial function does not appear to decline until postmenopause, the protective effect of aerobic fitness is not apparent in perimenopausal or postmenopausal women; although, fitness appears to modulate the response to acute exercise. These data suggest that targets other than aerobic fitness may be important for improving endothelial function, and therefore CVD risk, in menopausal women. **Funding:** ACSM Foundation Doctoral Student Research Grant (Serviente) & UMass Amherst Faculty Research Grant (Witkowski)

Impact of Remote Ischemic Preconditioning Post-application Delay on Muscle Oxygenation during Subsequent Cycling Intervals

Afton Seeley, Jesse S. Brenman, Kevin A. Jacobs, FACSM. *University of Miami, Miami, FL.* (Sponsor: Dr. Kevin A. Jacobs, FACSM)

(No relevant relationships reported)

INTRODUCTION: Remote ischemic preconditioning (RIPC) involves brief, repeated bouts of manually-imposed blood flow restriction of the arms or legs. The alternating periods of occlusion and reperfusion lead to endothelial adaptations, capable of enhancing blood flow and oxygen delivery. **PURPOSE:** The aim of this study was to investigate the effect of a lower limb RIPC protocol, with either a 5-min or 45-min post-application delay, on muscle oxygen saturation within that same limb at rest and during short-duration intense cycling. **METHODS:** Subjects included recreationally aerobically trained college-aged students (23± 3 years, 173.5± 5.4 cm, 69.2± 4.0 kg, 15.2± 4.0 % BF, VO_{2peak}: 46.6± 1.1 mL•kg^{-1}•min^{-1} at 215± 19 W). All subjects randomly completed four experimental trials: RIPC with 5-min delay, RIPC with 45-min delay, SHAM with 5-min delay, and SHAM with 45-min delay. For the RIPC conditions, each subject received 5-min of alternating-leg blood flow occlusion using a blood pressure cuff (220 mmHg) placed on the upper thighs for a total of 40 min. After a 5 or 45-min delay, the subjects completed 5, 1-min cycle sprints separated by 2 min of recovery. The SHAM conditions were identical to the RIPC, however, subjects laid supine for the same 40-min duration with alternating-leg cuff inflation to 20 mmHg. Muscle oxygen saturation was measured continuously using a portable NIRS-based sensor placed over the vastus lateralis (VL). **RESULTS:** RIPC decreased muscle oxygen saturation in the VL in a replicable manner (MD: 29.5± 13.4%, mean occlusion slope: -5.0± 2.4 %•min^{-1}, mean reperfusion slope: 38.5± 22.4%•min^{-1}) while SHAM conditions left muscle oxygen saturation largely unchanged (MD: 2.9± 1%). Mean VL oxygen saturation (RIPC45:71.9± 0.7%; RIPC5: 67.3± 1.7%; SHAM45: 72.0± 4.4%; SHAM5: 69.9± 3.0%) and preservation of muscle oxygen saturation (MD: RIPC45: -12.4± 6.2%; RIPC5: -14.4± 9.9%; SHAM45: -11.6± 6.4%; SHAM5: -13.0± 7.1%) during high intensity cycling intervals varied minutely between experimental conditions. **CONCLUSIONS:** The muscle oxygenation response during a standard occlusion/reperfusion protocol may lack assumed constancy. Furthermore, the use of RIPC and the length of the delay following RIPC did not greatly alter the muscle oxygenation response to repetitive high-intensity cycling intervals.

Effects Of Aerobic Exercise Habit On Age-related Arterial Stiffening: A 10-year Longitudical Study

Jun Sugawara, Tsubasa Tomoto, Naohiro Noda. *National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.*

(No relevant relationships reported)

Increased arterial stiffness has emerged as a strong predictor of future cardiovascular events and all-cause mortality. Cross-sectional studies and the relatively short-term exercise intervention studies suggested that regular aerobic exercise can restore and improve arterial stiffness. However, long-term longitudinal studies examining the effects of regular physical activity have been sparse. **PURPOSE**: The aim of this study was to elucidate influences of regular physical activity on age-related arterial stiffening through a 10-year longitudinal study. **METHODS**: A decadal change in brachial-ankle pulse wave velocity (baPWV), an index of arterial stiffness, was evaluated retrospectively among 92 volunteers (63 ± 14yrs, 51 men). Regular physical activity level over the past year was evaluated with a semi-structured interview via a questionnaire. Based on the distribution of aerobic exercise volume, subjects were divided into three groups: engaging <5 METs·h/wk (LO, n=50), 5-15 METs·h/wk (MID, n=24), and >15 METs·h/wk (HI, n=18) of aerobic exercise. **RESULTS**: baPWV was significantly elevated in the LO and MID groups (P<0.0001, for both), whereas it tended to increase in the HI group (P=0.06). The HI group exhibited a significantly smaller decadal increase in baPWV (+0.7±1.4 m/sec) than those in the LO and MID groups (+1.8±1.5 m/sec and +2.0±1.6 m/sec, respectively). These differences remained significant after the adjustment for confounding factors including the baseline baPWV and current age. **CONCLUSIONS**: Our current longitudinal study suggests that regular sufficient aerobic exercise attenuates age-associated increases in arterial stiffness.

Body Mass Index Does Not Influence the Endothelial Response to Acute Inflammation

Elizabeth C. Schroeder[1], Abbi D. Lane-Cordova[2], Sushant M. Ranadive[3], Tracy Baynard, FACSM[1], Bo Fernhall, FACSM[1]. [1]*University of Illinois at Chicago, Chicago, IL.* [2]*University of South Carolina at Columbia, Columbia, SC.* [3]*University of Maryland, College Park, MD.* (Sponsor: Bo Fernhall, FACSM)

(No relevant relationships reported)

Acute and chronic inflammation are associated with an increased risk of cardiovascular (CV) events in older adults and reduced endothelial function (flow-mediated dilation; FMD). Obesity is also associated with greater inflammation. Whether this greater inflammatory state in overweight/obese individuals plays a role in the endothelial response during acute inflammation is unknown. **Purpose:** To evaluate the role of obesity status in the endothelial response to acute inflammation in younger (YA) and older (OA) adults. **Methods:** An influenza vaccine was used to induce acute inflammation in 25 YA (13 male, 26±4 yrs) and 56 OA (18 male, 65±5 yrs). Blood pressure, FMD and serum inflammatory markers were measured before vaccination and 24 and 48-hours after. Participants were divided into normal weight (NW) (body mass index, BMI: 18-25 kg/m^2) and overweight/obese (O/OB) (BMI >25 kg/m^2) for analysis. **Results:** See table. All groups increased IL-6 at 24-hours (p<0.01), which returned to baseline at 48. CRP was elevated at 24- and 48-hours in all groups except NW OA (p for interaction = 0.04). Endothelial function (FMD) was reduced at 24- and 48-hours (p<0.01) in all groups. During the inflammatory bout, NW and O/OB YA had a greater FMD than both NW and O/OB OA (p<0.02). **Conclusion:** It does not appear body mass index influences the endothelial response during acute inflammation in YA or OA. In our sample, these results may be due to the similar baseline level of inflammatory markers between the NW and O/OB in each age category. Future studies are required to further investigate this relationship.

Evidence of Racial Differences in Microvascular Function Among College-Aged Women

Jordan C. Patik, Bryon M. Curtis, Aida Nasirian, Guillermo Olvera, R. Matthew Brothers. *University of Texas Arlington, Arlington, TX.*

(No relevant relationships reported)

Microvascular dysfunction contributes to the development of hypertension and insulin resistance. The black population is at an elevated risk of both conditions relative to other racial groups. Previous studies indicate that college-aged black men, compared to their white counterparts, exhibit impaired microvascular function as assessed by post-occlusion reactive hyperemia (RH). It is unknown whether this racial disparity is present in healthy, young adult black (BW) and white women (WW). Furthermore, whether nitric oxide-mediated cutaneous microvascular hyperemia during local heating

(LH) is different in these populations has not been determined. **PURPOSE**: The purpose of this study was to test the hypothesis that college-aged BW exhibit blunted RH and attenuated LH induced cutaneous hyperemia compared to age-matched WW. **METHODS**: College-aged BW (n=7) and WW (n=7) were studied during the early follicular phase of the menstrual cycle. For RH, brachial artery diameter and blood velocity were measured via Doppler ultrasound before and after 5 min of forearm occlusion. For LH, a microdialysis membrane was inserted in the dermis of the forearm and perfused with Ringer's solution. Red blood cell flux was assessed with laser Doppler after ~40 min of continuous 39ºC LH. Maximal flux was established with 28 mM sodium nitroprusside infusion and 43ºC LH. Brachial BP was measured throughout the protocol and cutaneous vascular conductance (CVC) was calculated as flux / MAP and reported as % of max CVC.
RESULTS: WW and BW were matched for age (21 ± 3 vs 20 ± 1 y, P = 0.58) and BMI (23 ± 2 vs 23 ± 3 kg/m^2, P = 0.94). There were no differences between WW and BW in baseline blood velocity (23.1 ± 5.7 vs 24.4 ± 11.6 cm/s, P = 0.79) or blood flow (98.9 ± 38.3 vs 114.5 ± 80.7 ml/min, P = 0.65). WW and BW also had similar peak blood velocity (109.2 ± 13.8 vs 109.7 ± 28 cm/s, P = 0.97), peak blood flow (453.7 ± 164.7 vs 482.5 ± 187.7 ml/min, P = 0.77), and total blood flow AUC during the 120 s after cuff release (487.4 ± 178.5 vs 486.8 ± 190.1 ml, P = 0.99). However, compared to WW, BW had a significantly blunted CVC during 39ºC LH (66 ± 17 vs 45 ± 10 %max, P = 0.02).
CONCLUSIONS: BW had blunted blood flow responses to LH compared to WW despite similar blood velocity and flow responses during RH. This suggests that LH is more sensitive than RH to early impairments in microvascular function.

Impact of Aerobic Capacity on Prolonged Sitting-Induced Vascular Dysfunction

Jennifer Weggen, Austin Hogwood, Richard Fralin, Kathryn LaRosa, Austin Michael, Ryan Garten. *Virginia Commonwealth University, Richmond, VA.*
(No relevant relationships reported)

Prolonged sitting has been reported to have deleterious effects on lower limb vascular function. High amounts of aerobic fitness are associated with positive vascular adaptations that could potentially provide a protective effect on this sitting-induced vascular insult. PURPOSE: This study examined the effect of aerobic capacity on vascular function after a bout of prolonged sitting. METHODS: Ten young (25 ±3 yrs) aerobically trained subjects (VO2max: 52 ±7 ml/kg −1min −1) and ten young (23 ±2 yrs) sedentary (VO2max: 38 ±5ml/kg −1min −1) subjects matched for age and gender were recruited for the study. During the prolonged sitting session, vascular function, via passive leg movement (PLM), was measured at baseline, 1.5 hours and 3 hours with Doppler ultrasonography. RESULTS: Vascular function data obtained prior to sitting revealed no significant difference between the high (HAC) and low (LAC) aerobic capacity groups. Independent of group, vascular function was significantly reduced after 1.5 and 3 hours of prolonged sitting, determined by Δ Peak LBF and LBF AUC. Interestingly, no significant between–group differences were revealed in Δ Peak LBF or LBF AUC at 1.5 hours [Δ Peak LBF (LAC: −370 ±317 ml·min-1; HAC: −167 ±258 ml·min −1; p>0.05), LBF AUC (LAC: -149 ±201 ml·min −1; HAC: −94.7 ±90 ml·min −1; p>0.05), or at 3 hours [Δ Peak LBF (LAC: −373 ±268 ml·min −1; HAC: -243 ±299 ml·min −1; p>0.05), LBF AUC (LAC: −119 ±202 ml·min −1; HAC: -91 ±132 ml·min −1); p>0.05]. CONCLUSION: This study found that aerobic capacity did not mitigate the vascular dysfunction resulting from prolonged sitting.

The Effect of Lower Body Aerobic Exercise on Forward and Backward Pressure Wave Amplitude

Joseph M. Stock, David G. Edwards. *University of Delaware, Newark, DE.*
(No relevant relationships reported)

In young healthy adults, acute lower body aerobic exercise increases central systolic blood pressure (cSBP) and central pulse pressure (cPP) while a reduction in cSBP and cPP are observed post-exercise. Exercise induces alterations in surrogate measures of wave reflection, augmentation pressure (AP) and index (AI), suggesting that exercise reduces wave reflection. However, wave separation analysis provides a more comprehensive method to examine relative contributions of the forward pressure wave (Pf), backward pressure wave (Pb), and reflection magnitude (RM = Pb/Pf) to central pressure. **Purpose:** To determine the effect of acute exercise on Pf, Pb, and RM using wave separation analysis. **Methods:** Applanation tonometry was performed to record radial artery pressure waveforms in 13 young (25 ± 4 years) male (n=8) and female (n=5) subjects during seated rest, incremental recumbent cycle exercise at 40, 50, and 60% age-predicted HR max, and 5 and 10-minute seated post-exercise. Radial waves were calibrated to respective brachial mean and diastolic pressure. Central pressure waves were synthesized from the calibrated radial pressure wave using a generalized transfer function. Pf, Pb, and RM were derived via wave separation analysis utilizing a modified triangular flow wave. Data were analyzed by repeated measures ANOVA

with post-hoc analyses when appropriate. **Results:** As expected, cSBP and cPP were increased during exercise (p <0.05) while AP and AI were reduced (p<0.05). Additionally, cSBP, cPP, AP, and AI were reduced post-exercise (p <0.05). Pf was increased at 40, 50, and 60%HRmax vs rest (27.6 ± 1.0, 38.7 ± 2.8, 44.2 ± 1.9 vs 24.3 ± 1.2mmHg, p < 0.05). Pb was increased at 60%HRmax vs rest (15.6 ± 1.3mmHg vs 13.2 ± 0.9mmHg, p < 0.05) and was reduced at 10-minute post-exercise vs rest (9.7 ± 0.9 vs 13.2 ± 0.9mmHg, p < 0.05). Lastly, RM was reduced at 50, 60%HRmax, 5 and 10-minute post-exercise vs. rest (32.8 ± 1.9, 34.8 ± 2.1, 40.0 ± 1.5, 41.4 ± 1.4 vs 52.7 ± 3.3%, p < 0.05). **Conclusion:** RM is reduced during lower body aerobic exercise coupled with an increase in Pf while a decrease in RM is maintained post-exercise as a result of a decrease in Pb. These findings suggest that the increase in exercising cSBP and cPP during exercise is driven by increased Pf while post exercise reductions in cSBP and cPP may be a result of reduced Pb.

Resistance Exercise on Pulse Wave Reflection and Arterial Stiffness Between Trained and Untrained Individuals

Jason C. Parks, Erica M. Marshall, Yu Lun Tai, Alaina Glasgow, Leslie Sensibello, Kathryn Geither, J. Derek Kingsley, FACSM. *Kent State University, Kent, OH.*
(No relevant relationships reported)

Pulse wave reflection [augmentation index (AIx), augmentation pressure (AP)], and arterial stiffness [pulse wave velocity (PWV)] are indicative of cardiovascular health. Acute resistance exercise (RE) alters pulse wave reflection, and arterial stiffness, but responses in resistance-trained individuals is unclear. **PURPOSE:** To examine the responses in pulse wave reflection and arterial stiffness after RE in resistance-trained (RT) versus untrained (UT) individuals. **METHODS:** Twenty-one (RT: n=14; UT: n=7) individuals volunteered. Pulse wave reflection and arterial stiffness were collected at rest, and 10min following a control, or RE consisting of 3 sets of 10 repetitions at 75% 1-repetition maximum (1RM) on the leg press, lat pulldown, leg extension, chest press and leg curl. A 2x2x2 ANOVA was used to examine group (RT, UT) differences across conditions (RE, control) and time (Rest, Recovery). **RESULTS:** The groups were similar (p>0.05) for age, height, and BMI, but not weight (p<0.05). The 1RMs for all exercises, except leg extension (p=0.26), were different between groups. At rest, the groups were statistically different for the tension-time index [TTI (RT: 1999±282ms; UT: 2192±209ms, p=0.04)], diastolic pressure-time index [DPTI (RT: 2817±316ms; UT: 3047±171ms, p=0.003)], and PWV (RT: 5.5±0.7m/s; UT: 6.3±0.4m/s, p=0.0001). There were significant time by condition interactions for aortic pulse pressure (Rest: 34±6mmHg; Recovery: 37±8mmHg, p=0.01), AP (Rest: 5±3mmHg; Recovery: 6±5mmHg, p=0.003), AIx normalized at 75bpm (Rest: 8.7±12.6%; Recovery: 16.4±6.0%, p=0.004), and TTI (Rest: 2084.6±273.4ms; Recovery: 2760.9±463.3ms, p=0.0001) such that they increased during recovery, compared to rest after RE, and the control. There were condition by time interactions for DPTI (Rest: 2889.6±297.0ms; Recovery: 2394.9±458.3ms, p=0.005) and subendocardial viability ratio SEVR (Rest: 138.4±19.3%; Recovery: 86.6±33.0%, p=0.006) such that they increased after acute resistance exercise, compared to rest and the control. There were no significant changes in arterial stiffness. **CONCLUSION**: These data suggest that resistance-trained individuals have reduced workload of the heart and lower arterial stiffness at rest, but are similar to untrained individuals after acute resistance exercise.

Effect of a High Fat Meal on Blood Flow and Endothelial Function during Passive Leg Movement

Morgan M. Monahan, Zakaria Alyousif, Britton C. Scheuermann, Timothy R. Rotarius, Christopher R. Silette, Barry W. Scheuermann. *The University of Toledo, Toledo, OH.*
(No relevant relationships reported)

Passive leg movement (PLM) leads to a significant increase in femoral artery blood flow (FABF). Recent studies suggest that the increase in FABF during PLM is mediated by the bioavailability of nitric oxide (NO) since inhibition of NO attenuates the FABF response. PLM has been gaining popularity as a simple, reliable method for assessing endothelial function. Since the consumption of a high fat meal (HFM) has been shown to induce endothelial dysfunction, investigators have used a HFM to demonstrate the therapeutic benefits of exercise, anti-inflammatories and anti-oxidants on endothelial function. Consumption of a HFM on the FABF response to PLM has not been previously examined but may prove useful in determining endothelial function in healthy and diseased populations. **PURPOSE:** To examine the effect of consuming a single HFM on FABF during PLM. It was hypothesized that consumption of a HFM would attenuate the FABF response compared to control, consistent with impaired endothelial function. **METHODS:** Eight healthy (31.8 ± 4.2 yrs, (±SEM)) men (n=5) and women (n=3) reported to the laboratory following a 12 h fast and no exercise. PLM was accomplished using an isokinetic (Biodex) machine which allowed the lower leg to move through 90° range of motion at 30 cycles/min. Femoral artery blood velocities (FABV) were measured continuously at baseline (60 s) and during PLM

(120 s) using Doppler ultrasound. FABF was calculated using the arterial diameter measured at baseline. Each subject consumed a HFM consisting of 90 g total fat (63 g saturated fat), 364 mg cholesterol, 17 g carbohydrate, and 139 mg sodium and after 2 hrs of rest, subjects returned to the isokinetic machine and completed a second PLM trial. **RESULTS:** Consumption of a HFM did not lead to any differences in baseline FABF (Pre-HFM, 139.1 ± 21.0 ml/min; Post-HFM, 165.8 ± 44.3 ml/min; p>0.05). Similarly, the peak FABF responses were not different (p>0.05) between Pre-HFM (301.1 ± 40.8 ml/min) and Post-HFM (359.3 ± 73.3 ml/min). **CONCLUSION:** In contrast to our hypothesis and in comparison to previous studies demonstrating a decrease in endothelial function following consumption of a HFM, we did not observe blunted FABF during PLM. The reason(s) for this discrepancy is not readily apparent but warrants further investigation if PLM is to be used to assess endothelial health.

Cardiorespiratory Fitness And Menopausal Symptoms: Effects On Quality Of Life And Cardiovascular Disease Risk

Sarah Witkowski[1], Corinna Serviente[2], Melody Chalvin[2]. [1]Smith College, Northampton, MA. [2]University of Massachusetts, Amherst, MA. (Sponsor: Jane Kent, FACSM)

(No relevant relationships reported)

Menopausal symptoms lead to reduced quality of life (QOL). Hot flashes have been associated with CVD risk and endothelial function. Aerobic fitness may improve QOL and endothelial function; however, these relationships are still unclear. **PURPOSE:** To determine if aerobic fitness is related to QOL, menopausal symptoms, and endothelial function in peri- (PERI), and post-menopausal (POST) women. **METHODS:** Healthy high- and low-fit PERI (HIGH n=9; LOW n= 6), and late POST (HIGH n=10; LOW n=8) women self-reported QOL (Utian questionnaire) and menopausal symptoms. Women were classified into fitness categories via treadmill VO_{2max} test (VO_{2peak}; HIGH 47.3±1.79ml/kg/min; LOW 29.1±0.95ml/kg/min). Brachial artery flow-mediated dilation (FMD) was assessed before and after treadmill exercise (30min, 60-64% VO_{2peak}). Associations between menopausal status, symptoms, fitness, and FMD were analyzed using Chi-squared or Fisher's Exact Tests. The influence of fitness, menopausal status and symptoms on QOL was evaluated with a 3x2 ANOVA. **RESULTS:** There was an association between menopausal symptoms and menopausal status (p=0.053, Phi=0.314). Menopausal symptoms were related to fitness (p=0.006) and menopausal status (p=0.029) such that a greater percentage of HIGH PERI women reported symptoms compared to LOW PERI women (HIGH PERI 100% vs. LOW PERI 46%). There was an effect of fitness on overall QOL (HIGH 95.44±2.189; LOW 78.05±2.476, p<0.0001) but not menopausal status or symptoms (p>0.05). High fitness was related to higher QOL for health (HIGH 30.45±0.746; LOW 22.083±0.0853, p<0.0001), occupational (HIGH 27.6±0.999, LOW 24.2±1.13, p=0.032), emotional (HIGH 25.461±0.741; LOW 23.017±0.847, p=0.014), and sexual QOL (HIGH 12.061±0.687; LOW 7.81±0785, p=0.004). There was no difference in pre-exercise (p>0.05), post-exercise (p>0.05), or change in FMD with exercise (p>0.05) in women who did vs. did not experience menopausal symptoms. **CONCLUSIONS:** High aerobic fitness was associated with higher QOL, independent of menopausal status or symptoms. Highly-fit perimenopausal women reported more symptoms compared to low-fit women; however, symptoms did not influence endothelial function or overall QOL in our population. **Funding:** ACSM Doctoral Student Research Grant (Serviente) & UMass Amherst FRG (Witkowski).

Arginase Activity in Red Blood Cells Is Not Altered with Sub-maximal Exercise.

Mirko Mandić, Anna Strömberg, Adrian Gonon, John Pernow, Eric Rullman, Thomas Gustafsson. *Karolinska Institutet, Stockholm, Sweden.*

(No relevant relationships reported)

Nitric oxide (NO) is an important mediator of exercise remodeling. Its role has been highlighted in the promotion of vascular growth as well as in mitochondrial function. While the endothelium has long been thought to be the dominant physiological source of NO, recent work has suggested that red blood cells (RBCs) express the enzyme endothelial nitric oxide synthase (eNOS) and may contribute to total NO production. Within RBCs, the NO production can be decreased by the activity of the enzyme arginase, which competes with eNOS for the substrate L-arginine. **PURPOSE:** The aim of the study was to test the hypothesis that RBC arginase activity is modulated by exercise. **METHODS:** Nine subjects (4 male and 5 females, age; 26±5 years, VO2peak; 54,8±8,1 mL/min/kg) performed a 60-min sub-maximal exercise bout corresponding to 65% of VO2peak. Blood samples were taken at rest (T0), 30 min in to the exercise (T1), directly after exercise (T2), 30 min post-exercise (T3) and 60 min post-exercise (T4). Arginase activity in RBCs was measured by colorimetric determination of urea formed from L-arginine substrate with α-isonitrosopropiophenone as a marker of urea content. **RESULTS:** Contradictory to our initial hypothesis, arginase activity was unaffected by exercise. No changes in

urea production (T0; 0.52±0.08, T1; 0.50±0.08, T2; 0.51±0.09, T3; 0.51±0.09 and T4; 0.52±0.08 mM/g Hb, p>0.05) was seen between the resting blood sample and the ones taken during or after exercise. **CONCLUSION:** Arginase activity in RBCs is not modulated by sub-maximal exercise in young healthy subjects. Hence, the increase in eNOS activity and NO production from RBCs with exercise is most likely not explained by a reduced activity of arginase.

Muscular Strength is Inversely Associated with Central Hemodynamic Load in Young Women.

Keller P. Allison, Wesley K. Lefferts, Jacqueline A. Augustine, Jacob P. DeBlois, Kevin S. Heffernan. *Syracuse University, Syracuse, NY.* (Sponsor: Bo Fernhall, FACSM)

(No relevant relationships reported)

Muscular strength is important for overall fitness. Strength is also associated with cardiovascular health; individuals with higher strength have a lower risk of developing hypertension. Muscular strength has been shown to be inversely associated with aortic stiffness, a precursor of hypertension. **Purpose:** Determine the relationship between muscular strength, aortic stiffness, and central hemodynamic load in young women. **Methods:** Seventy-two healthy young women (age 30 ± 14 years, body fat 24.7 ± 8.1 %) underwent muscular strength and vascular testing. Muscular strength was evaluated using a five-repetition maximum bench press and expressed relative to body weight. An aortic blood pressure waveform was derived from the brachial artery via an oscillometric cuff and used to estimate aortic pulse wave velocity (PWV). From this waveform, we also derived measures of central hemodynamic load: augmentation index (AIx@75, at heart rate of 75 bpm), forward wave pressure (Pf) and reflected wave pressure (Pb). Body composition was evaluated using air displacement plethysmography. **Results:** As seen in Table 1, after adjusting for age, mean arterial pressure and body fat, there was a negative correlation between relative strength and Pf (p=0.052), Pb (p<0.05) and PWV (p<0.05). There was a positive correlation between relative strength and AIx (p<0.05). **Conclusion:** Women who have higher relative strength have lower aortic stiffness and lower forward and reflected wave pressure suggesting lower central hemodynamic load. Maintaining strength is important for cardiovascular health in women.

Table 1. Correlation matrix between strength and central hemodynamics controlling for age, mean arterial pressure and body fat				
	Relative Strength	AIx @75	Pf	Pb
AIx@75	0.23*			
Pf	-0.20	-0.03		
Pb	-0.23*	0.21*	0.80**	
PWV	-0.32**	-0.02	0.67**	0.50**
AIx@75, augmentation index at 75 beats per minute; PWV, pulse wave velocity; Pf, forward wave pressure; Pb, reflected wave pressure (n=72). **. Correlation is significant at the 0.01 level (1-tailed). *. Correlation is significant at the 0.05 level (1-tailed).

Comparing Two Low-Intensity Strength Training Modalities on Vasodilatory Capacity in Postmenopausal Women

Salvador J. Jaime[1], Arun Maharaj[2], Stacey Alvarez-Alvarado[3], Arturo Figueroa, FACSM[2]. [1]University of Wisconsin-La Crosse, La Crosse, WI. [2]Texas Tech University, Lubbock, TX. [3]Florida State University, Tallahassee, FL. (Sponsor: Arturo Figueroa, FACSM)

(No relevant relationships reported)

PURPOSE: Dynapenia, the age-related loss in muscle strength, is an emerging risk factor for the development of cardiovascular disease and physical disability. Vasodilatory capacity, both endothelial-dependent reactive (RH) and active hyperemia (AH), are important for adequate blood flow to active muscles. Although high-intensity resistance training (RT) increases mass and strength, there are limited data regarding the effect of low-intensity RT (LIRT) on RH and AH in older adults. We investigated the effects of two low-intensity strength training modalities on RH and AH in postmenopausal women with low muscle strength. **METHODS**: Thirty-one postmenopausal women were stratified by age, body mass index (BMI), and maximal voluntary contraction (MVC) (age, 65 ± 4 years; BMI, 23.2 ± 2.6 kg/m²; MVC, 17.3 ± 2.7 kg) and randomized into isolated lower-body whole-body vibration training (WBVT) (n=12), LIRT (n=11) or control (n=8) groups for 12 weeks. Brachial and popliteal diameter, mean blood velocity, blood flow during RH (flow-mediated dilation, FMD) and AH after 6-minute walk test, and strength on the leg press (LP), flexion (LFlex), and extension (LExt) were measured at baseline and 12 weeks.

Abstracts were prepared by the authors and printed as submitted.

FRIDAY, JUNE 1, 2018

RESULTS: WBVT and LIRT similarly improved brachial (systemic) and popliteal (local) vasodilation compared to control ($P < 0.01$). Additionally, WBVT elicited a greater popliteal artery vasodilatory response (4.9 ± 1.4 %, $P = 0.007$) post-6MWT compared to no change in control. LIRT had no effect on post-6MWT popliteal artery vasodilatory response. WBVT and LIRT elicited similar increases in LP and LFlex strength compared to control ($P < 0.01$); however, WBVT induced a greater increase (19.2 ± 3.7%) in LExt strength compared to the LIRT (8.4 ± 2.6%, $P = 0.007$) and control groups. The increases in brachial FMD were correlated to the increases in LExt and LFlex strength ($r= .37$, $P = 0.04$ and $r= .37$, $P = 0.04$; respectively).
CONCLUSIONS: WBVT and LIRT elicited significant improvements in brachial FMD, which were related to the increases in leg strength. However, despite similar improvements in brachial and popliteal FMD, WBVT may be a more efficacious for improvements of leg post-exercise vasodilation and muscular strength than LIRT in non-obese postmenopausal women.

Prolonged Standing Increases Lower Peripheral Arterial Stiffness Independent Of Walking Breaks

Aaron R. Caldwell, Benjamin T. Harris, Megan E. Rosa-Caldwell, Marcus Payne, Bryce Daniels, Kaitlin M. Gallagher, FACSM, Matthew S. Ganio, FACSM. *University of Arkansas, Fayetteville, AR.*
(No relevant relationships reported)

Prolonged sitting creates an atherogenic environment that causes reductions in arterial function. Standing desks have been promoted as a healthy alternative to sitting, but the cardiovascular benefits of standing desks have not been thoroughly investigated. Physical activity, such as taking walking breaks, increases shear stress, and thereby prevents sitting-induced reductions in arterial function. Therefore, walking breaks, even when compared to standing may provide cardiovascular benefits **PURPOSE:** First, to observe changes in arterial stiffness, as assessed by pulse wave velocity (PWV), with a 2 hour bout of standing. Second, to determine if short, intermittent walking bouts provide a comparative advantage to standing alone. **METHODS:** 20 apparently healthy adults (BMI = 22.9 ± 3.2 kg/m^2; Age = 21 ± 5 years old) stood for 2 consecutive hours while being assessed for heart rate (HR), mean arterial pressure (MAP), and central (C_{PWV}), upper peripheral (U_{PWV}), and lower peripheral (L_{PWV}) PWV before, during, and after the standing bout. Subjects participated in two trials in a randomized order. In one trial, the subjects stood at a standing desk immobile for 2 hours. In the other trial, subjects performed 5 minute walking breaks after every 25 minutes of standing for a total of two hours of standing with 4 walking breaks. **RESULTS:** There was no time by trial interaction for any measure of arterial stiffness (p = 0.82, p = 0.21, and p = 0.15; for C_{PWV}, U_{PWV}, and L_{PWV} respectively). However, from beginning to end of each trial L_{PWV} increased 85 ± 126 cm/s independent of trial (i.e., main effect of time; p < 0.001). There was a non-significant tendency for greater increases in L_{PWV} during the standing (120 ± 142 cm/s) versus the walking trial (50 ± 127 cm/s; p = 0.15). Changes in HR and MAP were not dependent on time or trial (i.e., non-significant interaction time; p = 0.20 & p = 0.39, for HR and MAP, respectively). **CONCLUSION:** Standing for 2 hours leads to increases in peripheral arterial stiffness. Walking breaks during 2 hours of standing did not significantly attenuate these changes. However, the suggestive evidence (p=0.15) for walking breaks to improve L_{PWV} suggests that future studies should investigate longer duration trials and/ or longer walking breaks that are applicable to occupational settings, such as assembly-line work.

Hydrogen Sulfide Does Not Functionally Contribute to Acetylcholine-Mediated Vasodilation in Young Healthy Adults

Sean Shank, Jody Greaney, Lacy Alexander, FACSM. *Penn State University, University Park, PA.* (Sponsor: Lacy M. Alexander, FACSM)
(No relevant relationships reported)

Hydrogen sulfide (H_2S) is one of several endothelium-dependent vasoactive molecules that contribute to the regulation of vessel function. In the cutaneous vasculature, young adults express enzymes that synthesize H_2S, and exogenous delivery of H_2S elicits substantial dilation, suggesting that H_2S may be important for the regulation of vessel function *in vivo*. However, because there are several redundant endothelium-dependent contributors, the functional contribution of endogenous H_2S to dilation in the cutaneous circulation is unclear. **PURPOSE:** To quantify the contribution of H_2S to endothelium-dependent dilation in young adults and pharmacologically determine the primary enzymatic source of H_2S in the microvasculature. We hypothesized that CSE-derived H_2S would mediate a portion of acetylcholine (ACh)-induced dilation. **METHODS:** Four microdialysis fibers were placed in the ventral forearm skin of 10 young adults (22 ± 2 y). Red cell flux was measured (laser-Doppler flowmetry) during graded perfusion of the endothelium-dependent agonist ACh (10^{-10}-10^{-1} M) alone and during co-perfusion with D-Penicillamine [10mM DPen; selective inhibitor of the H_2S-

producing enzyme cystathionine γ-lyase (CSE)], aminooxyacetic acid [8mM AOAA; inhibitor of H_2S-producing enzymes CSE and cystathionine β-synthase (CBS)], and a combination of DPen+AOAA. Cutaneous vascular conductance (CVC=flux·mmHg^{-1}) was expressed as a percent of maximal CVC (CVC$_{max}$, 28 mM sodium nitroprusside + local heat 43º C). Sigmoidal dose-response curves were generated and the logEC$_{50}$ was used as an index of vessel sensitivity. **RESULTS:** ACh elicited endothelium-dependent dilation in all subjects (82.9±4.3% CVC$_{max}$; P<0.05). CSE inhibition alone or combined CSE/CBS inhibition had no effect on ACh-induced dilation (ACh: -4.1±0.5; DPen -3.2±0.5; AOAA -3.3±0.7; Combo -2.6±0.4; P>0.05). **CONCLUSION:** H_2S does not appear to have a functional role in mediating cutaneous dilation in response to ACh in young adults. Despite the ability to synthesize H_2S it is likely that other redundant mechanisms, including nitric oxide, mask any functional contribution of H_2S to endothelium-dependent agonists in the cutaneous circulation of young adults.

Associations Between Leg Lean Mass And Arterial Function In Pre-menopausal And Post-menopausal Women.

Stephen Fischer, Arturo Figueroa, FACSM, Youngdeok Kim, Joaquin Gonzales. *Texas Tech University, Lubbock, TX.* (Sponsor: Arturo Figueroa, FACSM)
(No relevant relationships reported)

Vascular dysfunction has been associated to sarcopenia, the age-related impairment in skeletal muscle mass, strength, and performance, in postmenopausal women. Previous research has shown inverse relationships between leg lean mass (LM) and arterial stiffness (measured as pulse wave velocity, PWV) or pressure wave reflection (augmentation index, AIx) in men and women. AIx is an appropriate vascular marker in young but not middle-age/older adults, especially in women.
PURPOSE: To examine the associations between leg LM and arterial function (cfPWV and aortic AIx adjusted to 75bpm (AIx@75) in pre-menopausal (PRE-M) and post-menopausal (POST-M) women.
METHODS: 47 women (24 PRE-M, age 36 ± 4 years; 23 POST-M, age 69 ± 4 years) participated in this study. Leg LM (expressed as kg/m^2) was measured by DEXA. cfPWV and AIx@75 were measured using applanation tonometry. The relationship between both cfPWV and AIx@75 to leg LM were analyzed using multiple linear regression analysis by each group. Results are reported as mean ± SD and unstandardized regression coefficient (b).
RESULTS: cfPWV (9.0 ± 1.3 m/sec vs. 6.9 ± 0.9 m/sec, $p < .001$) and AIx@75 (29.3 ± 5.3% vs. 18.1 ± 8.7%, $p < 0.001$) were significantly greater in POST-M compared to PRE-M. Leg LM was significantly lower in POST-M compared to PRE-M (4.30 ± 0.32 kg/m^2 vs. 4.67 ± 0.47 kg/m^2, $p = 0.003$). Leg LM was inversely associated with cfPWV ($b = -2.07$, $p = 0.02$) when adjusted for body mass index (BMI) in POST-M. This inverse association remained after adjustment for brachial systolic blood pressure (BSP), fasting blood glucose (FBG), and waist circumference (WC) ($b = -1.884$, $p = 0.02$). Leg LM was not associated with cfPWV in PRE-M. Leg LM was inversely associated with AIx@75 ($b = -9.95$, $p = 0.01$) in PRE-M when adjusted for BMI. The inverse association remained after adjusting for BSP, FBG and WC ($b = -10.52$, $p = 0.02$). No association was found between leg LM and AIx@75 in POST-M.
CONCLUSIONS: Our findings suggest that low leg LM may adversely affect pressure wave reflection in PRE-M and aortic stiffness in POST-M. Future studies will be necessary to investigate the potential benefits of strength training on arterial function in non-obese POST-M and PRE-M.

Increased Serum Irisin Level By Aerobic Training Is Involved In NO Production In Obese Rats

Kenichiro Inoue[1], Shumpei Fujie[1], Natsuki Hasegawa[1], Naoki Horii[1], Kiyoshi Sanada[1], Takafumi Hamaoka, FACSM[2], Motoyuki Iemitsu[1]. *[1]Ritsumeikan University, Kusatsu, Japan. [2]Tokyo Medical University, Shinjuku, Japan.* (Sponsor: Takafumi Hamaoka, FACSM)
(No relevant relationships reported)

INTRODUCTIN: Aerobic exercise training reduces arterial stiffness mediated by nitric oxide (NO)-derived vasodilation in obese patients. Irisin is mainly expressed in myocytes and promotes NO release by regulating endothelial nitric oxide synthase (eNOS) expression, leading to vasodilation. Although exercise accelerates irisin secretion, the involvement of irisin in the mechanism of exercise effect on arterial stiffness in obese patients remains unclear. PURPOSE: This study aimed to clarify whether aerobic exercise training-induced elevation of irisin secretion is associated with reduced arterial stiffness with elevation of NO production in obese rats. METHODS: 20-week-old male obese (OLETF) rats were randomly divided into two groups; 8-week sedentary control (CON) and aerobic exercise training (AT; treadmill running for 60min at 25m/min, 5days/week). After 8-week, in each group, we assayed aortic pulse wave velocity (PWV) as an indicator of arterial stiffness, and the aorta and gastrocnemius muscle were isolated after collection of blood. RESULT: Aortic

PWV in OLETF-AT group significantly decreased as compared with OLETF-CON group. Aortic Akt and eNOS phosphorylation and plasma nitrate/nitrite (NOx) level significantly increased in OLEFT-AT group. Additionally, the significant increased muscle FNDC5 protein expression and serum irisin level in aerobic exercise training group were observed. Circulating irisin level was positively correlated with aortic phosphorylation eNOS ($p<0.05$, $r=0.756$) and circulating NOx level ($p<0.05$, $r=0.697$). Additionally circulating NOx level was negatively correlated with aortic PWV ($p<0.05$, $r=-0.695$). CONCLUSION: These results suggest that aerobic exercise training-induced acceleration of irisin secretion may be involved in the reduced arterial stiffness in obese rats. Moreover, as its underlying molecular mechanism, irisin release via increased muscle FNDC5 expression may be involved in aortic eNOS activation, leading to reduction of arterial stiffness via NO-derived vasodilation. Cardiovascular Responses To Steady State Exercise In Well-healed Burned Survivors After Six Months Of Exercise Training

Gilbert Moralez[1], Steven A. Romero[2], Matthew N. Cramer[1], Amy N. Adams[1], Manall F. Jaffery[1], Mu Huang[1], Craig G. Crandall, FACSM[1]. *[1]Institute for Exercise and Environmental Medicine Texas Health Presbyterian Hospital Dallas, Dallas, TX. [2]University of North Texas Health Science Center, Fort Worth, TX.* (Sponsor: Craig G. Crandall, FACSM)
(No relevant relationships reported)

Aerobic exercise is an important component of rehabilitation in burn survivors, but no studies to date have examined whether burn survivors demonstrate cardiovascular adaptations to long-term training. It is well established that exercise training reduces heart rate at rest and during steady-state exercise in non-burned individuals. **PURPOSE:** To test the hypothesis that six months of aerobic exercise training reduces heart rate at rest and during two workloads of steady-state cycling in well-healed burn survivors. **METHODS:** Ten participants (7 males; aged 43 ± 14 years) with well-healed burn injuries covering an average total body surface area of 52±25% (range: 22-88%) participated in a progressive 6-month aerobic-focused exercise training regimen. Heart rate responses were obtained at rest and during two steady-state submaximal cycling workloads (SS1; 50 W) and (SS2; 75 W) prior to and after exercise training. **RESULTS:** Six months of exercise training tended to decrease resting heart rate (Pre, 77 ± 15 bpm vs Post, 70 ± 11 bpm, P=0.09)**.** During both workloads, heart rate was ~ 10 bpm lower post training (50W: pre 100 ± 26 bpm, post 90 ± 18 bpm, P=0.02; 75W: pre 113 ± 33 bpm, post 101 ± 23 bpm, P<0.01). **CONCLUSION:** These data show that cardiovascular adaptations to long-term aerobic exercise training can be obtained in well-healed burned subjects. Work funded by NIH GM068865

Repeated Bouts of Passive Limb Movement Result in a Sustained Hyperemic Response in Those with Paraplegia

Keith J. Burns[1], Brandon S. Pollock[1], Jon Stavres[2], John McDaniel[3]. *[1]Walsh University, North Canton, OH. [2]Penn State University, Hershey, PA. [3]Kent State University, Kent, OH.*
(No relevant relationships reported)

Previous studies have reported passive limb movement (PLM) could be used as a modality to increase blood flow and tissue perfusion in the paralyzed lower limbs of those with spinal cord injuries. However, the hyperemic response to PLM observed in these studies transient, lasting only 30-45 seconds despite continued limb movement. No studies have sought to determine if this hyperemic response can be sustained by using repeated bouts of PLM interspaced with recovery periods. **PURPOSE**: To investigate the feasibility of repeated bouts of PLM to invoke a sustained hyperemic response in those with paraplegia.
METHODS: Nine paraplegics with a clinically confirmed complete injury between the 3rd and 11th thoracic vertebra underwent 5 bouts of PLM. Each bout was 60 seconds in duration and the PLM was performed at a rate of 1 Hz and there was 60 seconds of recovery between each bout. Heart rate (HR), mean arterial pressure (MAP), femoral artery blood flow (FABF) and skin blood flow (SBF) above the vastus lateralis muscle were continually measured.
RESULTS: No change in HR (p=0.81) or MAP (p=0.40) were observed during any of the bouts of PLM. FABF showed a robust and sustained hyperemic response with increases in blood flow of 85±103%, 71±87%, 79±%90%, 76±87% and 88±93% for each of the five bouts of PLM, respectively (p=0.043). SBF values rose 497±373%, 465±302%, 503±315%, 523±332% and 582±309% across the five bouts, respectively (p=0.005).

CONCLUSIONS: With repeated 60 second bouts of PLM interspaced with 60 second recovery periods there is a consistent increase in FABF and SBF which could have implications on improving vascular health and tissue perfusion in the lower limbs in those with paraplegia.

Effects Of Physical Activity On Sympathetic, Cardiovascular, And Perceptual Responses To A Painful Stimulus

Danna V. Rodriguez Escobar. *Appalachian State University, Boone, NC.*
(No relevant relationships reported)

EFFECTS OF PHYSICAL ACTIVITY ON SYMPATHETIC, CARDIOVASCULAR, AND PERCEPTUAL RESPONSES TO A PAINFUL STIMULUS

Danna V. Rodriguez Escobar, Taylor R. Goodman, Emma K. Taylor, Abigail S.L Stickford
Appalachian State University, Department of Health and Exercise Science, Boone, NC
Purpose: The purpose of this study is to examine sympathetic neural, cardiovascular, and perceptual responses to the cold pressor test (CPT) in physically active and sedentary young women. **Methods:** After pre-health screening and consent, physically active (PA; n=4) and healthy sedentary (SED; n=2) women completed a VO_2max test on a cycle ergometer. Subjects returned to the laboratory for autonomic function testing, where arterial blood pressure (SBP; DBP), heart rate (HR), and muscle sympathetic nerve activity (MSNA) were continuously recorded before, during, and following a two-minute CPT. Subjects were asked to rate their pain on a scale of 1-10 immediately following the CPT. **Results:** PA and SED women were similar in age (22.8 ±1.3 vs. 20.5 ±0.7 yr, respectively), BMI (22.7 ±1.9 vs. 23.6 ±1.1 kg/m^2), and resting blood pressure (SBP: 115 ±3 vs. 113 ±15 mmHg; DBP: 72 ±8 vs. 75 ±7 mmHg). PA women performed more moderate-vigorous physical activity per week than SED (319 ±136 vs 0 ±0 min/week) and had higher VO_2max values (44 ±3 vs. 31 ±5 ml/kg/min). Resting HR (62 ± 11 vs. 76 ± 12 bpm) and MSNA (7 ± 7 vs. 17 ± 1 bursts/min) tended to be lower in PA compared to SED women. During the CPT, PA and SED groups had similar increases in SBP (peak Δ = +26 ±22 vs. +41 mmHg, respectively), DBP (peak Δ = +17 ±5 vs. +22 mmHg), HR (peak Δ = +14 ±4 vs. +10 ±1 bpm), and MSNA (peak Δ = +36 ±15 vs. +28 ±8 bursts/min). SED women reported slightly higher pain ratings than PA (8.8 ±1.1 vs. 7.4 ±1.5). **Conclusion:** Chronic aerobic physical activity appears to be related to lower pain sensitivity; however, both groups displayed similar sympathetic neural and cardiovascular responses to a painful stimulus.

Yap as an Indicator of Nuclear Mechanotransduction in Mature Myofibers

Shama R. Iyer[1], Sameer B. Shah[2], Christopher W. Ward[1], Eric S. Folker[3], Richard M. Lovering[1]. *[1]University of Maryland School of Medicine, Baltimore, MD. [2]University of California San Diego, San Diego, CA. [3]Boston College, Boston, MA.* (Sponsor: E.G. McFarland, FACSM)
(No relevant relationships reported)

Mechanical forces transduced through the extracellular matrix to muscle fibers are critical for regulating muscle development, hypertrophy, homeostasis, and response to loading. Force transmitting structures reside not only at the sarcolemma (e.g., dystrophin), but also at the nuclear envelope (e.g., nesprin) for direct nuclear mechanotransduction. YAP/TAZ (Yes-associated protein/transcriptional coactivator with PDZ-binding motif) is touted as a nuclear relay of mechanical signals in many cell types (i.e. epithelial & cardiac cells, osteoblasts, fibroblasts, mesenchymal stem cells, myoblasts), and can induce a wide range of downstream signaling cascades. However, localization of YAP/TAZ to the nucleus in mature skeletal muscle fibers in response to substrate stiffness and cell loading remains unclear. **PURPOSE:** To assess YAP/TAZ nuclear localization in healthy (WT), dystrophin null (*mdx*) and nesprin-1 null skeletal muscle with varying substrate stiffness and loading. We hypothesized that absence of dystrophin and nesprin-1 would prevent YAP/TAZ nuclear localization secondary to reduced mechanotransduction to the nucleus. **METHODS:** We measured

YAP/TAZ nuclear localization in WT (n=4), *mdx* (n=4), and nesprin-1[-/-] (n=4) isolated myofibers with different substrate stiffness or with 3% cyclic passive stretch for 30 minutes, and in whole muscle after *in-vivo* isometric contractions. **RESULTS:** With increasing substrate stiffness, we found that increased YAP/TAZ nuclear localization occurs in WT (25% increase at 50 kPa compared to 1 kPa, p<0.05) and *mdx* myofibers (64% increase, p <0.05), but not in myofibers lacking nesprin-1 (15% increase, not significant). Cyclic tensile loading resulted in YAP/TAZ nuclear signaling in WT myofibers, but significantly less in *mdx* myofibers and no signaling in nesprin-1[-/-] myofibers. A lack of nuclear localization in *mdx* was also observed after isometric contractions *in-vivo*. Interestingly, the centrally located nuclei in the *mdx* displayed YAP/TAZ nuclear translocation after isometric contraction loading. **CONCLUSIONS:** Nuclear mechanotransduction is nesprin-dependent and is impaired in dystrophic muscle, which can further the pathology due to altered nuclear function.

Skeletal Myotubes From Obese Individuals Display Attenuated Response to Resveratrol Treatment

Alec B. Chaves[1], Sanghee Park[1], Jonas J. Treebak[2], Seongkyun Kim[1], Joseph A. Houmard, FACSM[1]. *[1]East Carolina University, Greenville, NC. [2]University of Copenhagen, Copenhagen, Denmark.* (Sponsor: Joseph Houmard, FACSM)

(No relevant relationships reported)

Resveratrol is a polyphenol compound that has been used for the prevention and treatment of obesity-related diseases. Precisely, some studies have indicated that resveratrol improves insulin sensitivity *in vivo*, but these results are inconsistent and have yet to include a severely obese cohort (BMI > 40 kg/m^2). Preliminary research indicates that myotubes derived from obese individuals are resistant to the insulin sensitizing effects of resveratrol, but the mechanism remains undefined. PURPOSE: To determine the effects of resveratrol treatment on basal and insulin-mediated glucose metabolism in myotubes derived from lean, healthy and severely obese individuals. METHODS: Primary skeletal muscle cells were isolated from skeletal muscle biopsies taken from age-matched lean (BMI= 21.9 ± 0.7 kg/m^2) and severely obese (46.1 $\pm$ 3.1 kg/m2) Caucasian women, which were treated with 1μM resveratrol for 24 hours. Radio labeled 1-^{14}C glucose was used to measure glucose oxidation (GO) and glycogen synthesis (GS) with or without insulin. Additionally, western blot analysis was conducted on the cell lysate to measure changes in the phosphorylation status of proteins along the insulin signaling cascade. RESULTS: Resveratrol increased insulin-stimulated GS (9.4 ± 0.2 nmol/min/mg vs. 10.3 ± 0.5 nmol/min/mg, p < 0.05) and GO (211.69 ± 7.51 pmol/min/mg vs. 234.82 ± 11.52 pmol/min/mg, p < 0.05) in severely obese myotubes, but to lower extent when compared to the lean myotubes (GS: 12.8 ± 1.0 vs. 10.3 ± 0.5 nmol/min/mg; GO: 305.78 ± 23.36 vs. 234.82 ± 11.52 pmol/min/mg, for lean and obese, respectively, p < 0.05). In agreement, insulin-induced phosphorylation of IRS and AKT was increased by resveratrol in lean, but to a lesser extent in obese myotubes (IRS: 1.9 ± 0.2 vs. 1.3 ± 0.1; AKT: 3.4 ± 0.3 vs. 2.6 ± 2.4, fold increase over non-insulin, non-resveratrol treated condition, for lean vs. severely obese, respectively, p < 0.05). CONCLUSIONS: Resveratrol improved insulin-mediated glucose metabolism in myotubes derived from both groups. However, obese myotubes were not able to achieve the same improvements which may be due to underlying defects in the insulin signaling cascade.

Do Notch and mTOR Correlate for Myotube Formation In C2C12s?

Susan T. Arthur, Brian Q. Thompson, Charlotte McMullen, Josh R. Huot. *UNC Charlotte, Charlotte, NC.*

(No relevant relationships reported)

PURPOSE: Notch and Mechanistic Target of Rapamycin (mTOR) are important for myogenesis but their interaction is not well studied. The purpose of this project was to determine if Notch affects mTOR to correlate myotube fusion of C2C12s using a Notch inhibitor, Gamma Secretase Inhibitor (GSI) and mTOR inhibitor, Rapamycin. **METHODS**: C2C12s were seeded, proliferated to 90-100% confluence and then differentiated for four days. At the onset of differentiation, C2C12 cells were treated every 12 hours with one of the following conditions: 4 μmoL of GSI, 100 nmoL of Rapamycin, both, or control. At four days post-differentiation, the C2C12 cells were either fixed for immunofluorence and myotube fusion and area were determined, or were collected for western blot analysis for measurement of mTOR signaling protein expression.
RESULTS:GSI treatment increased fusion index compared to the other three treatments (fusing nuclei/total nuclei) (p < 0.0001). Rapamycin subsided fusion index relative to control (p < 0.0001). GSI and Rapamycin also decreased fusion index compared to control (p < 0.0001). GSI-treated myotubes displayed elevated p-mTORSer2448 compared to control (p < 0.05). Rapamycin and GSI+Rapamycin treated myotubes displayed reduced p-mTORSer2447 expression compared to control and GSI (p < 0.05).

CONCLUSIONS: Our data suggests that Notch is inhibited and mTOR activated for myotube fusion to occur.

Serial Passaging Reduces Replication and Fusion Capacity of Primary Human Skeletal Muscle Satellite Cells

Zachary R. Hettinger[1], Yaohui Nie[2], Ron T. Garner[1], Chris K. Kargl[1], Shivam H. Patel[1], Shihuan Kuang[1], Tim P. Gavin, FACSM[1]. *[1]Purdue University, West Lafayette, IN. [2]Harvard University, Cambridge, MA.* (Sponsor: Dr. Tim Gavin, FACSM)

(No relevant relationships reported)

Replication and fusion of skeletal muscle satellite cells (SkMSCs) are essential for skeletal muscle maintenance and repair. Advancing age impairs SkMSCs replication potential and fusion capacity, however SkMSCs isolated from older human skeletal muscle do not consistently demonstrate these defects, making it difficult to study SkMSC isolated from aged human muscle. **PURPOSE**: To investigate if serial passaging of SkMSCs can mimic aging associated defects in replication and fusion. We hypothesized that serial passaging of primary human SkMSCs induces replicative senescence and poor fusion capacity in part through inhibition of the cell cycle regulator cyclin-dependent kinase 4 (CDK4) through the activation of CDK inhibitor p16[Ink4a]. **METHODS**: SkMSCs were isolated from vastus lateralis biopsies of young men. SkMSCs were serially passaged every five days and passaging continued until SkMSCs were unable to replicate. Population doubling level (PDL) was calculated using passage specific final and starting SkMSC counts. Expression of the myogenic regulator, myogenin (MyoG) and the regeneration regulator, paired box 7 (Pax7) were analyzed via rt-PCR. Senescence was determined by SA-B-gal staining and fusion capacity determined by immunohistochemical staining. **RESULTS**: Primary human SkMSCs failed to replicate at passage 16 (Pass16) and Pass16 SkMSCs exhibited decreased fusion. PDL was decreased from passage 4 to 16 (Pass4: 3.9 vs. Pass16: 0.6, AU). CDK4 mRNA decreased (Pass4: 1.0 vs. Pass16: 0.4, AU) and p16Ink4a mRNA was increased (Pass4: 1.0 vs. Pass16: 4.9, AU). Pax7 mRNA was unchanged (Pass4: 1.0 vs. Pass16: 1.3, AU), while myoG mRNA was increased (Pass4: 1.0 vs Pass16: 8.6, AU). **CONCLUSIONS**: Serially passaging SkMSCs isolated from young humans mimics an aged phenotype evidenced by impaired replication and fusion. Our findings suggest serial passaging of primary human SkMSC may be used to study aged SkMSCs.

Effect of Acute Exercise on Skeletal Muscle Exosome Biogenesis

Ron T. Garner[1], Yaohui Nie[2], Timothy P. Gavin, FACSM[1]. *[1]Purdue University, West Lafayette, IN. [2]Harvard University, Cambridge, MA.*

(No relevant relationships reported)

Exercise training promotes a wide range of beneficial adaptations. Skeletal muscle is now considered an endocrine organ. Exosomes, small microvesicles, are produced by and participate in the endocrine function of skeletal muscle. Exosome biogenesis is regulated in part by components of the multivesicular body (MVB) processing pathway: hepatocyte growth factor-regulated tyrosine kinase substrate (HGS), signal transducing adapter molecule 1 (STAM), VTA1 homolog (VTA1), and vacuolar protein sorting-associated protein 4A (VPS4a). **PURPOSE:** Determine if exercise induces skeletal muscle exosome biogenesis. **METHODS:** Twelve lean, young men completed acute aerobic cycling at 55% VO$_{2Max}$ for 45 minutes followed immediately by single leg knee extensor resistance exercise (3 sets, 8-12 reps, 55% 1-RM). Vastus lateralis biopsies were obtained prior to (PRE) and 1-hour post aerobic (AEX) and aerobic+resistance (A+REX) exercise. Gene expression for proteins in the MVB pathway was analyzed using rt-PCR. **RESULTS:** There was no effect of exercise on STAM (PRE: 1.0; AEX: 1.03; A+REX: 1.28, AU), VTA1 (PRE: 1.0: AEX: 0.93; A+REX: 1.14, AU), or VPS4a (PRE: 1.0: AEX: 0.93; A+REX: 1.06, AU) . There was a trend for an increase in HGS at 1 hr post-exercise (PRE: 1.0; AEX: 0.97; A+REX: 1.27, AU). **CONCLUSIONS:** There was no effect of acute exercise on the gene expression of components of the exosome biogenesis pathway. However, activation of exosome biogenesis may be evident at different time points post exercise or with greater exercise intensities.

Differential Musculoskeletal Adaptations to Exercise of the Soleus and Vastus Lateralis: A Pilot Proteomics Approach

Mauricio Martinez, YuanYu Lee, Evan E. Schick, Joshua A. Cotter. *California State University of Long Beach, Long Beach, CA.* (Sponsor: Dr. Vincent J. Caiozzo, FACSM)

(No relevant relationships reported)

The vastus lateralis (VL) and soleus (SOL) muscles show vigorous changes when exposed to unloading conditions. There is evidence that the SOL muscle shows an increased sensitivity to loading yet has been shown to be resistant to exercise-induced adaptations. **PURPOSE:** To utilize high-resolution two-dimensional gel electrophoresis combined with mass spectrometry to identify anomalous biomarkers of the SOL muscle. **METHODS:** Biopsy samples of the VL and SOL muscles were obtained from three healthy, inactive individuals (1 male, 21 yrs, 92.5 kg, 167.5 cm; 2 females, 18 and 19 yrs, 66.6 and 71.7 kg, 153.3 and 161.9 cm respectively). Muscle tissue was homogenized in a bead homogenizer and protein quantified with a DC protein assay. Two-dimensional gel electrophoresis was performed and differences in spot abundance between the two muscles were used to select spots of interest. Proteins of the 24 selected spots were subsequently identified by MALDI-TOF MS/MS scanning and Mascot database searching against Swiss-Prot human protein database. **RESULTS:** Results from the 2D gel electrophoresis varied across the three subjects. Proteins identified from spots of greater intensity in the VL were myosin light chain isoforms, actin, adenylate kinase isoenzyme, alpha-crystallin B, ankyrin repeat domain-containing protein, plasminogen receptor, G-protein coupled receptor, and troponin I. The main proteins identified in the SOL were related to myoglobin with a protein phosphatase protein also being identified. Western blotting will be conducted to verify the identified proteins. **CONCLUSION:** This preliminary work has identified differential proteins between the SOL and VL relating to oxygen transport, cytoskeletal components, and energy regulation. Future work should examine changes to the proteome between these two muscle with exercise and unloading.

Whey Peptides Intake activates mTOR Signaling after Resistance Exercise Independent of Sex and Menstrual Cycle

Ryo Kakigi[1], Noriko Ichinoseki-Sekine[2], Toshiharu Natsume[1], Tomoharu Kitada[1], Toshinori Yoshihara[1], Takamasa Tsuzuki[1], Hiroyuki Kobayashi[3], Shuichi Machida[1], Hisashi Naito[1]. *[1]Juntendo University, Tokyo, Japan. [2]The Open University of Japan, Chiba, Japan. [3]Tsukuba University Hospital, Ibaraki, Japan.*

(No relevant relationships reported)

PURPOSE: Sex differences are evident in human skeletal muscle as the cross-sectional area of individual muscle fibers is greater in men than in women. In addition, the female steroid hormone fluctuates during menstrual cycle phase. We have recently shown that whey peptides intake after resistance exercise stimulates mammalian target of rapamycin (mTOR) signaling related to protein synthesis in young men. Therefore, the purpose of this study was to determine the effects of sex and menstrual cycle on mTOR signaling following resistance exercise and whey peptide intake. **METHODS**: Young healthy, recreationally active men (n=7) and women (n=16) performed a bout of one-leg isokinetic knee extension exercise (angular degree; 30º/sec, 6 reps. × 4 sets). Immediately after exercise, all subjects took a whey peptide drink (0.19 g/kg). At resting and 1h post-exercise, muscle samples were taken from vastus lateralis using needle biopsy technique. Phosphorylations of mTOR signaling transducers (mTOR, S6K1, 4E-BP1) was analyzed by western blotting. At rest, 30 min and 60 min post-exercise, blood amino acids and insulin concentrations were measured. **RESULTS**: Peak torques during resistance exercise was significantly greater in men than in women (p<0.05), but the relative value (% MVC) was the same between men and women. Blood amino acids and insulin concentration were significantly increased at 30 min after whey peptide intake (p<0.05), but there was no effect of sex and menstrual cycle. The phosphorylation of mTOR, S6K1 and 4E-BP1 after resistance exercise and whey peptide intake was significantly increased compared with that in the rest (p<0.05), but there was no effect of sex and menstrual cycle. **CONCLUSIONS**: Our data suggest that sex and menstrual cycle do not affect mTOR signaling in response to whey peptide intake after resistance exercise in human skeletal muscle. Acute and Chronic Resistance-Training Downregulates Select Line-1 Retrotransposon Activity Markers in Human Skeletal Muscle

Matthew A. Romero[1], C. Brooks Mobley[1], Paul A. Roberson[1], Cody T. Haun[1], Wesley C. Kephart[1], Petey W. Mumford[1], James C. Healy[1], Darren T. Beck[1], Kaelin C. Young[1], Jeffrey S. Martin[1], Christopher M. Lockwood[2], Michael D. Roberts[1]. *[1]Auburn University, Auburn, AL. [2]Lockwood Nutrition, Draper, UT.*

(No relevant relationships reported)

Transposable elements or "jumping genes" are mobile genetic elements with the ability to amplify themselves within the genome. This gene mobility lends itself to the possibility of mutagenesis within cells, which is further compounded by the fact that these elements constitute ~50% our genome. Transposable elements, most notably LINE-1, have important implications for both gene regulation and gene expression under a variety of conditions. **PURPOSE:** To better understand the role of LINE-1 in skeletal muscle physiology, we examined if acute and/or chronic resistance exercise affected skeletal muscle LINE-1 retrotransposon activity. **METHODS:** In study 1, 10 resistance-trained males performed three consecutive daily squat sessions. *Vastus lateralis* biopsies were taken Pre, 2 h post (Post1), and 3 days following session 3 (Post2). In study 2, 13 untrained males performed a full-body resistance-training program. *Vastus lateralis* biopsies were taken at weeks 0 and 12. **RESULTS:** Study 1: LINE-1 mRNA content was lower at both Post1 (p=0.028) and Post2 (p=0.013), while RT activity trended down at Post2 (p=0.067). A methylation assay at the LINE-1 promoter, however, did not yield significant results. Study 2: LINE-1 mRNA trended down by week 12 (p=0.056) along with RT activity (p=0.063) and ORF2p content (p=0.041). Although, mRNA was not significantly lower after training, LINE-1 promoter methylation significantly increased at week 12 (p=0.041). Interestingly, changes in RT activity versus satellite cell number were inversely associated (r²= -0.725). **CONCLUSION:** Resistance exercise downregulates select skeletal muscle LINE-1 markers and this may be suggestive toward an involvement of LINE-1 in satellite cell activity. A Preliminary Comparison Of Muscle Pennation Angle Measures To Explain Variance In Maximal Force Production

Micheal J. Luera, Carlos A. Estrada, Jesus A. Hernandez Sarabia, Julia Troung, Tyler W. D. Muddle, Jason M. DeFreitas. *Oklahoma State University, Stillwater, OK.*

(No relevant relationships reported)

Previous literature has shown that a muscle's pennation angle influences that muscle's force producing capabilities. However, how the pennation angle of mono- and bi-articular muscles are related to single- and multi-joint force production is less clear. **PURPOSE:** To examine the relationships between resting and contracting pennation angles of the biarticular rectus femoris (RF_{REST} + RF_{CONT}) and the monoarticular vastus lateralis (VL_{REST} + VL_{CONT}) muscles with maximal force production during single and multi-joint isometric tasks. **METHODS:** Eight lower-body resistance trained males (mean ± SD; 27 ± 3 yrs; 102 ± 6.55 kg; 197 ± 7 cm) performed maximal voluntary isometric contractions during the squat (SQ_{max}) and knee extension (KE_{max}) exercises at knee joint angles of 110° and 150°. The order of the joint angles were randomized. The hip angle was ~105° during KE_{max} and ~110° during SQ_{max}. Maximal force (N) was measured with an S-beam load cell. Muscle pennation angles were measured in both the RF and VL at rest and again during the maximal contractions using ultrasound imaging. **RESULTS:** Using multiple regression, RF_{CONT} at 150° was the only variable that contributed significantly to KE_{max} (R^2 = 0.758, p = 0.005) at the same angle. Interestingly, there were no significant relationships with RF_{REST} or RF_{CONT} during KE_{max} at 110°, or SQ_{max} at both knee joint angles. Furthermore, neither VL_{REST} nor VL_{CONT} were significantly related to either KE_{max} or SQ_{max} at any knee joint angles (all p-values ≥ 0.05). **CONCLUSION:** The finding that RF_{CONT} at 150° being related to KE_{max} at the same angle was the only significant outcome was surprising. However, caution should be applied in the interpretation of this preliminary examination, as

the sample size is underpowered to fully address the research question. Nevertheless, given that KE is a single-joint task, we expected pennation angles of the monoarticular VL to contribute more to the model than the biarticular RF.

Contribution Of Mono- And Bi-articular Muscle Sizes Of Single- And Multi-joint Maximal Strength

Jesus A. Hernandez Sarabia, Michael J. Luera, Carlos Estrada, Jason M. DeFreitas. *Oklahoma State University, STILLWATER, OK.*

(No relevant relationships reported)

Contribution of Mono- and Bi-articular Muscle Sizes to Single- and Multi-joint Maximal Strength

Jesus A. Hernandez-Sarabia[1], Michael J. Luera[1], Carlos Estrada[1], and Jason M. DeFreitas[1].
[1]Oklahoma State University, Stillwater, OK

The strong relationships between the size of monoarticular muscles and strength during single-joint contractions are well established (e.g. biceps brachii and elbow flexion force). However, the contributions of biarticular muscles during multi-joint contractions are less so. **PURPOSE:** To examine the relationships between the size of the vastus lateralis (VL, monoarticular) and rectus femoris (RF, biarticular) muscles with maximal force production during single- and multi-joint isometric tasks. We hypothesized that the size of the biarticular RF would demonstrate a stronger relationship with isometric squat force than VL size, and that VL size would have a stronger relationship with single-joint force. **METHODS:** Eight strength-training men were recruited for this study (M±SD 27 ± 3 yrs). First, three ultrasound images of the right VL and RF were obtained to calculate muscle cross-sectional area (CSA) and thickness. Isometric squats (SQ_{max}) and isometric knee extensions (KE_{max}) were performed to assess multi-joint and single-joint maximal strength. Both were performed at the same knee joint angle (110°). **RESULTS:** Using multiple regression, RF muscle size was significantly related to SQ_{max} ($R^2 = 0.878$, p = 0.005). Interestingly, both RF CSA and thickness contributed to the model. Also of surprise is that VL size did not contribute to SQ_{max}. VL thickness was significantly related to KE_{max} ($R^2 = 0.579$, p = 0.047), but none of the other measures contributed. **CONCLUSION:** Our primary finding was that RF muscle size contributes significantly to squat force, a multi-joint task, but not to the single-joint, knee extension force. Vice versa, VL size contributed to single-joint force, but not to squat force. While our hypotheses technically were supported, we did expect both muscle sizes to still contribute to the regression model (not either RF or VL only for each task). This lack of contribution to the statistical model by both muscles for each task is likely due to insufficient sample size.

Flexor Pollicis Brevis Muscle Provides Another Eccentric Contraction Model In Human

Karina Kozaki[1], Eisuke Ochi[2], Koichi Nakazato[1]. [1]*Nippon Sport Science Univercity, Tokyo, Japan.* [2]*Hosei University, Tokyo, Japan.*

(No relevant relationships reported)

PURPOSE: Exercise induced muscle damage (EIMD) impair the skeletal muscle functions. To induce EIMD, many studies have used unaccustomed eccentric muscle contractions (ECs). ECs is frequently applied on biceps brachii or quadriceps muscles in human experiments. Flexor pollicis brevis muscle (FPBM) is a small flexor muscle of thumb MP joint. We examined whether EIMD could be induced into FPBM by forced extension of the thumb MP joint. **METHODS**: Eleven men received description and provided informed consent. ECs was applied by custom-made torque dynamometer. They performed maximal ECs on their FPBM of non-dominant hand. Five subjects (years, 21.8 ± 0.4; height, 171.5 ± 7.1 cm; weight, 68.3 ± 6.9 kg) performed 60 (6 × 10 sets) ECs with 90 deg / s fast joint angular velocity (severe EIMD). Other 6 subjects (years, 21.0 ± 1.3; height, 166.8 ± 3.1 cm; weight, 65.2 ± 2.6 kg) were assigned to 60 deg / s slow joint angular velocity (mild EIMD) of 100 (10 × 10 sets) ECs. Maximal voluntary contraction (MVC), joint range of motion (ROM) and muscle soreness were assessed before, immediately post, and 1, 2 and 5 days after ECs. Muscle soreness was quantified by using of visual analog scale (VAS). Values were statistically analyzed and the significance level was set at *p* < 0.05. **RESULTS**: In the severe EIMD, MVC and ROM were significantly decreased at post compared with pre (MVC, 18%; effect size = 1.30, 95 % CI 0.17 - 2.51; ROM, 14 %; effect size = 0.49, 95 % CI 0.81 - 1.70 *p* < 0.05). Mild EIMD also showed significant deficit of MVC and ROM values after post (MVC, 5 %; effect size = 0.33, 95 % CI 0.83 - 1.45; ROM, 12 %; effect size = 0.61, 95 % CI 0.59 - 1.71; *p* < 0.05). VAS markedly developed at 2 days after ECs in both groups (severe EIMD, pre, 0 cm, 2 days, 3.9 cm; effect size = 3.73, 95 % CI 1.44 - 5.29; mild EIMD, pre, 0 cm; post, 2.46 cm, effect size = 2.53, 95 % CI 0.87 - 3.8; *p* < 0.05). **CONCLUSIONS**: This study showed similar results with previous ECs studies, suggesting that FPBM is another novel ECs model in human.

Stimulated, but Not Voluntary Critical Torque Differs between Men and Women

Cameron L. Lohman. *The University of Oklahoma, Norman, OK.* (Sponsor: Chris D. Black, FACSM)

(No relevant relationships reported)

Previous studies have demonstrated gender differences in fatigue with women showing small declines in force compared to men. To our knowledge no study has examined whether gender differences exist in critical power or its isometric analog critical torque (CT) which are strong predictors of endurance performance. **PURPOSE:** The purpose of the study was to assess gender differences during voluntary and stimulated assessments of CT. **METHODS:** Nineteen participants (10 women, 9 men) completed 4 assessments of their quadriceps femoris CT over 3 randomly assigned testing visits: 1) voluntary CT assessment (VOL), 2) stimulated CT assessment at 100Hz (STIM100-1), and 3) stimulated CT assessment at 100Hz (STIM100-2) and 15Hz (STIM15). The work to rest cycle was 3:2 (3-sec of contraction to 2-sec of rest) during VOL and 2:2 during the stimulated tests. Voluntary activation (%VA) and twitch-torque (TT) were determined every 30-sec during VOL to determine central and peripheral contributions to fatigue. **RESULTS:** Gender differences were not observed for VOL (p = 0.55) with CT occurring at 47.5 ± 9.9% and 43.9 ± 16.3% of MVC, respectively. %VA and TT declined over time during the CT test (p ≤ 0.001), but no effect for gender was found %VA (p = 0.76 for %VA) or TT (p =0.31 for TT). Initial torque values and CT values did not differ for STIM100-1 and STIM100-2 (p ≤ 0.51). Stimulated CT at 100Hz occurred at a higher percentage of starting torque in women compared to men—33.2 ± 5.8% vs. 26.8 ± 4.9% (p = 0.02) and 35.5 ± 7.6% vs. 28.9 ± 5.5% (p = 0.046) for STIM100-1 and STIM100-2, respectively. No gender difference was observed during STIM15 (p = 0.79). **CONCLUSION:** Unlike previous studies of voluntary endurance exercise, we found no gender differences in VOL CT which was supported by similar central and peripheral fatigue during the CT test. Interestingly, women demonstrated less peripheral fatigue and a consistently high stimulated CT during 100Hz stimulation. However, this gender difference was lost when stimulation frequency was reduced to 15Hz. This finding may indicate the gender difference may be in part mediated by initial torque values and/or the rate of fatigue during exercise.

Relationship Between Muscle Activation and Force Recovery Following Sustained Maximal Voluntary Isometric Contractions

Kade E. Kinney[1], Ellen V. Sloan[2], Katherine E. Houle[1], William F. Brechue, FACSM[1]. [1]*A.T. Still University of Health Sciences, Kirksville, MO.* [2]*University of Tennessee Health Sciences Center, Memphis, TN.* (Sponsor: William F. Brechue, FACSM, FACSM)

(No relevant relationships reported)

Previously we observed dissociation of skeletal muscle activation and force recovery following sustained maximal voluntary isometric contractions (MVIC). Fatigue was specifically related to reduced muscle activation within bouts; yet, incomplete recovery of force between bouts occurred with maximal muscle activation, suggesting interference in excitation-contraction coupling. **Purpose:** to investigate time-dependency of nervous system recovery following MVIC. **Methods:** Men (n=29) performed two bouts (B1, B2) of sustained handgrip MVIC preceded by 10-min recovery periods. Force (dynamometer) and surface EMG (sEMG) from the brachioradialis (BR), flexor carpi radialis (FCR), flexor carpi ulnaris (FCU), and flexor digitorum profundus (FDP) were collected continuously (1000 Hz) during bouts. sEMG signals were band pass filtered, rectified, and integrated (iEMG), then normalized (nEMG) to initial B1 iEMG. Force and sEMG were analyzed at 0.5 second intervals every 15 seconds. **Results:** Recovery (B2 initial force >90% of B1) response fell into two groups; recovered (R, n=13) and not recovered (NR; n=16). Force decreased similarly in B1 (R: 77%; NR: 78%) and B2 (R: 79%; NR: 80%), yet initial B2 force was less (22%) than B1 in NR. Fatigue progressed in two-phases; B1 fast-phase decreased more rapidly with slow phase inflection occurring earlier (60 sec; 35% initial force) in R compared to NR (90 sec; 26% initial force). In R, B2 had a similar rate of decline in force and inflection (60 sec; 32% initial force). NR B2 showed a similar rate of decline in force, but inflection occurred sooner (75 sec) at the same level of initial B1 force (22%). Muscle activation (iEMG) during B1 was reduced similarly in R and NR (R: BR: 68%; FCR: 63%; FCU: 73%; FDP: 75%; NR: BR: 61%; FCR: 67%; FCU: 43%; FDP: 57%). During B2, R and NR showed similar decreases as B1, but all muscles except FCR showed lower initial B2 muscle activation compared to B1. **Conclusions:** Fatigue manifested in two phases; fast and slow. Recovery of force following sustained MVIC appears to be related to initial rate of decline of force (fast phase) with earlier onset of phase two. Earlier onset of phase shift may be related to changes in external compressive force and blood flow through the muscle, reducing metabolic perturbation and reflex inhibition of activation.

2271   Board #107   June 1 9:30 AM - 11:00 AM

The Magnitude Of Hamstring Co-activation During A Knee Extension Is Dependent On Knee Flexor Strength

Cameron S. Mackey[1], Ryan M. Thiele[2], Eric C. Conchola[1], Jason M. DeFreitas[1]. *[1]Oklahoma State University, Stillwater, OK. [2]Kansas State University, Manhattan, KS.*
(No relevant relationships reported)

Involuntary muscle activation of the opposing muscles (antagonists) during agonist muscle actions is referred to as antagonist coactivation. It has been shown that strength training the agonist leads to a decrease in antagonist co-activation. However, it is unknown if the relative antagonist strength plays a role in the magnitude of co-activation. **PURPOSE**: To assess if antagonist coactivation of the knee flexors during a maximal knee extension is related to Hamstring-to-Quadriceps strength ratio (H:Q). **METHODS**: Twenty-two men (M ± SD age = 23.32 ± 3.17 years) visited the laboratory and performed isometric maximal voluntary contractions (MVC) of the knee flexors and extensors. Surface electromyography (sEMG) was recorded from the vastus lateralis (VL) and the biceps femoris (BF). The root-mean-square (RMS) value of the sEMG signal was used to calculate the EMG amplitude, which was then normalized to the RMS obtained during that muscle group's MVC. Pearson's correlation coefficients were used for statistical analysis. **RESULTS**: A significant, moderate, negative correlation (r = -0.569; R^2 = 0.324; p = 0.006) was observed between H:Q strength ratio (M ± SD = 52.6% ± 12.2%) and antagonist co-activation of the BF (M ± SD = 18.03% ± 9.48%) (Figure 1). **CONCLUSION**: The results of the present investigation reveal that as hamstring strength increases in relation to the quadriceps, coactivation may be reduced. Since a commonly proposed purpose of antagonist co-activation is to provide joint stability, it is possible that a stronger and stiffer hamstrings muscle group would require less co-activation during a knee extension to stabilize the joint.

Acute EMD Responses of the Knee Extensors Following Free-Weight Back Squat Protocols

Eric C. Conchola[1], Ryan M. Thiele[2]. *[1]Oklahoma State University, Stillwater, OK. [2]Kansas State University, Manhattan, KS.*
(No relevant relationships reported)

Electromechanical delay (EMD) may play a significant role in joint stabilization during mechanical loading. Fatigue-related deficits in EMD have been observed when the level of volitional fatigue has been controlled, primarily through isolated muscle actions. However, few studies have assessed EMD responses following bouts of practical compound movements in which joint stabilization is essential. **PURPOSE:** Investigate the effects of EMD following work-matched submaximal back squat protocols during a 30-minute recovery period. **METHODS:** Thirteen resistance trained males (mean ± SD: age = 22.08 ± 2.75 years) visited the laboratory on three separate occasions, separated by seven (±1) days. The first day included determining each participant's one repetition maximum (1-RM) for the back squat, followed by a familiarization trial of maximum voluntary isometric contractions (MVICs) for the knee extensors. Day two and three included performing either an explosive power (EP) (5×16 at 40% 1-RM), or controlled hypertrophic (CH) (5×8 at 80% 1-RM) exercise protocol. Participants performed MVICs prior to each squat protocol, and at each recovery time point (Pre, Post 0, Post7, Post15, Post30). CH repetitions were performed at a cadence of two-second eccentric and two-second concentric phases. The EP repetitions were performed at a cadence of a two-second eccentric phase but the concentric phase was performed as fast as possible. Surface electromyography (EMG) was recorded from the vastus lateralis (VL) and EMD was identified as the time (ms) between onset of VL EMG to the onset of torque during all MVICs. A two-way repeated measures ANOVA (intensity [PE vs CH] × time [Pre vs Post0 vs Post7 vs Post15 vs Post30]) was used to analyze all EMD data. **RESULTS:** No interaction

(P = 0.528) nor main effect for intensity (P = 0.202) was observed. There was however a main effect for time (P = 0.039), where only Post0 was lower compared to Pre (P = 0.039). **CONCLUSIONS:** The present findings suggest that work-matched submaximal back squat protocols elicited similar EMD responses for the knee extensors. Specifically, EMD was longer at Post0 compared to Pre. These findings indicate that caution should be exercised following compound movements, regardless of intensity, as acute deficits in EMD may have important injury and performance implications.

Acute Effect of Localized Vibration on Reducing Masseter Stiffness as Measured by Elastography

Jeffrey Brent Feland, Jonathan Blotter, Cameron Smallwood, Jonothan DiPeri, Blake Cowan, Kylan Vanderpool, Aaron W. Johnson. *Brigham Young University, Provo, UT.* (Sponsor: J. Ty Hopkins, FACSM)
(No relevant relationships reported)

PURPOSE: The purpose of this study was to determine if the application of localized vibration would reduce masseter muscle stiffness as measured by shear wave elastography (SWE).
METHODS: 12 female subjects (21 +/- 1.8. yrs) without any history of TMJ disorder underwent both control (vibrator turned off) and Vibration conditions (randomized) on two different days. Methods: Subjects relaxed in a reclined seated position for 5 minutes before having the baseline masseter SWE measures taken with the jaw in a relaxed position. A GE S8 ultrasound machine with a 9L probe was used under the elastography setting. SWE values were calculated using a minimum of 7 separate .5cm circles within the defined elastography box fit within the muscle borders. 8 total images were assessed and averaged for the calculation of the baseline SWE measure in kPa. Subjects then underwent localized vibration treatment using a Rezzimax™ handheld vibration module with a specialized 2-pronged contact extension. All Subjects underwent 2 x 60-second bouts of vibration at 3 different randomized points (supraorbital margin of both eyes (70 Hz), medial and lateral sides of the base of the neck (105 Hz), and inside the mouth at a point just in front of the mandibular ramus(105 Hz). Post-measures of SWE followed the same protocol as the baseline measures. **RESULTS**: All measures were compared using a general linear model repeated measures ANOVA. A group x time interaction existed $F_{(1,11)}$ = 31.184 with a p-value of .000. Mean values for baseline SWE were 16.55 ± 5.59 kPa for Control and 16.57 ± 6.06 kPa for Vibration. Post-measure means were 15.78 ± 4.73 kPa for Control and 8.05 ± 1.92 kPa for Vibration. A paired samples T-test showed no significant difference in Baseline Control vs Post Control measurements (p = .180) or Baseline Control and Baseline Vibration (p=.984). Baseline Vibration vs Post vibration was significant (p=.000).
CONCLUSIONS: Localized vibration to these three spots resulted in acute reductions in masseter stiffness as measured by SWE in normal individuals. Use of localized vibration may be beneficial in reducing tension/stiffness of the masseter muscle in those with chronic TMJ disorder. Future studies should look at it's effect on pain, duration effect, and consider measuring the lateral pterygoid.

Influence Of Various Forms Of Pressure Stimulation On Skeletal Muscle Condition

Masaki Deguchi, Tomonobu Sakurai. *Toin University of Yokohama, Yokohama, Japan.*
(No relevant relationships reported)

PURPOSE: We investigated the effect of various forms of pressure on skeletal muscle condition with muscle temperature, muscle stiffness, oxygen saturation and B-mode ultrasound. **METHODS;** Six young male students (age 22.7 ±1.8 y, height 177.1 ± 3.9 cm, weight 69.7 ± 2.1 kg) completed the following intervention protocols in a randomized order on separate days: non-stimulation (C: control condition), Low pressure stimulation (LP), and High pressure stimulation (HP) at the rectus femoral. Subjects kept rest on bed. After the various forms of pressure stimulation or control intervention, muscle temperature, oxygenated saturation, muscle stiffness, B-mode ultrasound. The indicators of muscle condition were measured pre-stimulation, immediately post, 10, 20, and 30 minutes afterward. **RESULTS:** The muscle temperature increase to 10 minute in the HP, and a significant difference was recognized as compared with the C and LP (p<0.01). However, no significant difference was observed after 30 minutes. Oxygen saturation showed that the HP tended to be high after stimulation. Muscle stiffness decreased in both HP and LP immediately after stimulation, and the HP showed to return to baseline after 30 minutes from immediately after stimulation, and no significant difference was observed. The LP showed to maintain and a significant difference was observed as compared with the C (p<0.01). B-mode ultrasound were analyzed and compared with muscle luminance histograms, and neither HP nor LP showed changes before and after pressure stimulation. **CONCLUSION:** There was no change in the B-mode ultrasound

in both the HP and the LP, and the muscle stiffness decreased. The muscle temperature also increased, but when looking at the oxygen saturation level, only the HP showed a high value, indicating an increase in blood flow rate.

Antagonist Coactivation During A Reactive Leg Drop In Young And Older Adults

Alejandra Barrera-Curiel[1], Mitchel A. Magrini[1], Ryan M. Thiele[2], Jesus A. Hernandez-Sarabia[1], Ryan J. Colquhoun[1], Patrick M. Tomko[1], Nathaniel D. M. Jenkins[1], Jason M. DeFreitas[1]. *[1]Oklahoma State University, Stillwater, OK. [2]Kansas State University, Manhattan, KS.*

(No relevant relationships reported)

It appears that older adults use a coactivation strategy to control body sway and stiffen the joint. However, this strategy might limit reaction times, increasing the risk of falling. **PURPOSE:** Examine the age differences in antagonist coactivation during a reactive leg drop; a lower-body sensory-motor integration test designed to predict fall risk and the ability to recover from a slip. **METHODS:** Thirteen older (74 ± 7 yrs.) and 11 younger (23 ± 3 yrs.) adults were included in this study. For the reactive leg drops, participants were seated in a dynamometer with their dominant leg passively extended to max range of motion supported by an elastic band. Once the participant was completely relaxed, the researcher suddenly released the elastic band allowing the lower leg to free-fall. The participants were instructed to kick up as soon as they felt or saw the drop. Surface electromyography (sEMG) was collected from the biceps femoris (BF). Drop angle (DA) was assessed as the difference in angle between the straight position and the lowest point reached during the limb's free-fall. BF coactivation (%) was quantified as the RMS of the first 50 ms of activation and was normalized to BF sEMG of a maximal voluntary knee flexion. Independent t-tests with a 95% CI were used to identify the differences between groups in BF coactivation. Pearson product-moment analyses were used to determine the relationship between DA and BF coactivation. **RESULTS:** There was no significant differences between the young and old participants in BF coactivation (Younger = $3.16 \pm 1.36\%$; Older = $4.34 \pm 2.40\%$; p > 0.05). However, there was a significant relationship between DA and BF coactivation in the older group (r = 0.719; p = 0.006), as well as when collapsed across both groups (r = 0.637; p = 0.001; shown below). **CONCLUSION:** Even though BF coactivation was similar between groups, it was negatively associated with DA; suggesting that higher coactivation in the older population may result in a slower motor response time.

Variations of Acute Bouts of High-Intensity Training Programming Minimally Influence Biomarkers of Growth

Brian Kliszczewicz[1], Chad Markert[2], Emily Bechke[1], Cassie Williamson[1], Michael McKenzie, FACSM[2], Khala Clemons[2]. *[1]Kennesaw State University, Kennesaw, GA. [2]Winston-Salem State Univeristy, Winston-Salem, NC.* (Sponsor: Michael McKenzie, FACSM)

(No relevant relationships reported)

Plasma biomarkers of skeletal muscle growth are influenced by the modality, duration, and intensity of an exercise bout. High-Intensity Training Programs (HITP) are prescribed using various modalities, orders, weights, and repetition schemes. The duration of these bouts varies greatly, from shorter bouts of less than 5 minutes to longer bouts of 15 minutes or more. **PURPOSE**: To examine the effects of short- (< 5min) and long- (15min) duration bouts of HITP on markers of skeletal muscle growth.

METHODS: Ten apparently healthy males (28.1 ± 5yrs) participated in this study. Two HITP sessions (SHORT and LONG) were performed in a randomized crossover fashion. Blood plasma was collected at five time points: PRE, POST, 1HR, 3HR, and 6HR in order to examine growth hormone (GH), insulin-like growth factor (IGF-1), and insulin-like growth factor binding proteins 1 & 2 (IGFBP-1, IGFBP-2). **RESULTS**: The repeated measures ANOVA revealed no trial differences among any of the markers (IGF-1, IGFBP-1 & IGFBP-2) except GH at POST, where the LONG bout produced a greater effect (p = 0.005). A repeated measures ANOVA revealed a main time effect in GH (p = 0.037), while a posthoc t-test demonstrated elevated GH at 1HR (p = 0.018) when compared to PRE, while no time-dependent change (p > 0.05) was observed in IGF-1, IGFBP-1, or IGFBP-2. **CONCLUSIONS**: The findings suggest that there are no differences in markers of skeletal muscle growth other than GH between the SHORT and LONG bouts of HITP.

Impact of Sitting on Different Types of Stability Balls on EMGs During Arm Ergometry

Michelle Nguyen, Charles RC Marks, Hayley MacDonald. *Oakland University, Rochester, MI.* (Sponsor: Jonathan K. Ehrman, FACSM)

(No relevant relationships reported)

Past studies have demonstrated that sitting on a stability ball (SB) elevates oxygen consumption (VO_2) and leg electromyography (EMG) activity during arm ergometry when compared to chair sitting. In addition, our laboratory has reported that a SB made of stiff material had lower VO_2s when compared to a more elastic SB but had not indicated if there was an impact on muscle activity. **PURPOSE:** To determine if the characteristics of a SB also affects muscle activity during arm ergometry. **METHODS:** Twenty apparently healthy young adults underwent rest and two stages of submaximal arm ergometry under three different conditions (order randomized): sitting on a stiff material SB (SMB), same size but elastic material SB (SEB), and a smaller SEB (SSEB). Exercise intensity was determined during a prior day's testing with stage 1 set at 20 to 40 b/min above resting heart rate and stage 2 set at 20 to 40 b/min above stage 1's heart rate. Anterior Deltoid (AD), External Oblique (EO), and Rectus Femoris (RF) EMGs were recorded during the last 10 seconds of each stage. Repeated Measures ANOVA was used to determine SB type effect (alpha= .05) for peak rectified EMG levels. **RESULTS:** There were no significant SB type effects for AD ($P = 0.553$) and EO ($P = 0.963$) EMGs. However, RF had significant ($P = 0.002$) SB type effect. The SMB (Stage 1: 283 ± 229 mv; Stage 2: 370 ± 248 mv) had 19% to 37% lower EMG levels than the SEB (Stage 1: 337 ± 256 mv; Stage 2: 461 ± 305 mv) or SSEB (Stage 1: 361 ± 300 mv; Stage 2: 508 ± 371 mv) EMGs. **CONCLUSION:** A SB made of more elastic material requires more leg muscle activity during arm ergometry and may account for the higher VO_2 response noted in previous studies.

Musculoskeletal Complaints Prevalence And Surface Electromyographic Recordings From Upper Limbs In Surgeons

Fernando Sotelo-Barroso, Karla S. Vera-Delgado, Sergio Márquez-Gamiño, Cipriana Caudillo-Cisneros. *Universidad de Guanajuato, León, Mexico.*

(No relevant relationships reported)

Purpose: to determine the prevalence of musculoskeletal complaints of the trunk and thoracic limbs and to characterize the electric muscular activity registered superficially in the forearms of physicians having surgical practice.
Methods: in a cross-sectional study 43 physicians actively practicing surgical specialties were assessed. After signing an informed consent, to determine the presence of musculoskeletal complaints (MMC) of the cervical and lumbar spine and upper extremity, answered The Nordic Questionnaire. 12 of the participants accepted a second phase, consisting of surface electromyography (EMGs) of the upper limbs (Flexor Digitorum Superficialis) while performing maximal handgrip contractions. Results were analyzed by descriptive statistics, using SPSSv21.
Results: the total sample was composed of 32 men, and 11 women, 42.7±9.0 years of age (mean±s.d). 71% of the surgeons declared the presence of at least one MMC. Out of them, the lumbar spine was the most affected (71%), followed by shoulder affection (53%); hand and wrist (45%), and the neck (44%).
In the EMGs analysis, 50% of the participants achieved normal responses, characterized as maximal, minimal response, and peak to peak amplitud. For the right arm 2.26±0.94 mV; 0.10±0.70 mV, and 2.15±0.94 mV, in the same order. The opposite arm displayed 2.29±0.94; 0.18±0.15, and 2.11±0.87, respectively.
Conclusions: prevalence of MME in surgeons is high, suggesting surgeons' maladaptation to the surgical environment. The EMGs results corroborate muscular function alterations in a similar proportion to the MMC for hand and wrist.

Pre-workout Supplementation Does Not Augment Intramuscular MAPK Phosphorylation Immediately Following an Acute Resistance Exercise Bout

Justin X. Nicoll, Andrew C. Fry, Eric M. Mosier. *University of Kansas, Lawrence, KS.*

(No relevant relationships reported)

Ingestion of multi-ingredient dietary pre-workout supplements (PWS) are popular, however the molecular responses of PWS have not been investigated. Mitogen-activated protein kinase (MAPK) signaling proteins respond differently depending on resistance exercise (RE) volume, load, and contraction mode. Since RE performance is improved with PWS consumption by increasing repetitions to failure; it is plausible MAPK activation may also be potentiated. **PURPOSE**: To determine if acute RE MAPK phosphorylation is augmented with PWS. **METHODS**: In a randomized, counter-balanced, double-blind, placebo-controlled, within-subject crossover study, ten resistance-trained males ((M±SD, age=22±2.4 yrs, hgt=175±7 cm, body mass=84.1±11.8kg) performed four sets of 8 repetitions of barbell back squats at 75% of their 1-repetition maximum (1-RM) with two minutes of rest between sets and a fifth set of barbell back squats at 60% of 1-RM until concentric failure. A PWS or flavor and color matched placebo (PL) was consumed 60-minutes prior to RE. Muscle biopsies were taken from the vastus lateralis prior to supplementation at rest (BL), and ten minutes post-exercise (POST). Biopsy samples were analyzed for the ratio of (pMAPK/totalMAPK) of extracellular signal-regulated kinase (ERK), c-Jun NH_2-terminal kinase (JNK), and p38 via western blotting. Wilcoxon sign-rank tests were utilized to determine pairwise differences from BL to POST and between PL and PWS conditions. Statistical significance was determined at $p \leq 0.05$. Data are expressed as median and interquartile range [25th-75th]. **RESULTS**: RE increased phosphorylation of JNK (PWS: 7.4 [4.6 - 17.3] vs PL: 8.2 [5.45 - 16.2] fold-change), p38 (PWS: 19.6 [7.4 - 27.3] vs PL: 9.9 [5.7 - 27.8] fold-change), and ERK (PWS: 9.0 [1.5 - 48.3] vs PL: 13.2 [3.8 - 20.5] fold-change) (all p < 0.005), with no differences between PWS and PL conditions (p>0.05). Repetitions to failure tended to favor the PWS condition (PWS: 20 [17-21] vs PL: 16 [14-22]; p=0.058). **CONCLUSIONS**: RE increased MAPK phosphorylation but was not augmented by PWS in the immediate recovery period. Future studies should investigate if molecular signaling responses are altered at later time periods or after a period of chronic supplementation.

Peripheral Fatigue Mechanisms During Voluntary and Stimulated Assessments of Critical Torque

Angelina M. Curiel, Natalie R. Janzen, Jason A. Campbell, Rebecca D. Larson, Christopher D. Black, FACSM. *University of Oklahoma, Norman, OK.* (Sponsor: Christopher D. Black, FACSM)

(No relevant relationships reported)

Critical torque (CT) is an integrative measure/concept that represents the "critical" or upper boundary of steady-state work that can be performed without leading to exhaustive fatigue. We have developed a stimulated CT test, but the extent to which the mechanism(s) of torque decline are similar between voluntary and stimulated CT is unknown. **PURPOSE**: The purposes of this study was to determine if the decline in torque production stimulated exercise occurred due to similar mechanism(s) as the decline in torque during voluntary exercise. **METHODS**: Nineteen (Women = 10) participants completed 5 CT assessments over 3 testing visits: 1) voluntary CT (VOL), 2&3) stimulated CT at 100 Hz (STIM100-1 and STIM100-2), 4) stimulated CT at 15Hz (STIM15) and 5) stimulated CT at a frequency that elicited a torque below CT determined at 100Hz (BELOW). Twitch torque (TT), low frequency fatigue (LFF), and M-wave amplitude were measured before, during, and after each protocol. **RESULTS**: Stimulated CT did not differ among STIM100-1 (30.2 ± 6.2%), STIM100-2 (32.3 ± 7.3), and STIM15 (33.9 ± 8.2%; $p \geq 0.127$). VOL (45.3± 13.1%) and BELOW (20.8 ± 5.5%) differed from the others (p < 0.01). TT declined to 49% of starting ($p \leq 0.014$) in VOL, to 60% during the 100 Hz protocols ($p \leq 0.018$), but did not decline in STIM15 or BELOW conditions ($p \geq 0.08$). LFF occurred in VOL (0.58 ± 0.8 vs. 0.34 ± 0.1; p < 0.001). High frequency fatigue occurred following the stimulated protocols (p ≤ 0.001). No changes were observed in M-wave amplitude in the VOL, STIM15, or BELOW conditions (p ≥ 0.29). Significant decreases were observed in STIM100-1 and STIM100-2 with amplitudes declining to 77 ± 30% and 82 ± 28% of pre (p < 0.01), respectively **CONCLUSIONS**: Despite differences in peripheral fatigue mechanisms, CT occurred at similar values regardless of whether 100 Hz or 15 Hz stimulation was used. Higher frequency stimulation appears to induce greater deficits in axonal and neuromuscular junction transmission than VOL and lower stimulation exercise. None of the stimulated exercise protocols exactly mimicked the peripheral fatigue profile of the VOL condition, but 15 Hz stimulation was a better approximation than 100 Hz. Further research is needed to develop a stimulated exercise protocol that more closely mimics voluntary exercise.

Overstretch-Induced Reactive Oxygen Species Formation and Functional Decline in Skeletal Muscle

Li Zuo, FACSM[1], Chia-Chen Chuang[1], Tingyang Zhou[1], Feng He[2]. *[1]Ohio State University, Columbus, OH. [2]California State University, Chico, CA.*

(No relevant relationships reported)

Lengthening of skeletal muscle in eccentric exercise is linked with reduced fatigue resistance and muscle injury. Previous study has shown that eccentrically-biased exercise (i.e., downhill run) induced muscle damage is associated with leukocyte apoptosis. However, molecular evidence of reactive oxygen species (ROS) in stretched or eccentric muscle activities induced muscle dysfunction and apoptosis is not clear. **PURPOSE:** To evaluate ROS formation and muscle function in overstretched skeletal muscle in mice and to determine the effects of antioxidant intake on peripheral leukocyte apoptosis following eccentrically-biased downhill running. **METHODS:** Diaphragm muscle strips were isolated from C57BL6 mice and mounted in a contractile chamber. The muscles were either kept at its optimal length (control) or stretched to 30% of the optimal length, followed by a 5-min tetanic contraction. Cytochrome *c* was used to monitor superoxide $O_2^{\cdot-}$ release during contraction. Muscle force was recorded during the contractile protocol. In human eccentric exercise model, 22 subjects were randomly assigned into two groups taking: i) vitamin C (1000 mg/day) and vitamin E (400 IU/day); ii) maltodextrin (placebo) in a double-blinded fashion. Supplementation was administered for two weeks before downhill running exercise and two additional days after the training. At 0, 6, 24, 48h following the trial or prior to the trial, blood samples were collected for anti-apoptosis Bcl-2 assay via ELISA. Data were statistically analyzed as mean ± SE using one-way ANOVA. **RESULTS**: Overstretched diaphragm showed compromised muscle function compared to control (n = 10-13; p < 0.05). More ROS were induced in overstretched groups than control during contraction (n = 6-10; p < 0.05). In human model, we observed an increase in circulating leukocyte apoptosis and muscle soreness/damage 24-48 hours following exercise. Antioxidant attenuates the decrease in Bcl-2 at 24 hours following acute downhill running. **CONCLUSION**: Overstretched skeletal muscle is subjected to declined contractile function and exacerbated ROS formation. The combination of antioxidants supplementation appears to have a protective role via the attenuation of decrease in anti-apoptotic protein during eccentric exercise.

Downhill Running Impairs Strength And Activation Of The Elbow Flexors

Kyle J. Brandenberger, Christopher P. Ingalls, Jeff S. Otis, Gordon L. Warren, FACSM, James A. Doyle, FACSM. *Georgia State University, Jonesboro, GA.* (Sponsor: Dr. J. Andrew Doyle, FACSM)

(No relevant relationships reported)

PURPOSE: The aim of this study was to determine if knee extensor injury induced by 1 h of downhill running attenuated force production in uninjured skeletal muscle (e.g., elbow flexors). **METHODS:** Recreationally active subjects (n = 12) completed a two group (injury vs control) repeated measures design with the injury group running downhill for 1 h and the control group performing only the measurement procedures. Strength and percent voluntary muscle activation were measured using an isokinetic dynamometer and electrical stimulation of the elbow flexors and knee extensors before and after a fatigue protocol at the following time points in relation to the downhill run: 15 min pre, 15 min post, 24 h post, and 48 h post. Blood samples were collected at the same time points to measure IL-1β and TNF-α concentrations. **RESULTS:** Knee extensor strength was significantly reduced by 53.5±9.9% immediately post-injury and remained reduced for up to 48 h in the injury group. Elbow flexor strength was significantly reduced immediately and 24 h post-injury by 13.2±3.9% and 17.3±4.0% respectively in the injury group. Elbow flexor electrically stimulated strength was not found to be different at any time point (P = 0.561). Elbow flexor activation was significantly reduced compared to control at 24 and 48 h post-injury by 22.9±9.1% and 13.5±5.7% respectively. No differences were observed in IL-1β or TNF-α between groups. **CONCLUSIONS:** A 1 h downhill run significantly injured the knee extensors. The elbow flexor muscles remained uninjured based on electrically stimulated strength, but voluntary strength of these muscles was impaired due to reduced activation. This suggests an injury to the knee extensors can impair strength in uninjured muscles by reducing voluntary activation. The mechanism behind this reduction remains undetermined.

Motor Unit Action Potential Amplitude Vs Recruitment Threshold Relationships In Endurance Runners And Sedentary Females

Hannah L. Dimmick, Adam J. Sterczala, Michael A. Trevino, Hannah L. Richardson, Jonathan D. Miller, Trent J. Herda. *University of Kansas, Lawrence, KS.*

(No relevant relationships reported)

PURPOSE: To examine potential differences in the motor unit action potential amplitude ($MUAP_{AMP}$) vs. recruitment threshold (RT) relationship between female cross-country athletes and healthy controls. **METHODS:** Eight chronically-endurance trained (ET) females (age=20±0.93 yrs; height=166.18±5.93 cm; body mass=54.44±5.47 kg) nine healthy sedentary (SED) females (age=19.7±2.12 yrs; height=167.2±8.9 cm; body mass=66.61±11.9 kg) volunteered for the study. The ET group consisted of NCAA Div. I collegiate cross-country runners that ran 10-20 hrs/week. The SED subjects participated in minimal regimented physical activity in the previous 6 months. Subjects performed three isometric maximal voluntary contractions (MVCs) followed by a 70% isometric trapezoidal muscle action performed at 70% MVC. Surface electromyography was recorded from the vastus lateralis via 5-pin surface sensor array. The EMG signals were decomposed and AP_{AMP} (mV) and RT (expressed as %MVC) were calculated for each MU. For each subject, $MUAP_{AMPS}$ were linearly regressed against RTs with the slope and y-intercept calculated and used for statistical analysis. Two independent samples t-tests were used to examine potential between-group differences in the slopes and y-intercepts from the $MUAP_{AMP}$ vs. RT relationships. Statistical significance was set at p ≤0.05. **RESULTS:** The average RT ranges for observed MUs were 23.4 – 55.7% and 16.1 – 44.4% MVC for the ET and RT, respectively. There were no significant differences between groups for the slopes (ET=0.0035±0.0016 mV/%MVC, SED=0.028±0.0021 mV/%MVC, p=0.47) or y-intercepts (ET=-0.032±0.068 mV/%MVC, SED=-0.018±0.0.067 mV/%MVC, p=0.67). **CONCLUSIONS:** Previously, increases in the slopes from the $MUAP_{AMPS}$ vs. RT relationships have been correlated with increases in muscle cross-sectional area following resistance training, which was suggested to indicate MU hypertrophy. The similar $MUAP_{AMP}$ vs RT relationships observed between the cross-country runners and sedentary controls may suggest that chronic endurance training did not result in hypertrophy of higher-threshold MUs of the vastus lateralis.

The Effect of Compression Garments Worn During Resistance Exercise on Muscle Damage, Fatigability and Hemodynamics

Makenzie Stade, Bria Morse, Evan Schick, Joshua Cotter. *California State University Long Beach, Long Beach, CA.*

(No relevant relationships reported)

Use of compression garments during and after exercise has gained notable popularity, yet, their utility in augmenting performance and recovery from resistance exercise remains elusive. **PURPOSE:** To evaluate the effects of wearing compression during resistance exercise on exercise induced muscle damage (EIMD), muscle oxygenation and muscular fatigue. **METHODS**: Ten healthy, untrained individuals ([mean ± SD] 8 females, 2 males, 22.10 ± 2.23 years, 159.09 ± 3.47 cm, 66.22 ±15.93 kg) performed two exercise trials: 1) wearing compression tights and 2) without compression. Exercise trials were randomized and separated by seven days. The exercise protocol consisted of 12 sets of 10 repetitions of knee flexion, at a velocity of 120 degrees per second, in the CON/ECC mode of an isokinetic dynamometer (HUMAC NORM). Muscle oxygenation of the vastus medialis oblique (VMO) was assessed by oxy-hemoglobin (HbO2) and deoxy-hemoglobin (Hb) through near-infrared spectroscopy (NIRS; TRS-21, Hamamatsu). Leg circumference, ratings of perceived muscle soreness (RPMS) and blood samples for creatine kinase (CK) were collected before, immediately after, and 24, 48 and 72 hours after exercise. **RESULTS**: Pre-exercise and inter-set rest period values for Hb, HbO2, total Hb (tHb) and tissue oxygenation index (TOI) were similar between conditions. Intra-exercise Hb and tHb were significantly (p<0.05) reduced with compression compared to control. Post-exercise Hb was significantly reduced and TOI was significantly increased (p<0.05) with compression compared to control. Main effects for time revealed significant (p<0.05) increases in leg circumference, RPMS and CK, however, no differences were observed between conditions. Additionally, a main effect for time revealed significant reductions in average torque (N*m) from the first four sets to the middle four sets and again during the final four sets but there were no differences between conditions. **CONCLUSION**: Lower body compression worn during resistance exercise did not impact muscular fatigue or damage, but venous return and muscle re-oxygenation may have been improved.

Muscle Architecture, Central Fatigue, and Contractile Properties Do Not Explain Age-Related Differences in Muscle Fatigue

Liam F. Fitzgerald, Margaret M. Ryan, Sydney L. Connor, Julia D. Miehm, Miles F. Bartlett, Jane A. Kent, FACSM. *University of Massachusetts Amherst, Amherst, MA.*

(No relevant relationships reported)

High-velocity contractions elicit greater muscle fatigue in older compared with young adults. In general, fatigue can occur due to failure at numerous sites from the central nervous system to the contractile machinery. Additionally, sarcopenia-induced architectural remodeling may place older muscle at a disadvantage for producing power at high contraction velocities. **PURPOSE:** To examine the potential roles of muscle architecture, central fatigue, and contractile properties on age-related differences in high-velocity knee extensor fatigue. **METHODS:** Baseline muscle architecture (thickness, MT; pennation angle, θ; fascicle length, FL) of the vastus lateralis was determined by ultrasonography in 7 young (YW; 21.6±0.4 yrs) and 7 older (OW; 69.6±1.3 yrs) women. Maximal voluntary dynamic (MVDC) and isometric (MVIC), and stimulated (80Hz and 10Hz, each 500ms) contractions were performed before and immediately after a fatigue trial consisting of 120 knee extensor MVDCs (240° s^{-1}, one every 2s). Muscle architecture, central fatigue (fall of MVIC:80Hz torque) and contractile properties (10Hz:80Hz torque ratio; torque half-relaxation time, $T_{1/2}$) were compared across groups using t tests and repeated measures ANOVA. **RESULTS:** Baseline MT (p<0.01) and FL (p=0.01) were lower in OW than YW, with no age-related difference in θ (p≥0.14). OW fatigued more than YW (to 33±5% and 56±5% initial power, respectively; p<0.01), with no evidence of central fatigue in either group (p≥0.35). Failure of excitation-contraction coupling (fall in 10:80Hz ratio) occurred in both groups (p≤0.02), with no group×time interaction (p=0.36). $T_{1/2}$ was longer in OW than YW at baseline (p<0.01), but no group×time interaction was observed (p=0.50). While neither MT nor FL were associated with fatigue (r²≤0.15), $T_{1/2}$ at baseline was associated with fatigue in OW (r²=0.59) but not YW (r²=0.11). **CONCLUSION:** These results indicate that muscle architecture, central fatigue, and excitation-contraction coupling did not explain the greater muscle fatigue in OW. Notably, $T_{1/2}$ at baseline was predictive of fatigue in OW only, suggesting that slowed torque relaxation may limit older muscle's ability to maintain power output during fast, repetitive contractions.

Effects Of Lactate Administration On Intracellular pH And Contractile Performance During Rhythmic Muscle Contractions

Yoshinori Tanaka[1], David C. Poole, FACSM[2], Yutaka Kano[1]. *[1]University of Electro-Communications, Tokyo, Japan. [2]Kansas State University, Manhattan, KS.* (Sponsor: David C Poole, FACSM)

(No relevant relationships reported)

Skeletal muscle fatigue during heavy or severe intensity exercise is accompanied by decreased intracellular pH (pH_i) and accumulation of lactic acid. The role of these perturbations in the fatigue processes are hotly debated with evidence for and against a deterministic role for each in muscle contractile tolerance and intolerance. However, it is unknown whether extracellular lactate level during exercise affects pH_i and contractile performance especially within a mixed fiber type muscle that is a close analog of the human quadriceps with respect to fiber type and oxidative capacity. **PURPOSE:** Using an *in vivo* bioimaging model, we tested the hypothesis that extracellular high lactic acid levels would increase endurance performance without changing pH_i during sustained contractions. **METHODS:** The intact spinotrapezius muscle of adult male Wistar rats was exteriorized and loaded with the fluorescent probe BCECF-AM (10 μM). Isometric (ISO) twitch contractions were evoked at the optimal muscle length via electrical stimulation for 10 min (2 Hz, 9 V, stimulus duration 4 ms). The rats were divided into two groups: buffer solution loading group (CONT, n = 7) and lactate solution loading group (LAC; 20 mM, n = 6). The fluorescence ratio (F500 nm/F445 nm) for pH_i estimation was determined from images captured pre-contraction (-10 min, -5 min) and < 1 min, 5 min, 10 min, 15 min, and 20 min after contraction. **RESULTS:** Muscle tension decreased significantly with time in both CONT and LAC groups. However, LAC muscles elicited a higher tension over almost the entire bout and the time to significant tension reduction was substantially increased in the LAC group (CONT: 2.5 min vs LAC: 7.5 min, p < 0.05). In the CONT group, no significant change in pH_i was observed after contractions, whereas a significant decrease in pH_i was observed in the LAC group during 20 min from immediately after muscle contractions. **CONCLUSION:** Within this preparation extracellular high lactic acid and lowered pH_i improved contractile performance substantially.

Exercise Induced SOD2 asa Predictor of Fatigability in Healthy Adults

Zoe Williams[1], Lisa Chin[1], Rebekah Feng[2], Leorey Saligan[2], Leighton Chan[2], Randall E. Keyser, FACSM[1]. *[1]George Mason Universtiy, Fairfax, VA. [2]National Institutes of Health, Bethesda, MD.* (Sponsor: Randall Keyser, FACSM)

(No relevant relationships reported)

Acute aerobic exercise has been reported to increase antioxidant levels in response to an increase in exercise-induced oxidative stress. However, there is limited knowledge regarding the acute exercise effects of serum SOD2 levels on fatigability measures in healthy adults. **Purpose:** The purpose of this study was to determine if physiological determinants of fatigue (such as time to fatigue, TTF; peak oxygen consumption, VO_2; peak work rate, WR) are significantly correlated to serum SOD2 levels before, immediately after and 60 minutes after an acute bout of aerobic exercise. **Methods**: Subjects were 19 healthy, adults (13 females, 6 males; age 26.58±9.1 years; BMI 24.2±2.7 kg/m[2]) enrolled in the National Institutes of Health Fatigue in Healthy Protocol Trial. Subjects completed a treadmill cardiopulmonary exercise test (CPET) to exhaustion during the first visit. On a subsequent visit, subjects performed a vigorous-intensity continuous work rate test on the treadmill to exhaustion, and serum samples were collected immediately before, immediately after and 60 minutes after exercise. Performance fatigability was represented by peak VO_2 and peak WR from the CPET, as well as TTF during vigorous exercise. A Human Oxidative Stress Multiplex panel was used to determine serum SOD2 levels. Pearson product-moment correlation analyses were performed on the identified physiologic determinants of interest and SOD2 at various time points. **Results:** Peak VO_2 (r = 0.57, p = 0.02) and peak WR (r = 0.62, p = 0.01) were significantly correlated to serum SOD2 levels immediately post exercise, while TTF was not significantly correlated to SOD2 at any time point. **Conclusions:** This study suggests that an exercise-induced increase in serum levels of SOD2 may be a predictor of fatigability in healthy adults. Further research and analysis of other physiological fatigability measures is needed to validate these findings. Funding: Intramural Funds from the National Institutes of Nursing Research

Cross Validation of Different Equations to Predict Knee Extensors Isokinetic Strength in Brazilian Older Women

Juscelia C. Pereira, Silvia G.R. Neri, André B. Gadelha, Martim Bottaro, Ricardo M. Lima. *University of Brasilia, Brasilia, Brazil.*

(No relevant relationships reported)

PURPOSE: to determine the accuracy of the equations in predicting knee extensors isokinetic strength in Brazilian older women. **METHODS:** A total of 453 elderly women aged 60 to 84 participated in the present cross-sectional study. Quadriceps isokinetic strength was measured using the Biodex System dynamometer, with participants performing two to three sets of four knee extensor contractions at 60°s[-1], with 30 seconds rest intervals between sets. The highest peak torque (PT) was recorded and compared to the PT predicted by two different equations (Neder et al. and Phillips et al.). Dependent t test, Pearson correlation (r), constant error (CE)/bias and standard error of estimate (SEE) were calculated to examine differences between the measured PT with values estimated by the equations. Concordance analysis was investigated using Bland-Altman technique. Statistical significance was set at p <.05. **RESULTS:** The Neder et al. (85.30 ± 18.60 Nm) and Gross et al. (85.00 ± 29.99 Nm) equations provided significantly lower estimates when compared with measured PT (92.26 ± 21.59 Nm) (p<.001 for both). Moderate correlations were observed for Neder et al. and Gross et al. in relation to actual values (0.53; 0.50, respectively). The mean ± SD CE/ Bias and SEE were high for the prediction equations (Neder et al. = 7.00 ± 19.70 and 18.36 Nm; Gross et al. = 7.30 ± 26.70 and 18.67 Nm, respectively). The 95% limits of agreement of the mean error were similar for the prediction equations, with values varying between 14.0 and 14.6 Nm. **CONCLUSION:** Because of the wide limits of agreement displayed by each studied equation and inflated values for error, the Neder et al. and Gross et al. equations were not accurate to predicting the knee extensors isokinetic strength in Brazilian older women. One possible reason for this finding is that these equations were derived from a wide age range (10 to 80 years), with limited data derived from older women. Future studies are necessary to develop a specific equation for elderly women, aiming to accurately predict isokinetic quadriceps muscle strength.

The Effects Of Cross-education On Critical Torque And Time To Task Failure

Alwyn Quarshie, Robert E. Hight, Bree S. Baker, Samuel R. Buchanan, Debra A. Bemben, FACSM, Christopher D. Black, FACSM. *University of Oklahoma, Oklahoma City, OK.* (Sponsor: Christopher D. Black, FACSM)

(No relevant relationships reported)

Debate exits regarding the extent to which resistance training may alter endurance performance. **PURPOSE:** To determine whether critical torque (CT) and time to failure (TTF) are influenced by a cross-education effect consequent to a 4-week unilateral isometric resistance training protocol. **METHODS:** A seven participant mixed-gender sample was tested prior to and following16 sessions of unilateral isometric resistance training. Sessions consisted of 6 sets of 6 maximal isometric contractions (MVCs) of the dominant plantar flexors. CT and TTF were assessed in the trained and the contralateral, untrained leg across 4 test days structured with a randomized pre-post design. CT was assessed from a 5-minute "all-out" test in which participants completed 60 MVCs at a 3:2 duty cycle. Time to task failure was defined at the point which a submaximal contraction set equal to 30% of the highest MVC could no longer be maintained. Changes in soleus muscle cross-sectional area (CSA) were calculated via peripheral quantitative computed tomography. When one-way repeated measures ANOVAs performed across the final 6 contractions of the CT tests were non-significant, these contractions were averaged to obtain the criterion CT value. Peak force, soleus CSA, CT, and TTF were evaluated independently in each limb using paired-samples t-tests. **RESULTS:** Peak force increased in the trained (25.5 ± 19.7%, p < 0.01) and the untrained limb (30.5 ± 16.3%, p < 0.01), indicating that cross-education occurred. There were no pre-post differences in soleus CSA in either limb; (trained: 5193 ± 1557 vs. 5139 ± 1504 mm[2], p > 0.05) or (untrained: 5246 ± 1432 vs. 5255 ± 1544 mm[2], p > 0.05). Peak force did not differ between the final 6 contractions during any CT test (p > 0.05). CT increased in the trained (322 ± 6 N to 402 ± 12 N, p < 0.01) and untrained (313 ± 12 N to 390 ± 13 N, p < 0.01) limbs, respectively, and TTF was reduced in the trained (410 ± 112 vs. 319 ± 85 s, p = 0.014), but not the untrained limb (424 ± 152 vs. 312 ± 79 s, p = 0.08). **CONCLUSIONS:** Improvements in strength and CT occurred in both the trained and untrained limbs indicating that strength training may play a role in improving endurance capacity and that this adaptation can occur in a contralateral limb. The decline in time to task failure may be a result of the increased absolute force output required to complete the task.

Heightened Sensory Signaling Does Not Alter Critical Torque

Darshit S. Patel, Natalie R. Janzen, Robert E. Hight, Christopher D. Black, FACSM. *The University of Oklahoma, Norman, OK.* (Sponsor: Christopher D. Black, FACSM)

(No relevant relationships reported)

Peripheral metabolic perturbations have been shown to activate group III and IV sensory afferents and lead to a decrease in central motor drive and an earlier onset of fatigue. Critical power or its isometric analog, critical torque (CT), is an important parameter of aerobic metabolic function and a strong predictor of endurance performance. **PURPOSE:** This study sought to examine the effects of heightened afferent signaling on voluntary CT and electrically stimulated CT. **METHODS:** Eleven participants performed a voluntary (VOL) 5-min all-out and a 5-min stimulated (STIM) isometric knee extension test with contralateral blood flow occlusion (CBFO) following fatiguing exercise and without occlusion (CONTROL). Stimulated CT was also assessed with occlusion applied to the ipsilateral leg (IBFO). Both the VOL and STIM protocols were performed at a 3-sec to 2-sec work to rest cycle. Stimulated contractions were performed at 50 Hz at a current eliciting 25% of MVC. **RESULTS:** There was a significant effect of time (p < 0.001) for VOL in both the CBFO and CONTROL conditions with torque declining to a critical level. VOL CT did not differ between the two conditions (360 ± 119 vs. 343 ± 108 Nm; p = 0.28). A significant condition x time interaction (p = 0.009) was found for STIM. Initial torque did not differ among the conditions (p = 0.876), but CT values were lower (p < 0.001) in IBFO (19.2 ± 15.8 Nm) compared to CONTROL (57.7 ± 15.6 Nm) and CBFO (62.1 ± 17.7 Nm). The CONTROL and CBFO conditions did not differ (p = 0.347). **CONCLUSIONS:** Heightened group III and IV afferent signaling has been shown to increase central fatigue and reduce endurance capacity. Our findings indicate the reduced endurance capacity is not due to reductions in CT—suggesting participants were able to maintain central drive to skeletal muscle. Our findings that stimulated CT fell with IBFO provides further evidence validating our stimulated CT test and it demonstrates its sensitivity to oxygen delivery.

The Effects of Repeated Shortening or Lengthening Muscle Actions on Knee Extensor Position Sense

Ryan M. Thiele[1], Jason M. DeFreitas[2]. [1]*Kansas State University, Manhattan, KS.* [2]*Oklahoma State University, Stillwater, OK.*
(No relevant relationships reported)

The effects of concentric, fatiguing muscle actions on muscle spindle function has been well studied. However, few studies have examined the effects of eccentric muscle actions on proprioceptive function. **PURPOSE:** Investigate the effects of fatiguing shortening or lengthening muscle actions on position matching (PM) tasks of the knee extensors. **METHODS:** Fifteen females (age = 21.67 ± 2.1 yrs.) participated in a familiarization trial, followed by two experimental sessions, separated by seven (± 1) days, consisting of either muscle- shortening (Concentric; CON) or lengthening (Eccentric; ECC) contractions of the right limb at $60° \cdot s^{-1}$ until 70% of peak torque (PT) could no longer be achieved. PM tasks included a randomly chosen limb fixed in a static position to serve as a reference of the contralateral test limb during active position matching tasks. Participants were asked to provide verbal feedback when they had matched the test limb with the reference limb, followed by a 2-second static hold. Four PM efforts were completed, with eyes closed, for each limb at two randomly assigned joint angles of 80° and 165° prior to the experimental protocols (Pre). Subsequent PM tasks were completed immediately after (Post 0) and ten (Post 10) minutes following the experimental protocols. Two separate, three-way repeated measure ANOVAs (condition [CON vs ECC] × limb [right vs left] × time [Pre vs Post 0 vs Post 10]) were used to analyze absolute PM error at 80° and 165°. An alpha value of $P \leq 0.05$ was considered statistically significant for all comparisons. **RESULTS:** A significant condition × limb interaction (p = 0.002) for 80° was observed in which PM error of the right limb was greater during the CON protocol compared to the ECC protocol (p = 0.011). Additionally, no differences in PT were observed for either experimental protocol between Pre and Post 10 (p = 0.097). **CONCLUSION:** These findings suggest that alterations in PM acuity may be more pronounced at joint angles in which passive muscle tension increases (80°), following concentric muscle actions. Furthermore, muscle spindle function may not be disrupted by repeated lengthening muscle actions when the protocol does not induce muscle damage.

2292   Board #128   June 1 9:30 AM - 11:00 AM

Muscle Acidification And Fatigue Kinetics During Intense Repeated Exhaustive Exercise

Magni Mohr[1], Jonathan Fulford[2], Joanna L. Bowtell[2], Peter Krustrup[3]. [1]*University of the Faroe Islands, Tórshavn, Faroe Islands.* [2]*University of Exeter, Exeter, United Kingdom.* [3]*University of Southern Denmark, Odense, Denmark.*
(No relevant relationships reported)

Skeletal muscle and fatigue responses during single high intensity exercise bouts have been examined extensively, while scientific reports on repeated high intensity exercise are limited. **PURPOSE:** To examine effects of muscle acidification on fatigue kinetics during repeated intense exhaustive exercise. **METHODS:** Eight active male participants (age: 26 ± 3 ($\pm$SEM) yrs.; VO_{2max}: 58 ± 1 $mlO_2 \cdot kg^{-1} \cdot min^{-1}$) completed two exercise trials in random order. Trials consisted of five intense single leg knee-extensor exercise bouts to exhaustion (EX1-5) separated by 5 min recovery, with (ARM) and without (CON) previous intense intermittent arm crank exercise. ^{31}P-MRS measurements of the quadriceps muscle were undertaken to assess muscle pH and venous blood was drawn. **RESULTS:** Quadriceps muscle pH was lower (P=0.002) prior to the knee-extension exercise in ARM compared to CON (6.948 ± 0.018 vs 7.040 ± 0.010, respectively). In CON muscle pH dropped to 6.370 ± 0.038 in EX1 and was progressively higher (P<0.05) in the following four bouts reaching 6.705 ± 0.045 in EX5. However, in ARM muscle pH reached similar levels in EX1-4 (6.490-6.579) and was elevated only in EX5 (6.637 ± 0.062). Pre-exercise blood lactate concentration was increased (1467 ± 111%, p<0.001) and pCO_2 (27.8 ± 14.4%, p=0.045), with concomitant reductions in blood pH (-0.24 ± 0.02, p<0.001) and HCO_3^- (-38.1 ± 2.2%, p<0.001) in ARM compared to CON. Exercise performance was 69 ± 20% shorter (P<0.05) in ARM compared to CON. Performance was attenuated (P<0.05) in ARM during the three first bouts compared to CON. There was a progressive reduction (P<0.05) in exercise performance in CON trial, while no significant differences were observed between the five bouts in ARM. **CONCLUSION:** Prior arm exercise markedly alters fatigue kinetics and muscle acidification during repeated intense knee-extension exercise. Muscle acidification may provoke fatigue during single bout intense exercise scenarios, but appears to play a minor role, when exercise is repeated.

Interference In Emphasis Of Muscle Actions In The Maximum Dynamic Strength And The Maximum Volume Of Repetitions

Cintia C. Rocha[1], Hiago L. R. de Souza[2], Yuri A. C. Campos[3], Gaspar P. da Silva[4], Miller P. Guimarães[5], Osvaldo C. Moreira[6], Sandro F. da Silva[4]. [1]*Presbyterian College Gammon, LAvras, Brazil.* [2]*Federal University of Triângulo Mineiro, Uberaba, Brazil.* [3]*Federal University of Juiz de Fora, Juiz de Fora, Brazil.* [4]*University of Lavras, Lavras, Brazil.* [5]*Presbyterian College Gammon, Lavras, Brazil.* [6]*University of León and Federal University of Viçosa, Florestal, Brazil.*
(No relevant relationships reported)

PURPOSE: The present study aimed to investigate the influence of different speeds of muscle actions on the maximum volume of repetitions and maximum dynamic muscle strength. **METHODS:** The study included 9 women. At first, the volunteers performed the anthropometric assessment and the evaluation of maximum dynamic strength through the 1RM test; In the second moment, the volunteers performed three series with 60% of 1RM as many repetitions as possible, with an emphasis on concentric phase of the movement (CP); in the third moment it was conducted the same exercise with emphasis on the eccentric phase of the movement (EP); and in the fourth moment the same procedure was conducted without emphasis on any stage of the movement (CoP). At the end of 3 series of each execution protocol was added the maximum volume of repetitions (MVR), the maximum dynamic strength was assessed 72 hours after each protocol. **RESULTS:** The results showed no statistically significant difference in maximum number of repetitions and maximum dynamic strength among the protocols CP, EP and CoP. The dynamic strength decreased 6% after the EP, the MVR also showed fewer number of repetitions (34.77) compared to other protocols. **CONCLUSIONS:** It was possible to conclude that the realization of protocols of exercises with speed movement that emphasize different muscle actions causes decreased maximal dynamic muscle strength and shows tendency to decrease the MVR when the movement speed prioritizes eccentric actions.

E-33   Free Communication/Poster - Motor Control

Friday, June 1, 2018, 7:30 AM - 12:30 PM

The Effect of Exercise Intensity on the Kinematics of Reach Performance and Brain-Derived Neurotrophic Factor

Jessica F. Baird, Mary E. Gaughan, Heath M. Saffer, Mark A. Sarzynski, FACSM, Troy M. Herter, Stacy L. Fritz, Dirk B. den Ouden, Jill C. Stewart. *University of South Carolina, Columbia, SC.*
(No relevant relationships reported)

PURPOSE: Acute exercise paired with practice of a motor task has been shown to enhance motor learning beyond task practice alone. However, it is unknown how exercise intensity affects movement kinematics during motor learning. Furthermore, the brain-derived neurotrophic factor (BDNF) response to exercise intensity needs to be examined because increases in BDNF are thought to mediate exercise-enhanced motor learning.
METHODS: 48 participants (23.3 ± 3.2 yrs) practiced a 3-dimensional motor learning task, which involved reach movements made to sequentially presented targets. Before task practice, participants were randomized so that 16 participants exercised on a cycle ergometer at a high-intensity, 16 participants exercised at a low-intensity, and 16 participants rested. Exercise intensity was determined as a percentage of max resistance obtained on a cycle-based graded exercise test, and duration was individually modified so that each participant in the low and high intensity groups expended 200 kcals of energy. Blood samples were obtained from all participants before and after exercise (exercise groups) or rest (control group) to assess changes in BDNF.
RESULTS: All participants significantly improved performance, as indicated by shorter times to complete the task. In the rest group, shorter times were associated with decreased distance traveled between targets, a spatial component of performance. In contrast, the exercise groups improved by altering temporal components of performance. The high-intensity group had significantly higher reach speeds (peak velocity), and the low-intensity group had significantly earlier peak velocities, an important feature of motor learning ($p < 0.001$ for all group differences). The percent change of the BDNF response was greater for the high-intensity ($164.53\% \pm 465.56$)

and low-intensity (152.76% ± 324.75) groups compared to the rest group (37.8% ± 195.65). However, group differences were not significant because of high variability in individual BDNF responses.

CONCLUSIONS: An acute bout of exercise facilitates temporal changes in movement kinematics that are associated with improvements performing a sequential target task. Regardless of intensity, the BDNF response to exercise has high inter-individual variability, which needs to be further investigated.

Agility of Adolescents with Attention Deficit Hyperactivity Disorder Compared with Normal Controls: A Preliminary Investigation

Laurie Simard[1], Tommy Chevrette[1], Julie Bouchard[1], Linda Pacquette[1], Jacinthe Dion[1], Claudia Verret[2], Alain-Steve Comtois[3], Jacques Leroux[4]. *[1]UQAC, Chicoutimi, QC, Canada. [2]UQAM, Montréal, QC, Canada. [3]UQAM, Montreal, QC, Canada. [4]HRDP, Montreal, QC, Canada.*

(No relevant relationships reported)

PURPOSE: Motor delay (MD) has been shown in children with Attention-Deficit/ Hyperactivity Disorder (ADHD), such as agility. Agility is involved in everyday movements and is essential to the development of sports skills. Recent imaging studies have shown delayed of the cerebral cortex development of near three years in children with ADHD, which could explain MD. This study aims to evaluate Agility in ADHD male adolescents compare to normal controls, group-matched for age. Moreover, if MD in agility is still observable in ADHD, to determine which group age they can be compared with. **METHODS**: This study included 40 adolescents; 20 with ADHD (ADHD-gr; age 13.8 ± 0.9 yr) and 20 normal controls (Control-gr; age 13.5 ± 1.0 yr). First, both groups were compared using the UQAC-UQAM Gross motor tests battery for agility: Shuttle, Circle, Side-stepping, and Slalom run. Agility scores (sec.) were compared between groups using One-way ANOVA. Then, descriptive comparisons were performed using results of the 50th percentile in 8 yr children (P50-8) and in 12 yr (P50-12) for each agility tests. **RESULTS**: Adolescents with ADHD were significantly slower when compared to control in Shuttle Run (11.2 ± 1.3 vs. 6.6 ± 3.1 sec., p<0.001) and Circle Run (22.3 ± 2.9 vs. 19.5 ± 2.2 sec., p<0.001). Results tending to be slower for Side-stepping, and Slalom Run but did not reach significance. When compared to norms across age group, ADHD-gr scores (sec.) were aligned to P50-8 and slower then P50-12 for all agility tests. However, as expected, the scores (sec.) of Control-gr, were aligned or better to P50-12. **CONCLUSIONS**: In this study, motor delay in agility is still observable in a group of adolescents with ADHD. It seems to have a delay of about 5 years between groups (ADHD vs Control) for all tests measuring agility. Further research is needed to clarify motor delay in adolescents with ADHD for all determinants of gross motor skills (agility, coordination, segmental velocity, balance, and reaction time).

Agility Score Test of Adolescents with ADHD Compared to Normal Controls						
Agility Tests (sec.)	50th percentile for 8yrs	50th percentile for 12yrs	N	ADHD	Control	p
Shuttle Run	11.3	10.3	36	11.2±1.3	6.6±3.1	0.00*
Side-stepping Run	11.4	10.1	38	11.3±2.3	10.5±1.4	0.21
Circle Run	22.3	20.3	40	22.3±2.9	19.5±2.2	0.00*
Slalom Run	20.1	16.8	40	18.9±2.3	17.5±2.3	0.15

A Muscle's Functional Role Influences Movement Accuracy Before and After Eccentric Exercise

Kurt W. Kornatz[1], Vasanth Subramanian[2], Yu-Kai Chang[3]. *[1]Winston-Salem State University, Winston-Salem, NC. [2]Rosalind Franklin Univerisity of Medicine and Science, North Chicago, IL. [3]National Taiwan Sport University, Taoyuan City, Taiwan.* (Sponsor: Michael McKenzie, FACSM)

(No relevant relationships reported)

Eccentric muscle contractions, especially if unaccustomed and intense, can cause fatigue and muscle damage that contributes to acute decrements in motor performance. Because performance of motor tasks requires the precise coordination of agonist and antagonist musculature, the effect of the eccentric activity on accuracy will likely depend on the damaged muscle's function as an agonist or antagonist in the task. **PURPOSE:** To compare the effect of fatiguing eccentric exercise (EE) on the accuracy of aiming movements when the EE muscle group's function is that of an agonist or antagonist. **METHODS:** 16 untrained subjects (9 M, 7 F; 27 ± 3 yrs.) completed discrete horizontal pointing movements between 2 targets (13mm diameter)

that required 40° of elbow movement. Twenty elbow-extension and 20 elbow-flexion pointing movements were performed with their right arm before and immediately after eccentric exercise of the elbow extensor muscles standardized by isokinetic dynamometry. Movement accuracy was quantified by the incidence (overall accuracy) and duration to initiation (magnitude of error) of secondary submovements that were identified by zero crossings in the tangential velocity and acceleration profiles. **RESULTS:** When the exercised muscles performed the pointing task as the agonist (i.e. extension movements), movement times (MT) were longer and peak velocity (PV) decreased after EE compared with before EE (MT= 222 ± 40, 248 ± 37ms, p<0.05; PV= 3.4 ± 0.6, 3.1 ± 0.6m/s, p<0.05). However, when the exercised muscle was the antagonist (i.e. flexion movements), MT and PV remained unchanged. There were more trials with no corrective submovements (i.e. more accurate) for the extension compared with flexion movements before EE (92% vs. 62%, p<0.001), but there was a greater decline in accurate trials after EE for the extension movements (78% vs. 41% decline p<0.0001). Furthermore, although initially similar, the duration of the primary submovement was shorter (further from target) after EE for the movements in which the agonist was the exercised muscle compared with an antagonistic role (62% vs. 73% of total movement time, p<0.001). **CONCLUSIONS:** There is a greater effect of EE-induced muscle fatigue and damage on movement kinematics and accuracy when the muscle's functional role is agonistic.

Alterations In Spinal Excitability And Descending Drive Following Cross-education

Robert E. Hight, Alwyn T. Quarshie, Samuel R. Buchanan, Bree S. Baker, Debra A. Bemben, FACSM, Christopher D. Black, FACSM. *University of Oklahoma, Norman, OK.* (Sponsor: Christopher D. Black, FACSM)

(No relevant relationships reported)

For over a century, there has been considerable interest in the so-called cross-education phenomenon, whereby training one limb augments performance in the contralateral untrained limb. The underlying adaptation(s) in the nervous system have yet to be fully elucidated. **PURPOSE:** To investigate contralateral neural adaptations via evoked spinal and supraspinal reflexes, EMG amplitude (EMG_{rms}), and voluntary muscle activation (%ACT) following a 4-week unilateral isometric resistance training program. **METHODS:** Seven untrained men and women completed a unilateral resistance training program which consisted of 6 sets of 6 maximal voluntary isometric contractions (MVCs) across 4-weeks (16 sessions) using the dominant plantar flexor muscle group. Prior to and following training, a battery of tests were conducted in both limbs. Surface EMG was recorded from the soleus, medial gastrocnemius, lateral gastrocnemius, and tibialis anterior muscles while transcutaneous electrical stimulation was applied over the tibial nerve across a range of intensities to determine maximal H-reflex (H_{max}) and M-wave amplitudes (M_{max}). Participants then performed 3, 3-second MVCs. During each contraction, a single, 1-ms supramaximal stimulus (150% M_{max}) was applied 2.5 seconds into the contraction to evoke a V-wave and interpolated torque with control twitches occurring 2 and 4 seconds following relaxation. The V-M ratio and %ACT were measured simultaneously during each MVC. **RESULTS:** Peak torque increased 26 ± 20% (p < 0.01) and 31 ± 16% (p < 0.01) in the trained and untrained limbs, respectively. Following training, there was an increase in the soleus V-M ratio in the untrained (32 ± 21% vs. 38 ± 19%, p = 0.01), but not the trained limb (p > 0.05). %ACT was not altered post training in either limb—96.9 ± 3.9 vs. 95.5 ± 3.4 (p = 0.56) and 95.7 ± 3.7 vs. 92.9 ± 4.2 (p = 0.10) No differences were found in the MG, LG, or TA V-M ratio for either limb (p > 0.05). Additionally, there were no changes in H_{max}/M_{max} and EMG_{rms} from pre to post training in either limb (p > 0.05). **CONCLUSIONS:** Our findings indicate significant cross-education of the contralateral limb. It is likely that increases in supraspinal activity (i.e. descending drive), rather than changes in spinal excitability or voluntary activation, are responsible for the contralateral torque increase.

Acute Effects of Unilateral Static Stretching on Contralateral Limb Range of Motion and Isometric Strength

Xin Ye[1], Benjamin Killen[2], Krista Zelizney[3]. *[1]University of Mississippi, University, MS. [2]University of Mississippi Medical Center, Jackson, MS. [3]Florida International University, Miami, FL.*

(No relevant relationships reported)

Static stretching (SS) is an effective exercise technique often used in sports performance and rehabilitation fields to improve one's range or motion (ROM). However, its effects on non-intervened contralateral limb's performance remain equivocal.**PURPOSE:** To examine the acute effects of unilateral hamstrings SS on the contralateral hip flexion passive ROM and the strength performance. **METHODS:** Twenty-three healthy young adults (male: n = 13, mean ± SD age = 26 ± 3 years; height = 176.9 ± 6.6 cm; body weight = 84.2 ± 12.5 kg; female: n =10, mean ± SD age

Abstracts were prepared by the authors and printed as submitted.

= 27 ± 2 years; height = 164.1 ± 3.5 cm; body weight = 59.3 ± 11.4 kg) participated in a 2-visit investigation which consisted of a familiarization visit and an experimental visit. During the experimental visit, 10 sets of 30-second SS were performed with the subjects' dominant hamstring muscles. Before (Pre-) and after (Post-) the SS intervention, the contralateral hip flexion passive ROM, the isometric strength of the contralateral knee flexors, along with the surface electromyography (EMG) were measured. Separate paired sample t-tests were used to examine the potential changes in the dependent variables described above.
RESULTS: The SS significantly increased the contralateral hip flexion passive ROM (Pre = 64.70 ± 19.19º vs. Post = 73.48 ± 22.60º, $p < 0.001$). In addition, the isometric strength of the contralateral knee flexor significantly decreased (Pre = 326.63 ± 91.81 N vs. Post = 310.44 ± 92.08, $p = 0.004$). For both biceps femoris ($p = 0.065$) and semitendinosus ($p = 0.083$) muscles, there were decreasing trends toward significance for the normalized EMG amplitude.
CONCLUSIONS: Prolonged unilateral SS intervention improved the contralateral hip flexion passive ROM but decreased the strength performance. In addition to the possible increased stretch tolerance, the high intensity and duration static stretches might have also induced the crossover inhibition of the spinal motoneurons, thereby reducing the neuromuscular performance of the contralateral muscle.

Symmetry Loading After Knee Injury Appear Different During Leg Press And Squat Activities

Thomas W. Kernozek, FACSM[1], Becky Heinert[2], Drew Rutherford[1], Jeremie Schiedermayer[1], Douglas Baumann[1]. [1]University of Wisconsin-La Crosse, La Crosse, WI. [2]Gundersen Health System, La Crosse, WI.
(No relevant relationships reported)

Patients post ACL R or meniscal repair often display weight bearing asymmetry post surgically during movement performance. PURPOSE: To determine if real-time force feedback can be used to increase weight bearing symmetry post-surgery immediately and has delayed retention during a leg press and squat exercise. METHODS: Fourteen patients were tested using load sensors under each foot while exercising on a leg press machine and while performing weight bearing squats. These load sensors depicted the magnitude of force normal to the foot at 62.5 Hz. During the pre-test, data were collected as patients performed the leg press and squat exercises blinded to any feedback. During training, data were streamed in a bar graph to a display in front of the patient with therapist instructions to attempt to maintain equal weight on each leg. After the training, each patient performed a post-test with no feedback. One week later, they had a delayed retention. A two way repeated measures analysis of variance was used to examine mean weight bearing asymmetry for each exercise (leg press and squat) across time (pre-test, post-test, and delayed retention). RESULTS: There was a main effect for exercise (p<0.05), no main effects for time (p>0.05) and there was an exercise by time interaction (p<0.05). Overall, during the leg press there was more weight bearing asymmetry compared to the squat (30% greater). The interaction showed that the leg press had nearly 9% improvement over the time compared to pre-test while the squat showed symmetry improvement of 19% post-test but delayed retention was poor. CONCLUSION: Weight bearing asymmetry appears different for different tasks (leg press vs. squats). It appears the feedback can produce immediate changes in symmetry but retention appears different for different tasks.

Is Aiming a Handgun Like Pointing a Finger?

Kyle J. Kelleran[1], Steven Morrison[2], David P. Swain, FACSM[2], Daniel M. Russell[2]. [1]Bridgewater College, Bridgewater, VA. [2]Old Dominion University, Norfolk, VA. (Sponsor: David Swain, FACSM)
(No relevant relationships reported)

PURPOSE: In aiming at a target, humans produce small involuntary fluctuations in the aiming limb that may hamper performance. While often studied in the vertical axis, these fluctuations occur in all axes. The current study compared vertical (VT), mediolateral (ML), and anterior-posterior (AP) tremor amplitude during finger pointing and handgun aiming. **METHODS:** Twenty volunteers, in a counterbalanced order, pointed their finger or aimed a training handgun for 10 seconds at a bullseye target 6.4 meters away. Participants performed five trials per condition. Accelerometers were affixed to the upper arm (UA), forearm (FA), hand (HA), and finger/gun barrel (GF). Amplitude (RMS) and regularity (ApEn) of the acceleration signals were computed. **RESULTS:** Compared to finger pointing (RMS: 0.238±0.146, APEN: 1.373±0.138), accelerations at the distal segment were significantly lower and more regular during the handgun aiming condition (RMS: 0.202±0.111, APEN: 1.112±0.146). Significant interactions were present between condition (pointing, aiming) and limb segment in each direction. The amplitude of tremor in the UA and FA segments were similar for pointing and aiming in all three directions (p's>0.05). Handgun aiming resulted in smaller amplitude tremor at the GF in both VT and ML directions and HA in the ML direction, but larger amplitude at the HA in the AP direction (p's<0.05). Aiming

increased regularity (decreased ApEn) at the GF in VT direction, both FA and GF in ML direction, and at the UA and HA in AP direction (p's<0.05). Pointing was more regular than aiming only for the HA in the VT direction (p<0.05). For all other directions and segments RMS and ApEn were similar between pointing and aiming (p's>0.05). **CONCLUSION:** Aiming with the mass of a gun in the hand has primarily a damping effect on the amplitude of tremor in the distal segments as well as resulting in more regular movements. Greater regularity in the VT axis of the HA during pointing suggests increased control of VT across the wrist in this task. Overall, these results suggest that aiming with a gun and pointing with a finger are similar tasks except for the added mass.

Motor Cortex Function in Symptomatic and Asymptomatic Individuals Following Mild Traumatic Brain Injury

Alia L. Yasen, Eli K. Edwards, Geeta Eick, Kirstin Sterner, Anita D. Christie. *University of Oregon, Eugene, OR.* (Sponsor: David Gabriel, FACSM)
(No relevant relationships reported)

While most individuals who suffer a mild traumatic brain injury (mTBI) recover within 1-2 weeks, approximately 10-15% have symptoms persisting beyond 3 months. The underlying physiology of this difference in symptom recovery remains unknown. **PURPOSE:** The aim of this study was to determine if measures of motor cortex excitability, inhibition, and associated neurotransmitters differ between individuals with and without history of mTBI or chronic symptoms from mTBI. A secondary aim of this study was to investigate the occurrence of the APOE4 allele, a suggested predictor of mTBI outcome, in each group. **METHODS:** Thirty five participants were assigned to one of four groups: (i) without history of mTBI (Control, n=10), (ii) within 72-hours of diagnosis of mTBI (Acute, n=9), (iii) with history of mTBI and no remaining symptoms (Chronic Control, n=10), and (iv) with chronic symptoms from mTBI, lasting at least 3 months post-injury (Chronic, n=6). Measures of glutamate and GABA concentrations in the primary motor cortex were obtained using proton magnetic resonance spectroscopy (^{1}H-MRS). Transcranial magnetic stimulation (TMS) was used to assess corticomotor excitability with the amplitude of the motor evoked potential (MEP_{amp}), and intracortical inhibition through the duration of the cortical silent period (CSP). **RESULTS:** Glutamate (p=0.88) and GABA (p=0.11) concentrations in M1 did not differ across groups. MEP_{amp} and CSP duration did not differ across groups (p= 0.07 and p=0.15, respectively). Four of the 21 participants who provided a sample for APOE genotyping were carriers of the E4 allele (2 Controls and 2 Chronic Controls), while 17 were not (7 Control, 7 Acute, 7 Chronic Control, 1 Chronic). **CONCLUSION:** The lack of differences in glutamate, GABA, and corticomotor excitability and inhibition across groups suggests that motor cortex function may not explain the physiology underlying difference in symptom recovery post-mTBI. Further data are required to fully understand the role of APOE4 in recovery from mTBI.

Physical Functionality In Mexican Elderly With Gerontological Care

Karla S. Vera-Delgado, Sergio Márquez-Gamiño, Francisco J. Alcantar-Aranda, Fernando Sotelo-Barroso, Cipriana Caudillo-Cisneros. *Universidad de Guanajuato, León, Mexico.*
(No relevant relationships reported)

It has been reported that Mexico has 1,137,647 of elder people, out of approximately 120 million inhabitants. Of them 26.3% have limitation in their activities. Older adults have the greatest risk of falls, because of the physical functionality (PF) reduction, both associate with sarcopenia. PF is defined as the capacity of the person for daily life and instrumental activities. To our knowledge no studies on PF have been done in Mexican Elderly. **Purpose:** to evaluate physical functionality in older Mexican adults. **Methods:** this study was performed in a first served basis including older Mexican individuals affiliated to a public gerontological system of attention. Anthropometric evaluations were carried out, including weight, height, abdominal and hip circumferences. Additionally, electric bioimpedance was used to determine muscular and bone mass. Physical functionality was assessed through the Short Physical Performance Battery Protocol and Score Sheet (SPPB) test. The data were analyzed by descriptive statistics. Results are reported as mean ± SD. **Results:** 186 older people (60 years and over) were evaluated, 154 women and 32 men. The average age was 69.76 ± 6.31 years for females, and 71.31 ± 7.21 years for males. Women mean weight (in kg) was 66.25 ± 11.36; height (in m) 1.51 ± 0.05. By the other side, men weighted 71.63 ± 12.59 Kg, and 1.65 ± 0.07 m. The march speed (m/s) was 0.83 ± 0.23 for woman and 0.97 ± 0.18 for men. In the timed up and go test females got 9.43 ± 3.23 s while men 7.90 ± 3.26 s. Repeated chair stand reported in the same order 16.61 ± 5.92 s vs. 14.54 ± 3.85 s. The speed of march is reduced in 78.50% of women, as in 51.72% of men. The dynamic equilibrium test revealed 56.26% of men, and only 51.07%

women in normal values. **Conclusion:** older Mexican adults, with gerontological care exhibits reduced Physical Functionality, with similar levels to data reported from other populations.

Relationship Between Muscle Activity And Isometric Force During Submersion In Shallow Water.

John Mercer, FACSM, Bryan Avendano, Andy Do, Leland Barker. *University of Nevada, Las Vegas, Las Vegas, NV.*

(No relevant relationships reported)

Shallow and deep water running are used by athletes as either substitute or in addition to running on land. However, it is not clear if the relationship between the ability to generate force and electromyography (EMG) is influenced by water submersion. **PURPOSE**: Compare isometric force-EMG relationship during on land and submersion in shallow water. **METHODS**: Participants (n=4; 29.7±20.2 yrs, 1.80±0.1 m, 82.2±24.3 kg) were fit with leads to measure rectus femoris (RF) EMG using a telemetry EMG system (Noraxon, 1000 Hz) while wearing a drysuit. Participants sat in a chair with the ankle secured in a cuff and knee angle at 90 degrees of flexion. One end of the cable was attached to the cuff and the other to a linear force transducer which was always above water level. The transducer measured the tension force created with the cable that resisted knee extension. The chair was portable and was used on the deck of a pool and in shallow water. Force data were recorded concurrent with EMG data. Participants completed four 5-sec isometric knee extension conditions ranging from submaximal to maximal effort. The maximal effort condition was always done first with submaximal efforts targeting 25%, 50%, and 75% of maximal effort with real time verbal feedback provided. Participants always completed these conditions on land first then in water submerged to about the xiphoid process while sitting. Rest was provided as needed between conditions. EMG data were processed by removing any offset and full-wave rectifying. Force and EMG data were each averaged over the last 1-sec. Force-EMG plots were generated for each participant for on land and in water data sets and fit with linear lines of best fit. The y-intercepts and slopes were recorded and each compared between on land and in water using paired t-tests (α=0.05). A group line of best fit was also calculated for descriptive purposes. **RESULTS**: The group linear line of best fit for Force-EMG during Land was EMG=2.3005(Force) + 4.9007 (R^2 = 0.9819) and during water was EMG=2.1759(Force) - 4.7535 (R^2=0.9874). Using individual data sets, neither the slope (p=0.133) nor y-intercept (p=0.131) were different between on land and in water. **CONCLUSIONS**: The relationship between knee extension force and EMG was the same while on land and in the water.

Muscle Activation and Motor Unit Behavior in the First Dorsal Interosseous of Children and Adults

Jonathan D. Miller, Adam J. Sterczala, Mandy E. Wray, Hannah L. Dimmick, Michael A. Trevino, Trent J. Herda. *University of Kansas, Lawrence, KS.*

(No relevant relationships reported)

PURPOSE: To examine motor unit (MU) behavior in the first dorsal interosseous (FDI) in children (CH) and adults (AD) during submaximal contractions. **METHODS:** Nineteen CH (11 male age=9.0±0.8 years, 8 female age=9.0±0.9 years) and 13 AD (6 males age=21.0±2.53 years, 7 females age=24.6±5.9 years) completed three maximum voluntary contractions (MVC) and 2 repetitive isometric contractions at a force of 30% MVC that was held for 40 s with 6-10 s rest between contractions. Surface EMG amplitude values from the 30% MVCs were normalized (N-EMG) to peak EMG amplitude from the MVC. For each MU, recruitment thresholds (RT) and mean firing rates (MFR) were recorded. MFRs and N-EMG were averaged in 10 s epochs at beginning (T1), middle (T2), and end (T3) of repetition 1 and repetition 2 (T4, T5, and T6). For each subject, MFR vs. RT relationships were calculated for each epoch. Two-way mixed factorial ANOVAs (group [CH vs. AD] × time [T1 vs. T2 vs. T3 vs. T4 vs. T5 vs. T6]) were used to analyze N-EMG and the slopes and y-intercepts from the MFR vs. RT relationships. **RESULTS:** N-EMG was greater for CH than AD when collapsed across time (P=0.006). The MFR vs. RT relationships changed in a time-dependent manner such that the y-intercepts decreased (P=0.044), however, there was no change in the slopes (P=0.072). No between group differences for slopes (P=0.360) or y-intercepts (P=0.063) suggested that MFR vs. RT relationships were similar between groups. **CONCLUSIONS:** CH required twice the level of muscle activation in comparison to the AD to complete the task. However, the MFR vs. RT relationships were similar between groups and changed in a time dependent manner.

Table 1. Mean±SDs for each ANOVA. *Indicates a main effect for group. †Indicates a main effect for time.

Time point		T1	T2	T3	T4	T5	T6
N-EMG (%MVC)*	CH	59.6± 33.7	57.9± 35.6	60.3± 38.7	61.5± 33.3	58.7± 30.3	62.1± 34.8
	AD	26.6± 5.9	26.4± 5.9	27.0± 5.6	29.3± 5.5	27.4± 5.6	28.1± 4.6

An Evaluation Of The Foot Tapping Test (ftt) In A Health Population

Brian A. Pribble, Daniel J. Larson, Christopher D. Black, Daniel J. Blackwood, Jacob Rookard, Rebecca D. Larson. *University of Oklahoma, Norman, OK.*

(No relevant relationships reported)

Simple in nature, the foot tapping test (FTT) has potential as an objective measure of upper motor function. Despite this, the reliability of the FTT has not been well identified. Furthermore, it is uncertain as to how to best measure the FTT as number of foot taps may vary upon counting methods. In order to make the FTT more clinically relevant, more research must be done on the FTT in healthy individuals in order to determine if it is a reliable measure of foot tapping ability. **PURPOSE:** The purpose of the study was to investigate reliability measures of the FTT in a healthy population using a variety of different measurement and counting methods. By identifying the reliability of the different measurement methods we hope to be able to make recommendations for future FTT research. **METHODS:** 20 healthy individuals, ages of 18-31, completed a series of foot tapping trials over 4 visits. While seated, subjects tapped their foot repeatedly for 10 seconds while researchers counted the number of foot taps. Starting foot was randomized for each visit and tested twice with shoes ON and twice with shoes OFF (8 trials * 4 visits = 32 trials per subject). The number of foot taps was determined for each trial via visual inspection, video playback (slowed and normal speed), and with the use of a force plate. The mean values of the FTT trials were compared across days, dominant vs. non-dominant foot, the shoes ON/OFF conditions, and with the different counting methods. **RESULTS:** Significant differences were found in foot tapping rates in the shoes ON (mean: 54.3 taps) vs shoes OFF (mean: 53.4 taps) and dominate vs. non-dominant (mean: 51.1 taps) foot analyses (p<0.05). Furthermore it was found that a significant difference in the mean number of foot taps existed between visit 1 (mean: 51.2 taps) and visits 2, 3, and 4 (mean: 54.3, 53.5, and 46.7 taps respectively) (p>0.05). It was found that the FTT exhibited high test-retest reliability (Pearson r >0.80) and high Cronbach's alpha (alpha >0.80) across the live, slowed video counts, and force plate measurements. **CONCLUSION:** It was found that the FTT exhibits a high level of reliability across the live, slowed video, and force plate measures with both the shoes ON and shoes OFF. Given the observed reliability, the use of force plate with the FTT offers an attractive alternative to live counting or video playback methods.

Association Between Motor Control Activation And Excitability Of The Quadriceps: An fMRI And TMS Study

Adam S. Lepley[1], Lindsey K. Lepley[1], Julie P. Burland[1], Steven M. Davi[1], Dustin R. Grooms[2]. *[1]University of Connecticut, Storrs, CT. [2]Ohio University, Athens, OH.*

(No relevant relationships reported)

Various neurophysiological assessments indicate that musculoskeletal injury causes alterations in nervous system function. Functional magnetic resonance imaging (fMRI) and transcranial magnetic stimulation (TMS) have been used as non-invasive assessments of motor cortex activation and excitability, respectively. Each of these tools provide unique insight on neurophysiology and it is unknown how musculoskeletal injury may influence the relationship between nervous system activity and excitability. **Purpose:** Investigate relationships between motor cortex activation (fMRI) and motor cortex excitability (TMS) of the quadriceps muscle. **Methods:** Twenty participants volunteered; 10 healthy controls (age, 23.2±1.61y; height 167.92±9.46cm; mass 66.27±11.7kg) and 10 with a history of unilateral anterior cruciate ligament reconstruction (ACLR; age 22.4±1.95y; height 166.37±7.11cm;

---

mass 65.62±12.10kg; yrs from surgery, 5.88±1.86). Motor cortex activation ($M1_{act}$) was assessed during unilateral knee extension-flexion using a 3T Siemens MRI and the peak voxel signal intensity was extracted for analysis. Motor cortex excitability was assessed during active contractions using motor evoked potentials (MEP) elicited at 120% of active motor threshold via TMS. Outcomes were assessed on the left limb of all participants. Pearson product moment correlations were performed to determine the association between $M1_{act}$ and MEP on the entire cohort, and individually for the healthy and ACLR groups. Alpha level was set at p ≤ 0.05. **Results:** For the entire cohort, $M1_{act}$ was significantly associated with MEP (r = 0.459, p = 0.04). For healthy controls, $M1_{act}$ was significantly associated with MEP (r = 0.707, p = 0.02). There were no significant relationships among the ACLR group (p > 0.05). **Conclusions:** Greater brain activation is associated with greater brain excitability in healthy controls, however no significant relationships were found for ACLR participants. For healthy individuals, cortical activity and excitability increase concurrently to engage the quadriceps during contraction. However, our ACLR data indicate that alterations in neural pathways following joint injury may influence the interaction between brain activation and excitability, providing an area for future investigation.

A History Of Sports-Related Concussions Does Not Influence Oculomotor Control

Kristen Neitz[1], Brian Szekely[1], Sydni Wilhoite[1], Peter Chrysosferidis[1], Barry A. Munkasey[1], Nicholas G. Murray[1], Doug W. Powell[2]. [1]*Georgia Southern University, Statesboro, GA.* [2]*University of Memphis, Memphis, TN.*
(No relevant relationships reported)

Recent research indicates that among those who have a history of multiple sport-related concussions (SRC) may have greater postural instability when compared to those that do not have a history of prior SRC. However, little is known regarding the effect on those who experienced multiple SRC on the visual system, specifically oculomotor control. **Purpose**: To investigate the effect that a prior history of SRC has on oculomotor control within 24-48 hours following SRC. **Methods**: Twenty-seven (13 female and 14 male; 20 ± 2 yrs) collegiate NCAA Division I athletes with SRC completed two trials of the sport-like antisaccade task (SLT) within 24-48 hours post-injury. Participants were sorted into three equal groups: no history SRC (NON), a history of one SRC (C1) and a history of two or more SRC (C2). During play of the SLT, all participants were instructed to minimize eye movements away from a central fixed area, while simultaneously swaying in a medial-lateral direction to direct an on screen avatar to meet the demands of the task. Raw ocular point of gaze coordinates were tracked using a monocular eye tracker (240Hz, Argus Science, H7, Medford, MA) that was synced with an 8 camera motion capture system (100Hz, Vicon Motion Ltd., Version 1.8.5, Oxford, USA) during the sport-like antisaccade task and further analyzed using a custom algorithm. A multivariate ANOVA analyzed resultant distance (RD), mean horizontal excursion velocity (HV) and prosaccade errors (PE) by groups (NON, C1, and C2). Mean and standard deviation values for RD, HV and PE were calculate for analysis. **Results**: No significant omnibus results were noted between the groups for RD (NON=5.780 pixels ± 1.527), (C1=4.953 pixels ±2.168), (C2=4.665 pixels ±1.305); p=0.370), HV (NON 9.912 pixels/second ±4.484), (C1= 7.250pixels/second ±2.458), (C2=8.05pixels/second ±2.363); (p=0.225), and PE (NON=3.370±3.924), (C1=1.629±1.635), (C2=2.167±2.324); (p=0.414). **Conclusion**: These data suggests that oculomotor control as measured by the SLT may not be sensitive to differentiated between those that have a prior history of SRC and those that do not have a prior history of SRC.

Influence of Sex and Cross-Sectional Area on Motor Unit Recruitment Patterns of the Vastus Lateralis

Michael A. Trevino[1], Trent Herda[2], Jonathan Miller[2], Adam Sterczala[2], Hannah Dimmick[2]. [1]*Georgia Southern University, Armstrong Campus, Savannah, GA.* [2]*University of Kansas, Lawrence, KS.*
(No relevant relationships reported)

PURPOSE: Strong relationships have been reported between the increases in muscle cross-sectional area (mCSA) and motor unit action potential sizes ($MUAP_{SIZES}$) for the vastus lateralis (VL). To date, it is unknown if sex-related differences in muscle cross-sectional area are correlated with the slopes and y-intercepts for the $MUAP_{SIZE}$ vs. recruitment threshold (RT) relationships.
METHODS: Ten males (21.10±1.97 yrs) and ten females (23.70±6.27 yrs) with no participation in any form of structured exercise for the previous 3 years volunteered for this investigation. Ultrasonography was used to examine mCSA, muscle echo intensity (mEI), and subcutaneous fat (sFAT) for the VL. Surface electromyographic decomposition techniques were applied to assess $MUAP_{SIZE}$ in relation to RT of the VL during isometric muscle actions at 40% and 70% of maximal voluntary contraction (MVC). Linear regressions were performed for each subject for the 40% and 70% MVC to determine the y-intercepts (millivolts [mV]) and slopes (mV/%MVC) for

the $MUAP_{SIZES}$ vs. RT relationships. Separate two-way mixed factorial ANOVAs (sex [male vs. female] x intensity [40% vs. 70%]) were used to examine possible differences in the y-intercepts and slopes from the $MUAP_{SIZE}$ vs. RT relationships. In addition, independent samples *t*-tests were used to examine differences in mCSA, mEI, and sFAT between sexes. Furthermore, Pearson's product moment correlation coefficients were calculated comparing mCSA, sFAT, mEI of the VL with the slopes and y-intercepts from the 40% and 70% MVCs.**RESULTS**: The males had greater mCSA (P = 0.002) and slopes for the $MUAP_{SIZE}$ vs. RT relationships (P = 0.001), whereas the females had greater sFAT (P = 0.003) and mEI (P = 0.001) for the VL. In addition, all relationships between ultrasound parameters and the slopes for the 40% and 70% MUAP size vs. RT were significant (P < 0.001 - 0.020), with the greatest amount of variance explained by mEI (*r* = -0.657 to -0.687).
CONCLUSIONS: The slopes for the $MUAP_{SIZE}$ vs. RT relationships are dependent on the physical properties of the muscle as measured by ultrasound. In addition, the sex-related differences in mCSA, mEI, and $MUAP_{SIZE}$ in relation to RT suggests greater muscle fiber sizes of the higher-threshold MUs for the males.

Simple Low-Cost Virtual Reality to Improve the Responsiveness of Clinical Balance Assessment

Janet E. Simon, Matt Rausch, Chad Starkey, Dustin Grooms. *Ohio University, Athens, OH.*
(No relevant relationships reported)

Concussions commonly affect postural stability, which incorporates the visual, vestibular, and somatosensory system. Postural stability post-concussion is commonly quantified via the Balance Error Scoring System (BESS). However, the BESS may not sufficiently challenge postural stability in an athletic population allowing potential deficits to go unquantified. Virtual reality (VR) devices may be capable of providing an increased visual-vestibular integration challenge to improve BESS responsiveness.
PURPOSE: Determine if a low cost and clinically applicable VR modification to the standard BESS can provide a superior challenge to postural stability than the traditional BESS.
METHODS: Twenty-eight adults (mean age 23.36 ± 2.38 years, mean height 1.74 m ± 0.13, mean weight 77.95 kg ± 16.63) were recruited. All individuals performed the standard BESS test and a VR modified BESS (VR-BESS) on a force plate. All participants completed a familiarization session to practice the traditional BESS and VR-BESS. Participants then performed two trials of the traditional BESS or VR-BESS in a counter-balanced randomized order. The VR-BESS used a headset (Google Cardboard) and phone (LG V10) to display a rollercoaster ride (FIBRUM) to induce a visual and vestibular challenge to postural stability. BESS postural control errors and center of pressure (CoP) velocity were averaged for the two trials and used for analyses. Separate repeated measures ANOVAs were conducted for the BESS errors and CoP velocity. Post hoc testing was conducted for the condition by stance by surface interaction with an alpha level set at p<0.05 with a Bonferroni correction for multiple comparison analyses.
RESULTS: The overall repeated measures ANOVA was significant for BESS errors ($F_{(2,26)}$= 6.37, p=.003) and CoP velocity ($F_{(2,26)}$= 5.19, p=.008).The VR-BESS significantly increased total errors (20.93 vs. 11.42, p<0.05) and CoP velocity summed across all stances and surfaces (52.96 cm/s vs. 37.73 cm/s, p<0.05) beyond the traditional BESS.
CONCLUSION: VR-BESS provides a standardized, efficient, and effective way to challenge postural stability to a greater extent than the traditional BESS. With technology quickly advancing and becoming less expensive, this modification may be immediately incorporated into balance training and assessment.

2310   Board #146   June 1 11:00 AM - 12:30 PM

Movement Variability and Accuracy Within the Temporal and Spatial Domains When Provided a Vibrotactile Stimulus

Matthew E. Holman, Benjamin J. Darter. *Virginia Commonwealth University, Richmond, VA.*
(No relevant relationships reported)

Different means of informing body movements can include visual, auditory, and vibrotactile (VT) stimuli. Each method may guide movements within the temporal (TEMP) and spatial (SPAT) domains in varying ways. As VT stimuli has become more accessible, it is important to understand how users interpret this method of instruction to promote patterned movements. **PURPOSE**: Determine the effects of VT stimulus pattern speed on TEMP and SPAT movement variability (VAR) and accuracy (ACC).
METHODS: Sixteen young healthy subjects were recruited. Participants completed a continuous wrist flexion and extension activity. The task involved matching wrist motion with two different VT pattern speeds (FAST, SLOW) provided via motors attached to the forearm. An electrogoniometer captured wrist movement. Five 20s trials with 2min rest periods were completed for the two speeds. Flexion/extension movements were combined for further analysis. Absolute (*STDEV*) and relative (*CV*) VAR, and ACC (mean absolute error) for TEMP and SPAT domains were calculated

within individuals. 5x2 linear mixed models accounting for repeated measures compared the variables across pattern speeds and trial numbers. Post-hoc Tukey HSDs identified differences for trial effects. **RESULTS**: No significant interactions were found in either domain. Significant pattern speed effects were observed in the TEMP domain for VAR (*STDEV*: FAST 0.07s, SLOW 0.13s, p < .05; *CV*: FAST 12.9%, SLOW 16.8%, p < .05), and ACC (FAST 0.05s, SLOW 0.10s, p < .05). VAR in the both domains and TEMP ACC changed significantly over the 5 trials (*all*, p < .05; ACC SPAT, p > .05). Post-hoc tests revealed trial 1 to be different from all subsequent trials for TEMP and SPAT VAR (*STDEV* TEMP: #1: 0.15s, #5: 0.08s, p < .05; *STDEV* SPAT: #1: 7.7deg, #5: 4.7deg, p < .05; *CV* TEMP: #1: 20.8%, #5: 13.2%, p < .05; *CV* SPAT: #1: 11.9%, #5: 5.9%, p < .05), and ACC TEMP (#1: 0.11s, #5: 0.07s, p < .05). **CONCLUSIONS**: VT stimulus appears capable of producing a desired continuous wrist movement at multiple pattern speeds. TEMP VAR was lower and TEMP ACC was higher for the FAST speed, while SPAT measures did not differ between speeds. Lower TEMP and SPAT VAR, and higher TEMP ACC were observed by trial 2, with improved performance maintained in the remaining trials. A lack of change in SPAT ACC may reflect limited SPAT guidance provided to subjects.

2311   Board #147   June 1 11:00 AM - 12:30 PM

The Effects of Resistance Training on Motor Unit Firing Rates and Muscle Activation

Adam J. Sterczala[1], Jonathan D. Miller[1], Mandy E. Wray[1], Hannah L. Dimmick[1], Michael A. Trevino[2], Trent J. Herda[1]. [1]*University of Kansas, Lawrence, KS.* [2]*Armstrong State University, Savannah, GA.*
(No relevant relationships reported)

PURPOSE: To examine the effects of lower body resistance training on motor unit (MU) firing rates and recruitment in the vastus lateralis.
METHODS: Seventeen recreationally active men (20.7 ± 1.9 years; 178.9 ± 7.8 cm; 76.8 ± 9.9 kg) completed three lower body resistance-training sessions per week for eight weeks. Exercise intensities and volumes were programmed according to a linear periodization model. Pre- and post-training, MU behavior of the VL was analyzed during isometric knee extensions performed at 40% maximal voluntary contraction (MVC) torque. Electromyographic (EMG) signals were collected via a 5-pin surface sensor array and decomposed to yield a mean firing rate (MFR) at steady torque and MU action potential amplitude ($MUAP_{AMP}$) for each MU. For each contraction, an exponential model was applied to the MFRs and $MUAP_{AMP}$s and the B and A terms were calculated. EMG amplitude (EMG_{RMS}) recorded during the steady torque region of the submaximal contractions was normalized to the peak EMG_{RMS} of the respective visit's MVC. Possible differences in the A and B terms of the MFR vs. $MUAP_{AMP}$ relationship and normalized EMG_{RMS} were analyzed via paired samples t-tests.
RESULTS: Post-training, subjects demonstrated similar B terms (p = 0.278; PRE: -4.06 ± 0.51 pps/mV; POST: -4.41 ± 1.36 pps/mV), which indicated a similar decline in MFR with increases in $MUAP_{AMP}$. However, there was an observed increase in the A terms (p = 0.005; PRE: 24.93 ± 2.79 mV; POST: 27.80 ± 4.57 mV) indicating an increase in MFRs for a given $MUAP_{AMP}$ post-training. Additionally, subjects demonstrated reduced normalized EMG_{RMS} post-training (p = 0.029; PRE: 37.9 ± 8.0% ; POST: 33.6 ± 8.7%) suggesting reduced muscle activation.
CONCLUSIONS: $MUAP_{AMP}$ is an indirect measure of MU size, thus the larger A terms suggest that similarly sized MUs had greater firing rates post-training. EMG_{RMS} is influenced by MU firing rates and recruitment, therefore, the decrease in normalized EMG_{RMS} despite increases in firing rates suggest decreased MU recruitment. Thus, resistance-training induced firing rate increases allowed subjects to produce the same relative torque with fewer active MUs. Given that later recruited MUs are more fatigable, the reduced MU recruitment could delay fatigue during submaximal contractions.

Reproducibility Of Isokinetic Strength Assessment Of Knee Extensors And Flexors Adopting Concentric And Eccentric Contractions

João Pedro Duarte[1], João Valente-dos-Santos[1], Daniela Costa[1], Paulo Sousa-e-Silva[1], Diogo Martinho[1], Edilson Cyrino[2], André Seabra[3], Rui Soles-Gonçalves[4], Manuel Coelho-e-Silva[1]. [1]*University of Coimbra, Coimbra, Portugal.* [2]*Londrina State University, Paraná, Brazil.* [3]*University of Porto, Porto, Portugal.* [4]*Polytechnic Institute of Coimbra, Coimbra, Portugal.*
(No relevant relationships reported)

PURPOSE: The reproducibility of isokinetic strength assessment for testing knee extensors (KE) and knee flexors (KF) was determined. The examination was performed on single measurements (peak torques) and also on conventional and functional ratios obtained from concentric (cc) and eccentric (ecc) contractions of the above mentioned muscle groups.
METHODS: The sample was composed of 26 male adult athletes (aged 18.6-33.9 years) who completed two test sessions of five repetitions of reciprocal concentric and

eccentric extensions and flexions at 60°.s^{-1}. Intra-individual differences were tested using paired *t*-test and effect size was determined using cohen's d-value. Cefficients of variation (%CV) and Intra-class correlation (ICC) were also calculated.
RESULTS: Regarding peak torques, intra-individual mean differences were trivial for KEecc (t=0.176, p=0.86, d=0.08), small for KEcc (t=2.001, p=0.06, d=0.53) and KFecc (t=0.797, p=0.43, d=0.35) and moderate for KFcc (t=2.062, p=0.05, d=0.65). Although values of ICC (between 0.961 to 0.993), technical errors of measurement (TEM) ranged from 5.2 to 8.1 N.m and %CV fluctuated between 18.6% and 23.8%. Similar statistics were determined for conventional ratio (KFcc/KEcc: t=1.026, p=0.32, d=0.01, TEM=0.1, %CV=13.1%, ICC=0.956), functional extension ratio (KFecc/KEcc: t=1.911, p=0.07, d=0.01, TEM=0.1, %CV=14.9%, ICC=0.950 and functional flexion ratio (KFcc/KEecc: t=2.006, p=0.06, d=0.01, TEM=0.1, %CV=16.3%, ICC=0.977).
CONCLUSIONS: The current study showed an apparent reasonable reliability for the isokinetic peak torques of knee extensors and knee flexors. Derived ratios showed higher values for %CV. Note, however, that the composite scores were obtained from information of the extensors and flexors at different angles and future research is recommended to assess the reproducibility of functional ratios using the torque of the numerator (knee flexor) at the specific angle of the knee extensor peak torque angle (denominator). Funding (FCT): SFRH/BD/101083/2014, SFRH/BPD/100470/2014, SFRH/BD/121441/2016 and CIDAF (UID/DTP/04213/2016).

E-34   Free Communication/Poster - **Posture and Balance**

Integration of a Complex Balance Task into a Concussion Management Protocol Specific to Dancers

Caroline J. Ketcham, Corinne M. Kenny, Lauren W. Kearns, Eric E. Hall, 27244, FACSM. *Elon University, Elon, NC.* (Sponsor: Eric E. Hall, FACSM)
(No relevant relationships reported)

Mechanisms for concussions in dance include drops from lifting, falls from stage sets, and contact with the floor or fellow dancers that happen during class, rehearsal, or performances. Despite the recent awareness of sports-related concussions, there are gaps in knowledge regarding dance-specific concussions and what a "return to dance" protocol should look like for dancers. Although dance is not a high-impact sport like football or rugby, concussions still occur and can be calamitous for a collegiate and professional dancer's career. Balance tests, standard in concussion management protocols, are useful tools for evaluating the motor domain of balance functioning and are considered reliable and valid assessments of athletes suffering from concussions. **PURPOSE:** Develop and investigate a complex balance task to integrate into a concussion management protocol specific to dancers. **METHODS:** 31 participants, pre-professional dancers (n=12) and recreational dancers (n=19), completed an multipart evaluation to assess static and dynamic balance. They were tested using the Balance Error Scoring System (BESS) test which assessed static balance through performing 3 stances on 2 surfaces (ground and Airex Balance Pad). The modified Dance BESS (DBESS) test assessed static and dynamic balance of the participants through performing 10 dance movements on 3 surfaces (ground, Airex Balance Pad and foam balance beam). Participants were monitored and scored for errors on each balance test. **RESULTS:** Pre-professional dancers and recreational dancers were not significantly different for static balance on the BESS and DBESS (p>0.05). There was significant difference between the pre-professional dancers and recreational dancers (p<0.05) for the dynamic balance conditions in the Dance BESS. **CONCLUSIONS:** More skilled dancers show greater differences with dynamic balance conditions. Thus, creation of more dynamic balance tasks would be useful for baseline and post concussion testing and aid in the overall tracking during the concussion rehabilitation period for dancers.

Effects of Backpack Load and Load Height on Arm Reaching Ability in Several Directions

Patrick O'Malley, Matthew D. Beekley, FACSM. *DePauw University, Greencastle, IN.*
(No relevant relationships reported)

PURPOSE: The ability to reach with the arm has not been examined during load carriage with a backpack, or with the load distributed high or low in the backpack.
METHODS: Arm reach was tested using the Functional Reach Test (Forward), Multi-directional Reach Test (Backward, Right, Left), Upward Reach Test (Upward) at a 50° angle, and Forward Reach to the Floor Test (Low). Subjects were healthy males (n=7)

and females (n=2), 19-21 years, who wore a hiking backpack and performed using the dominant arm. Subjects were tested with no backpack, and then (in random order on different days) with the backpack empty, or load (weight) equivalent to 10, 30, and 50% of bodyweight in the bottom of the backpack. Trials were repeated with the load high in the backpack using a custom designed box. Three trials were completed for each reach. Mean values were analyzed with repeated measures ANOVA and Tukey's post-hoc test with significance level p < 0.05.
RESULTS: (Data are presented as reach in cm normalized for arm length, mean ± SD). When compared to no backpack, load high (30, 50% BW) in the backpack resulted in significant reductions in arm reach (all directions; Low = 140.5±13.8 vs 124.3±6.7, 115.5±7.7; Upward = 165.1±10.7 vs 159.9±9.3, 155.3±12.9; Left = 196.2±8.5 vs 181.6±7.3, 173.4±4.5; Right = 194.0±8.9 vs 181.7±8.0, 175.5±8.4; Backward = 180.2±9.1 vs 160.9±5.7, 153.5±7.9; Forward = 218.2±10.8 vs 208.9±8.1, 200.9±10.1) and load low (all loads) in the backpack resulted in significant reductions in arm reach for backward reach only (180.2±9.1 vs 176.8±8.1, 169.5±9.5, 164.5±1.3). When compared to empty backpack, load high (30, 50% BW) in the backpack resulted in significant reductions in arm reach (all directions; Low = 137.1±1.1 vs 124.3±6.7, 115.5±7.7; Up = 163.9±10.6 vs 159.9±9.3, 155.3±12.9; Left = 194.3±8.6 vs 181.6±7.3, 173.4±4.5; Right = 194.7±8.7 vs 181.7±8.0, 175.5±8.4; Backward = 177.9±7.4 vs 160.9±5.7, 153.5±7.9; Forward = 215.1±11.3 vs 208.9±8.1, 200.9±10.1) and load low (50% BW) in the backpack resulted in significant reductions in backward reach only (177.9±7.4 vs 164.5±1.3).
CONCLUSIONS: Backpack load weight and height differentially affects arm reach. This project was funded in part by the Douglas A. & Phyllis G. Smith Student Faculty Collaborative Research Fund.

Muscle-specific Cortical Adaptations To Balance Training With Electromyographic Biofeedback In Able-bodied Individuals

Alan R. Needle, Rachel A. Sledge, J. Horton Doughton, Mark C. Zrull. *Appalachian State University, Boone, NC.*
(No relevant relationships reported)

The use of electromyography biofeedback (EMG-BF) is frequently incorporated among patients with neurological and musculoskeletal injury to restore neuromuscular function and improve real-time awareness of muscle function. Its effects on central nervous system function are not well documented in lower leg models, leaving its efficacy in certain populations unclear. **PURPOSE**: This study aimed to measure reflexive and cortical excitability before and after a balance training intervention with and without EMG-BF. **METHODS**: Nineteen healthy participants volunteered for this study (183.0±20.1cm; 69.0±13.1kg; 21.1±2.3yrs). Reflexive excitability was assessed using the Hoffmann reflex from the tibialis anterior (TA), peroneus longus (PL), and soleus (SOL) through peripheral stimulation of the sciatic nerve in the popliteal fossa to obtain $H_{max}:M_{max}$ ratios. Cortical excitability was assessed via transcranial magnetic stimulation to quantify motor evoked potential (MEP) size at 110 percent of TA resting motor threshold. Neural excitability was measured before and after two 30-minute balance training sessions. The control group (n=9) performed only balance training while the experimental group (n=10) received balance training with EMG-BF to maintain 30 percent of maximal PL contraction. Differences before and after training across groups were assessed using factorial analysis of variance (α=0.05). **RESULTS**: No differences between groups were observed for reflexive excitability (F=0.00, p=0.96). No MEP size differences were observed for TA (F=0.63, p=0.45) or PL (F=0.53, p=0.48); but a significant time by group interaction was observed for SOL (F=4.315, p=0.044). EMG-BF decreased SOL MEP size after training (0.083%M_{max} to 0.048%M_{max}). **CONCLUSIONS**: EMG-BF with short-term balance training decreased cortical excitability to SOL compared to balance training alone, perhaps representing reciprocal inhibitory mechanisms for the postural plantarflexors. These findings may have implications when considering interventions for dystonic or spastic populations.

Anthropometrics are Associated with Static Balance Performance in Intercollegiate Athletes

Amanda Robertson, Timothy Sell, FACSM, Mallory Faherty. *Duke, Durham, NC.* (Sponsor: Timothy Sell, FACSM)
(No relevant relationships reported)

Balance has been identified as a risk for lower extremity musculoskeletal injury (LEMSI). Anthropometric measurements (AM) may affect static balance (SB) performance. Understanding the relationship between AM and SB may affect how measures of balance are utilized in predicting risk of LEMSI. **PURPOSE:** To determine if sex and AM including height, mass, and BMI are predictive of SB performance in intercollegiate athletes. **METHODS:** A total of 190 intercollegiate athletes participated in the study (Males: 138, Females: 52; Age: 19.5 ± 1.3 years, Height: 181.9 ± 10.1 cm, Mass: 79.6 ± 15.2 kg). Ground reaction forces were collected utilizing a force plate during a test of single-leg SB under eyes open (EO) and eyes closed (EC) conditions. The variability (standard deviation) of the ground reaction

forces for each direction (anterior/posterior (AP), medial/lateral (ML), and vertical (V)) and the resultant (R) was calculated in order to explain the subject's overall static postural stability under each condition. Data from three trials for each condition were averaged for analysis. A stepwise regression analysis procedure was utilized to determine if AM and sex would significantly predict each of the calculated variables. Significance of <0.05 was set *a priori* for inclusion of predictor variables in the final regression equation. **RESULTS:** The final regression equations revealed that AM were predictive of performance (p<0.05 for all) across all the variables analyzed but sex was not. Height was predictive of worse EO SB performance (AP, ML, V, R). BMI was predictive of worse EO SB performance (AP, ML). Height was predictive of improved EC SB performance (AP, V, R). Mass was predictive of worse EC SB performance (AP, ML, V, R). BMI was predictive of improved EC SB performance (AP, ML, V, R). **CONCLUSION:** These findings indicate that AM predicts performance during SB measures with EO and EC. These results would indicate that prospective risk factor analysis studies may need to account for AM when determining if SB is a predictor of LEMSI.

Cognitive Dual-tasking Augments Age-differences In Dynamic Balance While Walking On A Narrow Beam

Azusa Uematsu[1], Kazushi Tsuchiya[2], Hajime Yokei[3], Shuji Suzuki[3], Tibor Hortobagyi, FACSM[4]. [1]*Dokkyo Medical University, Shimotsuga-gun, Japan.* [2]*Yamagata Prefectural University of Health Sciences, Yamagata, Japan.* [3]*Waseda University, Tokorozawa, Japan.* [4]*University of Groningen, Groningen, Netherlands.* (Sponsor: Tibor Hortobagyi, FACSM)
(No relevant relationships reported)

Beam walking is a measure of dynamic balance. We tested the idea that cognitive dual-tasking during beam walking could be an effective method to detect age-related differences in dynamic balance.**PURPOSE**: To determine the effects of age and cognitive dual-tasking on dynamic balance measured during narrow-beam walking. **METHODS**: 16 old (7M, 71.2 ±3.5 y, foot width: 9.2 ±0.5 cm, MMSE score ≥ 27) and 20 young (10M, 22.0 ±1.5 y, foot width: 9.3 ±0.8 cm) healthy volunteers participated in the study. Subjects walked on a 4-m long and 2-cm high beam with a width of 4, 8, and 12 cm, arms crossed in front of the chest. Subjects completed 3 walking trials with or without performing a calculation task. We recorded the gait trials from the subject's right side with a digital video camera at 60 Hz, and computed walking distance, step number, and average step length. Average of 3 was used for the statistical analyses. **RESULTS**: There was a Group (old, young) by beam width (4, 8, 12 cm) by task (dual task, no dual task) interaction (F = 4.0, P < 0.05). In the young group, beam-walking distance decreased similarly with descending beam width while no dual-tasking (12 cm: 3.88, 8 cm: 3.62, 4 cm: 2.49 m) and dual tasking (12-cm: 3.87, 8-cm: 3.76, 4-cm: 2.59 m). In the old group, beam-walking distance decreased substantially and most in the narrowest beam width during no dual-tasking (12-cm: 3.85, 8-cm: 3.72, 4-cm: 1.46 m) but decreased extremely in both narrower widths during dual-tasking (12-cm 3.91, 8-cm: 2.63, 4-cm 0.66 m). Further, only in the old group, the distance walked was shorter while dual-tasking compared with no dual-tasking at 8 and 4 cm beam widths (both P < 0.01). Depending on beam width, step length decreased in the young while both step number and step length decreased in the old group. **CONCLUSIONS**: Beam width but not dual-tasking affected young adults' dynamic balance whereas both beam width and dual-tasking affected substantially and interactively old adults' dynamic balance as quantified by beam distance walked and stride properties. These results suggest that, if validated and cognitive performance also quantified, dual task beam walking could be a sensitive measure of dynamic balance and motor-cognitive function in aging. Supported by JSPS KAKENHI Grant Number 16K21320.

Association between Y Balance Test Performance and Noncontact Lower Extremity Injury in High School Athletes

MARY NADELEN, Emily Hildebrand, Kyle Leppert, Peter Lisman. *TOWSON UNIVERSITY, TOWSON, MD.*
(No relevant relationships reported)

The Y Balance Test (YBT) is an assessment of dynamic balance that requires participants to maintain a single-leg stance while performing three lower extremity reaching tasks. Research has shown that an anterior reach distance difference ≥ 4cm and a normalized composite score (CS) ≤ 89.6% are associated with an increased risk of non-contact lower extremity (NCLE) injury in collegiate athletes; however, few studies have examined this relationship in high school (HS) athletes. **PURPOSE:** To determine the association between YBT performance (asymmetry and CS) and NCLE injury in HS athletes. **METHODS:** A total of 88 HS male athletes (16.3 ± 1.4yrs; 179.6 ± 6.9cm; 82.7 ± 15.2kg) underwent YBT prior to the start of the 2016 season: football (n=53), lacrosse (n=25), or baseball (n=10). An injury history questionnaire was completed to identify previous history of lower extremity injury. Incidence of NCLE injuries was tracked throughout the season. All participants performed 3

maximum anterior (ANT), posteromedial (PM) and posterolateral (PL) reaches on each leg. Right-to-left (R/L) side reach distance differences were calculated in cm while the CS was calculated for each leg as (ANT + PM + PL / (3 X limb length) X 100. Receiver Operating Characteristic (ROC) curves were first calculated by paring ANT, PM, and PL reach distance differences and CS with NCLE injury. Since ROC curves were unable to maximize sensitivity and specificity for any YBT measure, further analysis was conducted using cutpoints previously shown to be associated with injury. Logistic regression models adjusted for previous history of injury, sport, and age were used to examine the association between YBT measures and NCLE injury. **RESULTS:** Mean R/L reach differences for ANT, PM, and PL directions were 3.2 ± 2.9, 4.6 ± 3.5, and 4.7 ± 4.2cm, respectively. Mean CS was 86.8 ± 8.0%. No significant associations were found between NCLE injury and R/L side reach distance differences ≥ 4 cm for any direction or CS ≤ 89.6%. Though not statistically significant, the odds for sustaining a NCLE injury was 2.1 and 1.3 times higher for those with PM (95% CI = 0.45-2.11; p=0.34) or ANT (95% CI = 0.26-5.82; p=0.78) asymmetry ≥ 4cm in comparison with those with asymmetry < 4cm. **CONCLUSION:** YBT performance was not associated with the incidence of NCLE injury in this sample of HS athletes.

Influence of Inflatable Anti-fatigue Mats on Center of Pressure Displacement during Prolonged Standing

Sean E. Higinbotham[1], Adam E. Jagodinsky[1], John W. Fox[2], David C. Grieshaber[1]. [1]*Illinois State University, Normal, IL.* [2]*Methodist University, Fayetteville, NC.* (Sponsor: David Thomas, FACSM)

(No relevant relationships reported)

INTRODUCTION: Many workers are exposed to prolonged periods of standing, which has been linked to musculoskeletal pain, discomfort and other serious health conditions. Additionally, standing desks that do not promote regular bouts of movement may also lead to prolonged standing exposures and increase the risk for pain and discomfort. Traditional foam anti-fatigue mats have been shown to increase foot pressure displacement during prolonged standing and mitigate factors associated with pain and discomfort. However, the purported efficacy of novel inflatable anti-fatigue mats to promote foot pressure displacement has not been investigated. **PURPOSE**: The aim of this study was to evaluate the effect of inflatable anti-fatigue mats on center of pressure (COP) displacement compared to foam mat and hard surface conditions during prolonged standing. **METHODS**: 18 healthy individuals (Ht: 1.77±0.11m, Wt: 79.41±19.60kg, Age: 20.5±1.6yrs) stood for one hour on one of three floor conditions: Inflatable mat (IM, 3psi), foam mat (FM; EVA foam, 16mm), and hard surface (HS; force platform). Participants were instructed to stand normally at a standing desk and perform office work tasks with their feet inside the dimensions of the force platform. COP data were collected (1000Hz) for one minute at 0, 15, 30, 45 and 60min. COP data were normalized to foot position, and root mean square COP displacement (RMS) and velocity (RMSv) in the medial-lateral (x) and anterior-posterior (y) directions were calculated as the dependent variables (DV). For each DV a mixed ANOVA was conducted to investigate the between group (condition) and within group (time) differences. **RESULTS**: A significant main effect of condition was observed for RMSy variable [F (2, 15) = 8.24, p = .004, partial η^2 = .52]. Post-hoc tests revealed that IM (2.35±1.10mm) yielded significantly more RMSy than FM (1.13±0.47mm) (p=.016) and HS (0.92±0.32mm) (p=.005). **CONCLUSION**: The results reveal that inflatable anti-fatigue mats induce greater COP displacement in the anterior-posterior direction compared to hard surfaces and traditional foam mats during one hour of standing. Further research is needed to investigate the relationship between COP displacement and pain/discomfort measures when an inflatable mat is utilized during prolonged standing.

Effects of Stroboscopic Vision on Reactive Balance

Kyung-Min Kim[1], Joo-Sung Kim[1], Dustin Grooms[2]. [1]*University of Miami, Coral Gables, FL.* [2]*Ohio University, Athens, OH.* (Sponsor: Arlette Perry, FACSM)

(No relevant relationships reported)

Stroboscopic Vison (SV) is characterized by intermittent visual obstruction via the use of goggles with lenses that can switch between opaque and transparent. Recently, SV was found to disrupt balance during upright posture. However, the strength of this tool is that visual feedback can be perturbed during more complex reactive maneuvers that require environmental interaction, but no study has quantified the SV effect on reactive balance control. **PURPOSE:** To determine effects of SV on reactive balance. **METHODS:** Nineteen healthy subjects (9 males, age=22±2.2yrs, height=170.8±9.2cm, mass=68.9±14.2kg) participated. All participants performed the Motor Control Test (MCT) with and without SV (random order), created by specialized eyewear that intermittently cycled between opaque and transparent for 100 milliseconds at a time. MCT assesses reactive balance by measuring the time between onset of external perturbation and initiation of reaction to recover balance: the shorter reaction time equates to the better reactive balance. The 6 MCT tasks are completed in

a bilateral stance, and involve posture recovery after the support surface quickly moves in either anterior or posterior directions at 3 different distances: small, medium, large, which were scaled according to participant's height. Reaction time in milliseconds (ms) was averaged across three trials of all tasks for analysis. Separate two-way (2 visual conditions, 2 limbs) repeated ANOVAs were performed for each size of perturbation in either direction, with the alpha level set at <.05. **RESULTS**: There were no significant interactions across perturbation levels or directions: posterior-small (P=.99), posterior-medium (P=.42), posterior-large (P=.77), anterior-small (P=.99), anterior-medium (P=.75), anterior-large (P=.79). Similarly, there were no significant main effects for visual condition and limb (P>.05): for display of descriptive data for SV effects, posterior (SV:128.5±9.9, No-SV:131.6±12.0ms) and anterior (SV:131.6±15.9, No-SV: 130.2±16.6ms). **CONCLUSION**: SV did not significantly delay reactive balance to surface perturbations. This indicates that reactive balance is likely modulated by proprioceptive inputs and is less dependent on visual feedback than maintaining upright stance without surface perturbation.

2321   Board #157   June 1 11:00 AM - 12:30 PM

The Effects of Concussion History on Postural Control

Brian J. Szekely[1], Sydni V. Wilhoite[1], Peter Chrysosferidis[1], Kristen L. Neitz[1], Douglas W. Powell[2], Barry A. Munkasy[1], Nicholas G. Murray[1]. [1]*Georgia Southern University, Statesboro, GA.* [2]*University of Memphis, Memphis, TN.*

(No relevant relationships reported)

Postural deficits have been extensively noted in sport-related concussions. There have been postural instabilities in concussed athletes anywhere from 24 hours, up to six months. Altered postural control has been noted in those that have a history of concussion when compared to those that do not. However, there is sparse literature that assesses the effect of those with a history of concussion on postural control at the 24-48 hour mark post-concussion. **Purpose:** To investigate how postural control is affected by previous concussions in Division I athletes. **Methods:** Twenty-one Division I athletes (7 no history [NON], 7 with a previous concussion [CONC1], and 7 with 2 or more concussions [CONC2]) participated in this study. The participants performed 3 trials of quiet stance in the eyes open (EO) and eyes closed (EC) conditions for 30 seconds each on a force platform (1000 Hz). The Data were analyzed with Peak Excursion Velocity (PEV) and Root Mean Square (RMS) in the anteroposterior (AP) and mediolateral (ML) directions with a custom MATLAB software. The data was then statistically analyzed with SPSS *v.23*. Two 3x2 MANOVAs were run by direction for group comparisons. **Results:** Overall model showed significant differences for the AP direction (F(26,12) = 2.424; η^2 = 0.528; p = 0.029), but not the ML direction. Follow up assessments revealed that CONC2 (0.094 ± 0.021m*s^{-1}) swayed faster than both NON (0.057 ± 0.015m*s^{-1}; p < 0.01) and CONC1 (0.058 ± 0.011 m*s^{-1};p < 0.05) during EC. Also, NON (0.004 ± 0.001m) swayed less than CONC2 (0.006 ± 0.001m) in EC (p < 0.05). Furthermore, NON (0.003 ± 0.001m) swayed less than CONC1 (0.005 ± 0.001m) and CONC2 (0.005 ± 0.001 m; p < 0.05) in the EO condition. **Conclusion:** These data suggest that among those who have a history of 2 or more sport-related concussions (SRC) postural control is unstable when compared to those who do not have a history of SRC. The deficits in the AP direction may suggest that due to the increased degrees of freedom, the athletes that have multiple concussions may lack the ability to control their postural sway around their ankle.

2322   Board #158   June 1 11:00 AM - 12:30 PM

Both Slower Sensory Response Time and Electromechanical Delay Explain Age-related Differences in the Reactive Leg Drop

Mitchel A. Magrini[1], Alejandra Barrera-Curiel[1], Ryan M. Thiele[2], Jesus A. Hernandez-Sarabia[1], Ryan J. Colquhoun[1], Patrick M. Tomko[1], Nathaniel D.M. Jenkins[1], Jason M. DeFreitas[1]. [1]*Oklahoma State University, Stillwater, OK.* [2]*Kansas State University, Manhattan, KS.*

(No relevant relationships reported)

The reactive leg drop (RLD) is a test designed to assess the rapid sensory-motor integration necessary to recover from a slip and avoid a fall. The lowest drop angle from the RLD has shown to be sensitive to age-related changes, but the underlying mechanisms for this are unknown. **Purpose:** The purpose of this study was to examine the various subcomponents of a RLD to elucidate the underlying mechanisms of age differences. **Methods:** Fourteen older adults (OA: mean 74 yr) and 15 young adults (YA: mean 24 yr) participated in a familiarization session followed immediately by a testing session. For the RLDs, each participant was seated with their leg passively raised to full extension and supported by an elastic band held by the investigator. Each participant performed the Jendrassik maneuver with the upper body while their eyes were closed. Once their leg was relaxed, the researcher would then abruptly release the band allowing the lower leg to free-fall. The participants were instructed to kick up to full extension as fast as possible once they felt the lower leg dropping. Drop angle, measured with an electro-goniometer secured to the knee, was measured

as the difference in angle between the start position and the lowest point achieved prior to kicking back up. Surface EMG was recorded from the vastus lateralis (VL) muscle during the RLDs. The RLDs were divided into 2 subcomponents: 1.) Sensory Response Time (SRT), calculated from the start of the drop (as shown in the goniometer signal) to the onset of VL EMG; and 2.) Electromechanical Delay (EMD), measured as the time between the onset of VL EMG to the time point when the leg started to move back up (i.e. onset of concentric portion). Separate independent t-tests with a Bonferroni correction (alpha: $p \leq 0.016$) were used to analyze the differences between YA and OA. **Results:** As expected, there were significant group differences in drop angle (p = 0.0006). Interestingly, both subcomponents, EMD (YA: 127.9 ± 22.8 ms, OA: 160 ± 24.9 ms; p = 0.0004) and SRT (YA: 94.9 ± 28.6 ms, OA: 140 ± 59.3 ms; p = 0.0004), showed significant differences between YA and OA. **Conclusion:** Both sensory response time and electromechanical delay are mechanisms that explained age-related differences in RLD performance. As such, both variables may separately play significant roles in slip recovery and fall avoidance.

Postural Control of Voluntary and Involuntary Sway Movements in Healthy Young Adults

Zhengquan Chen[1], Jia Han[1], Gordon Waddington[2], Roger Adams[2], Judith Anson[2]. [1]Shanghai University of Sport, Shanghai, China. [2]University of Canberra, Canberra, Australia.
(No relevant relationships reported)

PURPOSE: Control of postural sway is essential for high level sport performance. Structural and situational factors can affect involuntary sway, so a measure of voluntary sway movement sensitivity is needed. This study set out to evaluate the reliability of a novel device to measure voluntary lateral sway when standing, and to test the hypothesis that enhanced voluntary lateral sway discrimination ability is associated with better control of involuntary postural sway.
METHODS: 44 healthy young adults (21M, 23F, mean age 23.8) were recruited. During the voluntary lateral sway test, the participants were asked to discriminate between four possible medial-lateral sway extents. Movement extents were made commencing from the neutral standing position and moving either left or right until contact on a physical stop at the greater trochanter (Extent 1=4cm, Extent 2=4.5cm, Extent 3=5cm, and Extent 4=5.5cm). The involuntary postural sway control test required the participants to stand as still as possible on a force plate.
RESULTS: Voluntary lateral sway extent AUC discrimination scores (SD) for Day 1 and Day 8 were 0.679 (0.056) and 0.682 (0.040) for voluntary sway to the left, and 0.645 (0.059) and 0.644 (0.063) for sway to the right. There was no significant difference in AUC scores between Day 1 and Day 8 (p>0.05). ICC(3,1) values were 0.706 for sway to the left and 0.871 for sway to the right, representing good to excellent test-retest reliability. Left and right voluntary lateral sway discrimination scores were significantly correlated (r=0.669, p<0.01), however there was no significant relationship between voluntary lateral sway AUC scores and postural sway displacement scores (all r<0.14, p>0.05). Repeated Measures ANOVA showed significant linear deterioration in extent discriminability across the 3 pair-wise voluntary lateral sway AUC scores (F=6.094, p=0.019), indicating that as sway extent increases, discrimination sensitivity decreases.
CONCLUSIONS: Voluntary lateral sway measurement showed good to excellent test-retest reliability. Because of the low correlations, voluntary postural sway and involuntary postural sway appear to be subserved by different neural mechanisms. Voluntary lateral sway sensitivity is magnitude dependent, with greatest sensitivity in the most-used sway region.

Relationship Between The Sport-like Antisaccade Task And Postural Control Following Sport-related Concussion

Nicholas G. Murray[1], Brian Szekely[1], Sydni Wilhoite[1], Kristen Neitz[1], Peter Chrysosferidis[1], Douglas Powell[2], Barry A. Munkasy[1]. [1]Georgia Southern University, Statesboro, GA. [2]University of Memphis, Memphis, TN.
(No relevant relationships reported)

Postural instability and visual system dysfunction are two of the most prevalent signs immediately following a sport-related concussion. However, little is known regarding the relationship between postural control and visual system assessments in a population of sport-related concussion. PURPOSE: To investigate the relationship between postural control center of pressure metrics and eye movements during the sport-related antisaccade task in a group of healthy matched controls (CON) and sport-related concussions (SRC) within 24-48 hours post-injury. METHODS: 37 SRC NCAA Division I athletes (23 females, 14 males) and 37 sport matched CON (23 females, 14 males) between the ages of 18-25 yrs completed two trials of the sport-like antisaccade task (SLT). During play, all participants were instructed to minimize eye movements away from a central fixed area, while simultaneously swaying in a

medial-lateral direction to direct an on screen avatar to meet the demands of the task. Monocular raw point of gaze coordinates (240Hz, Argus Science) where recorded in coordination with a synced 8 camera motion capture system (120Hz, Vicon) while raw center of pressure (1000Hz, AMTI) coordinates were collected simultaneously and further analyzed using a custom algorithm. Pearson product correlations examined the relationship between the gaze variables Resultant Distance (RD), Prosaccade Errors (PE), Mean Horizontal Velocity (HV), Microsaccades (MS) to center of pressure Root Mean Square (RMS) and Peak Velocity (PV) in the anteroposterior (AP) and mediolateral (ML) directions within each group. RESULTS: In the SRC group, a significant moderate positive correlation between RD (4.71±1.35 pixels) and RMS in the AP direction (0.011±0.002 meters) (r=0.361, p=0.028) was observed. No other significant relationships were observed between any other gaze and posture variables in the SRC group. In the CON group, no significant relationships were observed between any gaze and posture variables. CONCLUSION: These results suggest that as SRC gaze travels a greater RD, their postural sway increases in the AP direction during the SLT. However, the lack of any other significant relationship may indicate that these assessments are measuring two separate neuronal constructs.

2325   Board #161   June 1 11:00 AM - 12:30 PM

Repetitive Trunk Loading Leads to Faster Trunk Movement in Response to External Perturbation

Michael W. Olson, FACSM[1], Li Li, FACSM[2]. [1]Southern Illinois University Carbondale, Carbondale, IL. [2]Georgia Southern University, Statesboro, GA.
(No relevant relationships reported)

PURPOSE:The purpose of this study was to examine the responses of trunk movement patterns to mechanical perturbation before and after two different repetitive trunk flexion-extension loading schemes. Spatial and temporal biomechanical parameters were studied to further understand the ability of the trunk to recover from anterior directed perturbations.
METHODS: Eighteen male (n=9) and female (n=9) participants (21.7 ± 2.3 yrs, 1.75 ± 0.08 m, 72.5 ± 12.0 kg) were recruited. They participated in active and passive trunk flexion-extension loading, performed at least 7 days apart. Participants performed 60 trunk flexion-extension repetitions in each condition. Participants either volitionally moved their trunks (active condition) or relaxed during dynamometer controlled movements (passive condition). Trunk perturbations occurred before and immediately after two 30-repetition sessions. Temporal measures included perturbation onset to initial trunk movement (T_D), movement initiation to peak trunk velocity (V_P) (T_{MIPV}), and perturbation onset to V_P (T_{PPV}). Recovery measures included peak recovery velocity (V_{PR}), recovery time (T_R), velocity slope (V_S), and recovery slope (R_S). Repeated measures ANOVA was used to analyze the data. Alpha level was set at 0.05.
RESULTS: There was no sex by session interaction observed. Significant sex differences were present for T_{MIPV} (Male 112.4 ± 74.6 ms, Female 96.5 ± 44.6 ms, p < 0.02), V_{PR} (Male -12.0 ± 8.6 deg/s, Female -15.6 ±13.0 deg/s, p < 0.01), and V_S (Male -273.3 ± 215.9 deg/s/s, Female -332.4 ± 363.8 deg/s/s, p < 0.05) measures. Differences between loading sessions were present for T_{PPV} (Block1: 212.8 ± 239.6, Block2: 168.3 ± 46.7, Block3: 171.7 ± 82.1 ms, p < 0.039), and R_S (Block1: -6.65 ± 5.6, Block2: -4.76 ± 3.7, Block 3: -5.28 ± 5.2, p < 0.02).
CONCLUSIONS: Distinct sex and time-dependent modifications to the kinematics parameters are attributed to the altered mechanical behavior of the lumbar tissues as well as volitional loading by the trunk extensors. Overall, results indicate repetitive loading leads to lower resistance to perturbation, but faster recovery from perturbation although no differences to active or passive repetitive loading were observed.

2326   Board #162   June 1 11:00 AM - 12:30 PM

Construct Validity of Three Clinical Tests of Core Neuromuscular Control

Travis R. Pollen[1], Eric J. Folkins[2], Jason H. Mohring[1], Brian W. Noehren, FACSM[3], David Ebaugh[1], Sheri P. Silfies[1]. [1]Drexel University, Philadelphia, PA. [2]University of the Sciences, Philadelphia, PA. [3]University of Kentucky, Lexington, KY.
(Sponsor: Brian W. Noehren, FACSM)
(No relevant relationships reported)

PURPOSE: To determine construct validity of three clinical tests of core neuromuscular control (CNC). METHODS: 15 healthy adults (8 females, age = 26 ± 3 years, height = 1.69 ± 0.07 m, mass = 69.1 ± 10.2 kg) performed 3 clinical tests: unilateral hip bridge endurance (UHBE; mean time in position for left and right sides, 1 trial per side), double leg lowering (DLL; mean degree of hip flexion, 3 trials), and a newly developed seated trunk proprioception test using a wobble board (STP; mean time to first error, 5 trials). Biomechanical tests of static and dynamic CNC were assessed via an unstable chair on a force plate. Static control (SC) was determined by ability to maintain seated balance with eyes closed (3 trials), with performance assessed by a 95% confidence ellipse area (SC CEA; mm²) and mean velocity (SC MVEL; mm/s) of the center of pressure (COP). Dynamic control (DC) was assessed during 4 trials of a speed and accuracy target acquisition task where

targets were located along the vertices of an octagon. DC performance was assessed by precision control (movement around select targets prior to acquisition) (DC CEA; mm^2) and directional control (perpendicular distance off direct COP path to target) (DC OFF; mm). One-tailed Spearman's rho (ρ) was used to assess relationships between clinical and biomechanical variables. Interpretations of the correlations were as follows: 0.25 to 0.50 (fair) and 0.50 to 0.75 (moderate to good). **RESULTS:** Significant fair to good correlations were found between CNC clinical tests and both SC and DC biomechanical variables: SC CEA and UHBE and DLL; SC MVEL and UHBE; DC CEA and UHBE and DLL; and DC OFF and all clinical tests (Table). **CONCLUSION:** The data suggest the UHBE, DLL, and STP demonstrate construct validity for measurement of CNC, with individual clinical tests explaining 21-43% of the variance in performance on the biomechanical tests. These data provide preliminary support for the use of these clinical tests as measures of CNC.

Descriptive statistics and Spearman's ρ between clinical and biomechanical core tests					
--	--	Static Control		Dynamic Control	
--	Median $\pm$ IQR	CEA	MVEL	CEA	OFF
UHBE	24.3 $\pm$ 26.9 s	ρ = -0.50, p = 0.03	ρ = -0.61, p = 0.01	ρ = -0.56, p = 0.02	ρ = -0.47, p = 0.04
DLL	75 $\pm$ 28°	ρ = 0.49, p = 0.03	ρ = 0.04, p = 0.45	ρ = 0.66, p < 0.01	ρ = 0.54, p = 0.02
STP	3.7 $\pm$ 4.5 s	ρ = -0.43, p = 0.05	ρ = -0.11 , p = 0.35	ρ = -0.28, p = 0.15	ρ = -0.46, p = 0.04

E-35   Free Communication/Poster - **Injury**

Descriptive Epidemiology Of Injuries In National Collegiate Athletic Association Water Polo: 2012/13 - 2015/16

Erin B. Wasserman, Sarah N. Morris, Kelsi L. Jones, Christy L. Collins. *Datalys Center for Sports Injury Research and Prevention, Indianapolis, IN.*
(No relevant relationships reported)

Water polo is a contact sport, but it also involves repetitive motion, increasing risk of overuse injuries. However, little is known about the injury incidence in water polo; previous reports have focused on specific diagnoses or a single tournament. **PURPOSE**: Describe injury incidence, common diagnoses, and outcomes in men's and women's National Collegiate Athletic Association (NCAA) water polo. **METHODS**: Athletic trainers reported injury and athlete-exposure (AE) data as part of the NCAA Injury Surveillance Program. Data for men's water polo were reported across 4 team-seasons from 2014/15 - 2015/16. Data for women's water polo were reported across 6 team-seasons from 2012/13 - 2015/16. Injuries occurred during a school-sanctioned practice or competition and required medical attention. Injury frequencies, rates per 1,000 AEs and 95% Confidence Intervals (CI) were calculated. **RESULTS**: In men's water polo, 26 injuries were reported in 9,964 AEs (2.61/1,000 AEs, 95% CI:1.61-2.61; 6.5 injuries/team/season). In women's water polo, 36 injuries were reported in 15,000 AEs (2.40/1,000 AEs, 95% CI:1.62-3.18; 6 injuries/team/season). The most common mechanism of injury for both men and women was player contact (men:13/26, women:18/36), followed by ball contact in women (9/36) and overuse in men (4/26). Among men, 23 of 25 injuries with a known outcome resulted in time loss >24 hours compared to 28/36 among women. Concussions comprised nearly half of reported women's injuries (17/36), but only 2/26 reported men's injuries were concussions. **CONCLUSIONS**: Although water polo is a contact sport with repetitive motion, preliminary data indicate that injury rates are low relative to other contact sports. Injury rates are similar between men's and women's water polo, but a larger proportion of reported women's water polo injuries are concussions. Further research is needed to determine if the reporting of injuries varies by gender or if there is a true difference in concussion incidence.
The Injury Surveillance Program is funded by the NCAA. The content of this abstract is solely the responsibility of the authors and does not necessarily represent the official views of the NCAA.

2328   Board #164   June 1 9:30 AM - 11:00 AM

Comparison of Orthopedic Injuries in American Flag Football to American Tackle Football.

Ajit Vakharia[1], Michael Mijares[2], Rushabh M. Vakharia[3], Tsun Law[3], Fernando Manalac, Jr[3], Martin Roche, Jr[3]. *[1]Morehouse School of Medicine, Atlanta, GA. [2]University of Miami, Miami, FL. [3]Holy Cross Hospital, Fort Lauderdale, FL.*
(No relevant relationships reported)

Purpose: Comparison of American Flag Football (AFF) to American Tackle Football (ATF) with respect to their injuries is not well documented. The purpose of this study was to compare Orthopedic injuries between the two sports.
Materials and Methods: A retrospective analysis of patients having injuries from AFF or ATF were identified from 2009 – 2016, using the Pearl Diver database (Pearl Diver Technologies, West Conshohocken, PA USA). International Classification of Diseases, ninth and tenth edition (ICD-9 and ICD-10) were used to query our cohort. Our query found patients having injuries in AFF (ICD-9-D-E0070;ICD-10-D-Y9361) and ATF (ICD-9-D-E0071;ICD-10-D-Y9362). The sample size was further narrowed searching for fractures of the upper (FUE) and lower extremities (FLE), dislocations (DI), sprains and strains (S&S), and concussions (CO). Statistical analysis was done between the sports.
Results: 7,896 (696 = AFF; 7,200 ATF) patients with injuries were found. 15-19 (n = 3,169) was the most injured age group in AFF and ATF. Fractures of middle or proximal phalanx/phalanges of hand was the most common FUE in AFF (n = 54), whereas fractures of distal end of radius was predominant in ATF (n = 263). Fractures of the ankle were the most common FLE in both groups (AFF = 11; ATF = 155), along with tear of the medial cartilage of the knee (AFF = 19; ATF = 170). Sprains of the cruciate ligament of the knee was commonly seen in AFF patients (n = 42); whereas in ATF patients, ankle sprains of unspecified sites were commonly seen (n = 383). Concussion rates were higher in the ATF group (n = 883) compared to AFF (n = 47), with 15-19 (n = 484) year olds comprising 54% of concussions in ATF, followed by 10- 14 years olds (n = 399, 46%). Statistical analysis found a p-value of 0.01 when comparing injuries between AFF and ATF.
Conclusion: Appropriate protection such as ACL injury prevention program, ankle taping or bracing, and training should be given when engaging in either sport. Children and adolescents interested in seeking to play either AFF or ATF should: be properly equipped, perform an injury prevention program prior to play, seek appropriate medical counseling prior to and after injury, and be educated of the potential sequelae from playing these sports.

2329   Board #165   June 1 9:30 AM - 11:00 AM

Sport-related Injuries In Elite Para Powerlifters: A Prospective Analysis Of 1410 Athlete-days At The Rio 2016 Summer Paralympic Games

Kimberly E. Ona Ayala, B.A., Patrick Huang, B.A., B.S., Yetsa A. Tuakli-Wosornu, M.D., M.P.H.. *Yale School of Medicine, New Haven, CT.*
(No relevant relationships reported)

PURPOSE: To describe the injury epidemiology of Para powerlifters during the Rio 2016 summer Paralympic Games. METHODS: This cohort study was a sub-analysis of the comprehensive WEB-IISS study (WEB-based Injury and Illness Surveillance System) carried out at the Rio 2016 Paralympic Games by the International Paralympic Committee (IPC) Medical Committee. The WEB-IISS survey was administered to the Chief Medical Officers of each Para powerlifting federation daily. Injury data was prospectively collected and securely housed by the IPC. The main outcome measures were injury incidence rate (IR; number of injuries per 1000 athlete-days) and injury incidence proportion (IP; number of injuries per 100 athletes), assessed against demographic data, type of injury, and anatomic location of injury. RESULTS: 141 athletes participated in the 7-day Para powerlifting competition period, accounting for 1410 athlete competition days of exposure. Overall IR was 15.6/1000 athlete days (95% CI; 9.1 - 22.1) while IP was 15.6 injuries/100 athletes. Most injuries were chronic overuse in nature (63.6%). The most commonly injured anatomical region was the shoulder (45.5%; IR=10.1), followed by the neck (13.6%; IR=3.0), and the chest and elbow (each 9.1%; IR=2.0). There were no significant differences in injury patterns between male and female powerlifters [IRR=0.8 (95% CI; 0.3-2.0)]. The oldest age group (age 35-75) had the highest IR [IR=21.8 (95% CI; 11.4-32.2), followed by the middle age group (age 26-34) [IR=10.0 (95% CI; 1.2-18.8)]. CONCLUSIONS: Data from this study indicate that 1. IRs were lower than those reported at the London 2012 Paralympic Games, 2. chronic overuse injuries, as opposed to acute traumatic, remain most common among elite Para powerlifters at Games-time, 3. the shoulder remains the most commonly injured anatomical site, 4. age was a significant risk factor for injury in Rio, which was not shown in London. Comparative data can be collected at future Games' settings and in combination with current data, used to inform injury prevention programs. As upper extremity injuries impact Para powerlifters' ability

to participate in sport as well as activities of daily living, this study helps open an important door for the development of injury prevention protocols in this high-risk Para sport.

Injuries Related To Fitness Trends: Is CrossFit The Newest Contributor?

Nicole D. Rynecki, Brianna L. Siracuse, Joseph A. Ippolito, Kathleen S. Beebe. *Rutgers New Jersey Medical School, Newark, NJ.*

(No relevant relationships reported)

Purpose: Over the past decade, high intensity interval training (HIIT) and high intensity power training (HIPT) have become popularized by programs like CrossFit. The objective of this study was to determine injury incidence coinciding with increased popularity of CrossFit and identify ways physicians can advise patients prior to participation.

Methods: The National Electronic Injury Surveillance System (NEISS) was queried from 2007 through 2016 to estimate injury incidence related to exercise equipment most frequently utilized in programs like CrossFit. Injury incidences were calculated and compared between 2007-2011 and 2012-2016. Over the same time period, Google Trends was used to determine the popularity of CrossFit

Results: There were an estimated 3,988,903 injuries, mostly in males (58%) aged 20 to 39 years (39%). Most commonly, injuries were in the lower extremity (35.3%), trunk (28.5%), and upper extremity (19.6%). From 2012-2016 versus 2007-2011, there was a 144% increase in all injuries including a 159% increase in trunk injuries, a 137% increase in lower extremity injuries, and a 132% increase in upper extremity injuries. There was also a 127% increase in lower extremity strains and a 124% increase in upper extremity strains. Additionally, knee and ankle sprains increased 125%. These increases in injury incidence correlated with a 203% increase in CrossFit interest.

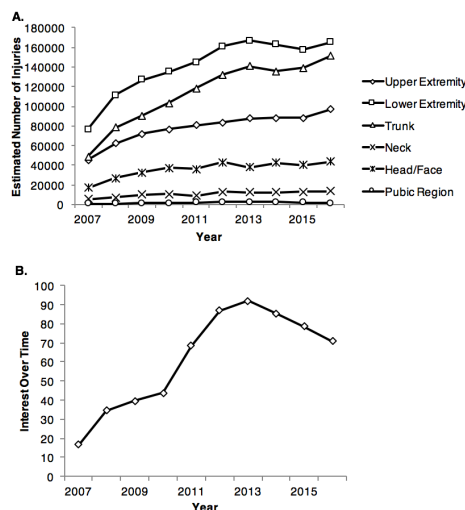
Conclusion: Given increases in injuries related to high-intensity workout programs like CrossFit, athletes should be educated on how to minimize preventable injuries. With particularly high rates of knee and ankle sprains and strains, neuromuscular training and pre-strengthening programs as previously demonstrated among young athletes may be particularly worthwhile in prospective participants. Physicians must be up to date with current fitness trends to best advise patients appropriately.


Figure 1. 1A shows the estimated number of injuries by body region caused by exercise, exercise equipment, and weight lifting by year recorded by the National Electronic Injury Surveillance System from 2007 through 2016. 1B shows the popularity of CrossFit by year using Google Trends data from 2007 to 2016.

2331   Board #167   June 1 9:30 AM - 11:00 AM

Epidemiology Of Upper Extremity Injuries In The National Collegiate Athletic Association: 2009/10 - 2015/16

Christy Collins, Erin B. Wasserman. *Datalys Center for Sports Injury Research and Prevention, Inc., Indianapolis, IN.*

(No relevant relationships reported)

Participation in sports places athletes at risk of sustaining an upper extremity injury. These injuries may be acute, resulting from a single traumatic event, or associated with repetitive motions and overuse. Previous studies have examined upper extremity injuries; however, most have focused on specific sports, body parts, diagnoses, or mechanisms of injury.

PURPOSE: To describe the epidemiology of upper extremity injuries in National Collegiate Athletic Association (NCAA) sports.

METHODS: Athletic trainers participating in the NCAA Injury Surveillance Program reported athlete-exposure (AE) and injury data for 25 collegiate sports during the 2009/10-2015/16 academic years. Upper extremity injuries, including those to the shoulder/clavicle, upper arm, elbow, forearm, wrist, and hand/finger, occurred during a school-sanctioned practice or competition, and required medical attention. Injury frequencies, rates per 1,000 AEs and 95% Confidence Intervals (CI) were calculated.

RESULTS: The overall rate of upper extremity injuries was 1.07 (95% CI:1.04-1.10) per 1,000 AEs. Men's ice hockey (2.88; 95% CI:2.73-3.04), wrestling (2.64; 95% CI:2.35-2.94), and football (2.11; 95% CI:2.03-2.18) had the highest rates while men's (0.00) and women's (0.02) cross country had the lowest. Overall, 57.9% of upper extremity injuries occurred during practice. Nearly half (46.6%) were to the shoulder/clavicle, followed by hand/finger (24.8%). The most common diagnoses were sprain (27.7%) and strain (18.4%). Player contact (36.9%) and overuse (18.6%) were the most common mechanisms. 17.7% of injuries resulted in a time loss of 7 or more days, and 10.6% were recurrent.

CONCLUSIONS: While upper extremity injuries occur across a wide variety of collegiate sports in both competition and practice, the sports with the highest rate of injury were contact/collision sports. Many upper extremity injuries were not severe; however, nearly one in five kept the athlete out of play for a week or more. More research is needed to determine how to effectively reduce the incidence of upper extremity injuries among all collegiate athletes. The Injury Surveillance Program is funded by the NCAA. The content of this abstract is solely the responsibility of the authors and does not necessarily represent the official views of the NCAA.

Ten-year Trends In Major Trauma Or Death Resulting From Sport And Recreation In Victoria, Australia

Christina L. Ekegren, Ben Beck, Pamela Simpson, Belinda J. Gabbe. *Monash University, Melbourne, Australia.*

(No relevant relationships reported)

Sports injuries which result in major trauma or death are associated with significant health-care burden and societal costs. Understanding changes in injury trends, and their drivers, is needed to implement policy aimed at risk reduction and injury prevention. To date, there has been no population-level reporting on trends in serious sport and recreation injuries anywhere in Australia over such an extended period, nor any studies of this length capturing comprehensive data on all sports-related major trauma internationally. **PURPOSE**: The aim of this study was to describe the incidence of sport and active recreation injuries resulting in major trauma or death for a 10-year period from July 2005-June 2015 in Victoria, Australia. **METHODS**: All sport and active recreation-related major trauma cases and deaths in Victoria, a state of Australia, were extracted from the population-level Victorian State Trauma Registry and the National Coroners Information System, over a 10-year period. Poisson regression analysis was used to examine trends in the incidence of sport and active recreation-related major trauma and death.

RESULTS: There were 2,847 non-fatal major trauma cases and 614 deaths (including 96 in-hospital deaths) over the 10-year study period. The highest frequencies of major trauma cases and deaths were in cycling, motor sports and equestrian activities. The participation-adjusted major trauma and death rate was 12.2 per 100,000 participants per year. There was an 8% increase in the rate of major trauma (IRR=1.08, 95%CI, 1.06, 1.10; p<0.001), and a 7% decrease in the death rate (IRR=0.93, 95%CI: 0.90, 0.97; p<0.001). Out of all sports, there were significant increases in the rate of major trauma (including deaths) in equestrian activities, motor sports and cycling.

CONCLUSIONS: The rate of major trauma due to participation in sport and recreation has increased over the past 10 years in Victoria, which was largely attributable to equestrian activities, motor sports and cycling. Study findings highlight the need to prioritize investment in the prevention of trauma in these activities.

2333   Board #169   June 1 9:30 AM - 11:00 AM

Epidemiology of Lower Extremity Musculoskeletal Injury in US High School Girls' Soccer and Basketball

Daniel R. Clifton[1], R. Dawn Comstock[2], Thomas Best[3], Ajit Chaudhari[1], Andrew Persch[1], Jingzhen Yang[4], James A. Onate[1]. *[1]The Ohio State University, Columbus, OH. [2]University of Colorado-Anschutz, Aurora, CO. [3]University of Miami, Coral Gables, FL. [4]Nationwide Children's Hospital, Columbus, OH.*

(No relevant relationships reported)

Sports with rapid directional changes and the potential for player contact (e.g. soccer and basketball) have relatively high risk of lower extremity (LE) musculoskeletal

(MSK) injury. Effectively reducing the risk of LE MSK injury in high school girls' soccer and basketball may require sport-specific interventions, but minimal research has compared patterns of injury in these sports.

PURPOSE: Describe the epidemiology of LE MSK injuries in high school girls' soccer and basketball athletes.

METHODS: Data from the 2012/2013 through 2015/2016 academic years were collected from High School Reporting Information Online (HS-RIO). Certified athletic trainers (ATs) from participating high schools reported injury incidence and athlete exposures (AE). Injury was defined as an event causing an athlete to seek care from an AT or physician and resulting in at least one missed practice or competition. AE was defined as one athlete's participation in one practice or competition. Injury rates per 1000AE were calculated. Injury proportions were calculated to assess distributions of injuries by body part, diagnosis, injury mechanism, and time loss. Injury rate ratios (IRR) and injury proportion ratios (IPR) were calculated to compare differences between sports. IRRs and IPRs with 95% confidence intervals (CI) not including "1.00" were considered statistically significant.

RESULTS: The injury rate was higher in soccer than basketball (IRR = 1.31, 95%CI = 1.19, 1.44). The most common injuries for both sports were sprains and strains (73.86% basketball; 68.96% soccer); most injuries affected the ankle (47.20% basketball; 35.03% soccer) and knee (32.64% basketball; 29.38% soccer). The proportion of injuries affecting the hip (IPR = 1.74, 95%CI = 1.06, 2.88) or thigh/upper leg (IPR = 1.97, 95%CI = 1.44, 2.70) was greater in soccer than basketball. Injuries for both sports were most commonly caused by player contact (27.70% basketball; 40.80% soccer) or noncontact mechanisms (41.35% basketball; 34.15% soccer).

CONCLUSIONS: Injury patterns were similar between sports suggesting both sports should emphasize preventing sprains and strains affecting the ankle and knee, specifically those resulting from player contact or noncontact mechanisms. Additional efforts are needed to prevent hip and thigh/upper leg injuries in soccer.

2334   Board #170   June 1 9:30 AM - 11:00 AM

Opiate Knowledge Among High School Athletes

Elton Li[1], Adam N. Van Horn[1], Jacob W. Poynter[1], Jonathan Im[1], Jennifer Heronema[2], Carol Janney[1]. [1]*Michigan State University College of Human Medicine, East Lansing, MI.* [2]*The Legacy Center, Midland, MI.*
(No relevant relationships reported)

Opiate use and abuse amongst adolescents has become an epidemic in the United States. Use of prescription pain medication is of particular concern for adolescent athletes due to their propensity for injury and need for pain control either acutely or post-surgically.

Purpose: To evaluate changes in opiate knowledge of high school (HS) athletes after a national opiate education program.

Methods: Fall (HS) sport teams separately attended 45-min, multi-media presentations, focused on opiate education. Athletes completed an anonymous survey before and after the educational program. Paired T-tests were performed.

Results: Overall, 491 of 504 HS athletes completed surveys (males= 310 and females=181). HS athletes represented 9-12 grades (n=126, 152, 115, and 111, respectively). Participating sports teams included football (n=174, M), cross-country (n=81, M&F), soccer (n=65, M), pompon (n=64, F), swimming (n=50, F), tennis (n=31, M), volleyball (n=30, F), and golf (n=9, F). During the last year, 42% of athletes reported an injury that prevented them from playing sports, 46% of athletes had taken a pain medication, and 41% have taken pain medication prior to a game. Prior to the program, 72%, 63%, 57%, and 78% of HS athletes correctly identified codeine, Norco, tramadol and heroin, respectively, as opiates, while 34%, 41%, and 44%, incorrectly classified marijuana, Tylenol, and Molly (street name for Methylenedioxymethamphetamine, or MDMA), respectively, as opiates. After the program, athletes had significantly improved their knowledge in recognition of common opiates (p<0.01) and opiate overdose symptoms (p<0.01). Prior to the program, 32% (SEM 2.4%) felt that they were aware of community resources available for those who misuse opiates vs. 88% (SEM 1.5%) (p<0.01) after the program.

Conclusion: HS athletes attending a brief opiate educational program significantly improved their knowledge in recognizing opiates and overdose symptoms, as well as community resources available for those who misuse opiates. Our results suggest, that increasing knowledge of opiates in teen athletes is critical to a successful prevention strategy.

Anterior Cruciate Ligament Injuries in Missouri High School Male and Female Soccer Athletes

Aaron D. Gray, Scott Miller, Seth L. Sherman, Emily Leary, Brad W. Willis. *University of Missouri, Columbia, MO.*
(No relevant relationships reported)

Purpose: To investigate the incidence of anterior cruciate ligament (ACL) injury in Missouri High School male and female soccer players during the 2011-2013 seasons, using a retrospective method for calculating athletic exposures. **Methods**: A web-based survey was created and sent to every high school soccer coach in Missouri using the Missouri State High School Activities Association (MSHSAA) database. The survey investigated the number of athletic exposures over the course of the season and number of ACL injuries for each team in both the 2011-2012 and 2012-2013 seasons. The primary outcome measure was ACL injuries. Secondary endpoints included specific characteristics of each ACL injury including contact or non-contact, position, practice or game, school grade, and playing surface. **Results**: During the study period 330,062 athletic exposures (163,511 male and 166,551 female) were reported. 36 ACL tears (28 female and 8 male) occurred. ACL injury rates were calculated per 1000 estimated athletic exposures: Female: total, 0.17; match, 0.47; practice, 0.02. Male: total, 0.05; match, 0.18; practice, 0. Female high school soccer athletes had a 3.4 times greater risk of ACL tear than male high school soccer athletes. Female athletes were 27x more likely to tear their ACL in a match compared to practice. **Conclusions**: Female high school soccer athletes had an increased susceptibility to ACL tear compared to male athletes. For both female and male athletes, a large majority of ACL tears occurred during matches.

Prevalence Of Musculoskeletal Injuries And Dysfunction Amongst Physical Education Teachers In Singapore

Swarup Mukherjee, Muhammad Ridhuan Johari, Ying Hwa Kee. *Nanyang Technological University, Singapore, Singapore.*
(No relevant relationships reported)

Occupational demands in PE teachers (PETs) require them to cope with heavy workloads, subject their bodies to impact-loading activities like running and jumping, carrying loads, asymmetrical and stressful postural techniques. This subjects the PETs to a high risk of musculoskeletal (MSK) injuries and dysfunction-related problems that can affect PE teaching and quality-of-life in the long-term.**PURPOSE**: To determine the prevalence of injuries and MSK dysfunction in PETs in Singapore.

METHODS: A retrospective injury registration questionnaire and Short Musculoskeletal Function Assessment (SMFA) was used. 152 full-time PETs (116 male; 36 female) participated in the study.

RESULTS: 66 PETs reported 73 injuries over a 6-month recall period. In both males and females, knee was the most commonly injured body part, followed by the lower back and shoulder in males and foot and the patella in females. 21 (28.7%) new injuries, 22 (30%) recurrences of an old injury and 27 (36.9%) aggravations of pre-existing injuries were documented. Incomplete ligament sprain followed by muscle tendon strain were the most common injuries. 48 (65.7%) injuries did not lead to any absence from work, 11 injuries (15%) led to 1-2 days of absence while 14 cases (19.1%) led to 3-15 days of absence. 51 injuries did not affect teaching PE, while 15 injuries lead to some PE teaching time loss (range, 1-10 days). In five cases, the injuries were severe enough to require surgery and these PETs were unable to teach PE for the entire term. 31 PETs reported to be continuing to teach PE with some pain and discomfort due to effect of injuries.

On the SMFA, 132 PETs reported sub-optimal functional index while 112 reported sub-optimal bothersome index. 95 PETs had sub-optimal standardized mobility score, 132 had sub-optimal standardized functional score and 112 PETs had sub-optimal standardized bothersome score. Scores on all three scales were comparable between males and females. However, MSK dysfunction was more prevalent in primary PETs compared to secondary school PETs.

CONCLUSIONS: There is a high prevalence of injuries and MSK dysfunction amongst PETs in Singapore. Knee, shoulder and foot are at the highest risk of injury. This can adversely affect their PE teaching capacities as well as quality of life in both short and long-term.

2337   Board #173   June 1 9:30 AM - 11:00 AM

Evaluating the Concussed Athlete: Co-Occurring Psychiatric Conditions Predict Psychological Function and Recovery

Jeremy P. McConnell[1], Cali A. VanValkenburg[1], Vincent C. Nittoli[2], Adam W. Shunk[2], Courtney D. Jensen[1]. [1]*University of the Pacific, Stockton, CA.* [2]*St. Vincent Sports Performance, Indianapolis, IN.*
(No relevant relationships reported)

More than 35 million American children ages 5 to 18 and approximately 400,000 collegiate athletes engage in organized sports. Sport participation bears a risk of traumatic brain injury (TBI). The annual incidence of sport-related TBI exceeds 1.5 million and is increasing among youth athletes. Many sufferers of TBI present with co-occurring psychiatric conditions, such as anxiety, depression, and learning disabilities. The effect of these conditions on diagnosis and prognosis remains largely unexplored. **PURPOSE:** To assess the effect of co-occurring conditions on TBI symptoms in youth athletes. **METHODS:** We analyzed 80 student-athletes (primary education through college) who underwent comprehensive evaluation following a TBI. Medical histories were collected, neuropsychological tests were conducted, and co-occurring

psychiatric conditions were diagnosed. Co-occurring conditions were 1) attention deficit and hyperactivity disorders, 2) anxiety disorders, 3) depression and mood disorders, 4) adjustment disorders, and 5) learning disabilities. Tests of behavior and cognitive function were 1) the ImPACT test, and 2) the Behavior Assessment System for Children 2nd Edition (BASC). Linear regressions tested the effect of co-occurring conditions on psychological and behavioral outcomes. **RESULTS:** Subjects were 16.0 ± 2.6 years of age, 56.3% were male, and 72.5% were diagnosed with ≥1 co-occurring condition. Linear regressions revealed the number of diagnoses to predict poorer visual motor speed (p=0.031), poorer reaction time (p=0.010), and, summarizing speed and accuracy indices, poorer performance on the cognitive efficiency index (p=0.043). The number of co-occurring conditions was also a significant predictor (p<0.05) of 13 individual BASC categories and all BASC composite assessments, indicating poorer behaviors and attitudes. **CONCLUSION:** TBI associates with acute neural deficits and psychological changes. We found that co-occurring psychiatric diagnoses may compound these complications in youth athletes. When appraising the severity of a TBI in this population, a comprehensive psychiatric evaluation may be warranted to understand and accurately characterize the scope and prognosis of the condition.

2338   Board #174   June 1 9:30 AM - 11:00 AM

Seasonal Distribution Of Cold Weather Injuries In The U.s. Army

David W. DeGroot, FACSM[1], Catherine Rappole[2], Robyn Martin[3]. *[1]Tripler Army Medical Center, Honolulu, HI. [2]Army Public Health Center, Aberdeen Proving Ground, MD. [3]Naval Health Research Center, San Diego, CA.*

(No relevant relationships reported)

The incidence of and risk factors for cold weather injury (CWI) in the US Army have been well characterized. Unlike the 'heat season,' when the risk of heat illness is highest and application of risk mitigation procedures is mandatory, there is no definition of the 'cold season' and the proportion of CWI that occur outside of a defined cold season is unknown. **PURPOSE**: To identify the cold season and to determine the within-year seasonal distribution of CWI at select Army installations. **METHODS**: The 10 US Army installations with the highest frequency of CWI from 1 July 2008-30 June 2013 were identified and used for analysis. In- and out-patient CWI data (ICD-9-CM codes 991.0-991.9, first, second or third diagnoses only) were obtained from the Defense Medical Surveillance System. Piecewise regression analysis was utilized to determine the critical cut points at which trends in CWI significantly increased or decreased, indicating the start and end, respectively, of the cold season. The proportional distribution of EHI within the cold season, overall and by installation, was determined. **RESULTS**: During the study period there were 1,012 CWI and the overall rate was 0.79 per 10,000 person-months. The highest rate occurred during the month of February (2.16 per 10,000 person-months) and the installation with the highest rate was Ft Drum, NY (5.40 per 10,000 person-months). There was at least one CWI during every week of the year during the 5 year study period. Piecewise regression analyses indicated that on average the cold season started during week 14 (Sept 30) and ended during week 39 (March 24). Using this definition, 83.2% (842/2012) of CWI occurred during the cold season. The longest cold season occurred at Ft Wainwright, AK (34 weeks) and the shortest at Ft Carson, CO (17 weeks), illustrating the considerable variability between locations. **CONCLUSIONS**: Our data suggest that the risk of CWI exists year round at select Army installations, though further research sub-grouped by type of CWI is warranted. Based on the piecewise regression analysis, we recommend that the 'cold season' starts 1 October and continues through March, as ~83% of CWI occurred during this period.

2339   Board #175   June 1 9:30 AM - 11:00 AM

Incidence and Severity of Game-Related College Football Thoracoabdominal Injuries on Artificial versus Natural Grass

Theresa M. Gustaveson, Michael C. Meyers, FACSM, Shad K. Robinson. *Idaho State University, Pocatello, ID.*

Reported Relationships: T.M. Gustaveson: *Contracted Research - Including Principle Investigator; Partial support by FieldTurf USA.*

In the past, serious injuries have been attributed to playing on artificial turf. Newer generations of artificial turf, however, have been developed to duplicate the playing characteristics of natural grass. No long-term studies have compared articular and muscle trauma of the thoracoabdominal region between the two surfaces. **PURPOSE:** To quantify incidence and severity of game-related thoracoabdominal collegiate football injuries on artificial turf vs natural grass. **METHODS:** A total of 24 universities were evaluated over 8 competitive seasons for injury incidence rates (IIRs) across injury severity, injury category, injury mechanism and situation, primary type of injury, anatomical location, type of tissue injured, elective imaging and surgical procedures, and turf age. **RESULTS:** Of the 1,237 collegiate games documented, 628 (50.8%) were played on artificial turf vs 609 (49.2%) played on natural grass. A total of 379 thoracoabdominal injuries were reported with 147 (38.8%) occurring on

artificial turf, and 232 (61.2%) on natural grass. MANOVAs per 10 games indicated a significant playing surface effect by injury severity ($F_{2,379}$ = 7.505; P = .001), primary type of injury ($F_{12,379}$ = 4.412; P = .000), tissue type ($F_{3,379}$ = 9.412; P = .000), elective imaging and surgical procedures ($F_{3,379}$ = 3.517; P = .007), and turf age ($F_{2,379}$ = 91.093; P = .000), but not by injury category ($F_{3,379}$ = 2.175; P = .089), injury mechanism ($F_{3,379}$ = 1.439; P = .133), or injury situation ($F_{8,379}$ = 1.329; P = .181). Univariate analyses indicated significantly lower (P = .05 - .0001) IIRs across severity, both in 1st degree, 2.1 (95% CI, 1.8-2.5) vs 2.9 (2.5-3.2), and 2nd degree IIRs, 0.1 (95% CI, 0.1-0.2) vs 0.7 (0.5-0.9); defensive positions, 0.8 (95% CI, 0.6-1.1) vs 1.4 (1.2-1.7); contusions, 1.3 (95% CI, 1.1-1.6) vs 2.0 (1.7-2.3); muscle, 2.0 (95% CI, 1.7-2.3) vs 3.0 (2.6-3.4); MRI, 0.1 (95% CI, 0.0-0.2) vs 0.2 (0.1-0.4); and turf lasting 4-7 years, 0.8 (95% CI, 0.6-1.1) vs 0.9 (0.7-1.2), and 8+ years 0.1 (95% CI, 0.1-0.2) vs 0.5 (0.4-0.8) when comparing artificial turf vs natural grass, respectively. **CONCLUSION:** Since minimal differences existed between artificial turf and natural grass over an 8-year period of competitive play, artificial turf is a practical alternative when comparing thoracoabdominal injuries in collegiate football.

Racquet Sport-Related Injuries Treated in United States Emergency Departments, 2007-2016

Andrew McBride, Morteza Khodaee, 80045, FACSM. *University of Colorado - Denver, Aurora, CO.* (Sponsor: Morteza Khodaee, FACSM)

(No relevant relationships reported)

Title: Racquet Sport-Related Injuries Treated in United States Emergency Departments, 2007-2016
Authors: Andrew J. McBride, Morteza Khodaee, FACSM
Institutions: University of Colorado-Denver
Purpose: Racquet sports, especially tennis, have grown in popularity in the United States. There are limited studies analyzing injuries in badminton, squash, and other lesser-known racquet sports. We aimed to analyze the injury pattern in all racquet sports that resulted in the United States emergency department (USED) visits.
Methods: This was a retrospective analysis of National Electronic Injury Surveillance System data on racquet-sport related injuries that presented to the USEDs for the past 10 years.
Results: From 2007-2016, there were 8,024 cases of racquet-sports related injuries that presented to USEDs. The majority of these injuries were in men (61%). Caucasians had the highest percentage of injuries (47%) followed by African Americans (7%) and Asian Americans (3%). Sprain were the most common types of injuries (34%) followed by fracture (13%) and contusion/abrasion (12%) The body part most frequently injured was the ankle at 13% followed by facial injuries at 10%. Over 93% of injuries were treated and released from the USED while 5% of patients were admitted for hospitalization. Approximately two third of injuries occurred at a place of recreation or sport. Tennis was the most common sport of injury at 68% followed by one of squash, racquetball and paddleball at 17%. The summer months were the most common months of injury and adolescence was the most common age group injured. Women tennis players (75% compared to 63% in men) and men squash/racquetball/paddleball players (22% compared to 9% in women) were more likely to present to the USED with injuries.
Conclusion: Racquet sport-related injuries are varied in their presentation and body part involvement. Gender differences were seen in injury rates for tennis and squash/racquetball/paddleball. Tennis-related injuries make up two-thirds of racquet sport-related injuries making knowledge of other racquet sport injuries important.

Incident and Severity of Lower Leg NCAA Women's Soccer Trauma on Artificial versus Natural Grass

Sarah Friend, Michael C. Meyers, FACSM. *Idaho State University, Pocatello, ID.* (Sponsor: Michael Meyers, FACSM)

Reported Relationships: S. Friend: *Contracted Research - Including Principle Investigator; Partial support by FieldTurf USA.*

Recently, artificial turf has been developed to duplicate the playing characteristics of natural grass. No long-term studies have compared game-related, NCAA women's soccer musculoskeletal trauma of the lower leg between surfaces. **PURPOSE:** To quantify incidence, mechanisms, and severity of game-related lower leg NCAA women's soccer injuries on artificial turf vs natural grass. **METHODS:** 13 universities were evaluated over a 5-year period for injury incidence rates (IIR) across injury category, severity of injury, primary type of injury, elective imaging/ surgery, type of tissue injured, field conditions, position played at time of injury, turf age, anatomical location, injury mechanism, and injury situation. **RESULTS:** In sum, 797 collegiate games were evaluated for women's soccer injuries sustained on artificial turf or natural grass, with 355 games (45%) played on artificial turf and 442 games (55%) played on natural grass. A total of 245 injuries were documented, with 91 occurring on artificial turf and, 154 occurring on natural grass. MANOVAs per 10 games indicated a significant playing surface effect by severity of injury ($F_{2,242}$ = 7.865; P < .001), field

conditions ($F_{3,241}$ = 6.862; P <.0001), skill position at time of injury ($F_{9,235}$ = 2.821; P = .002), turf age ($F_{3,241}$ = 13.612; P < .0001), injury situation ($F_{8,236}$ = 2.411; P = .006), but not by primary type of injury ($F_{87,238}$ = 0.997; P = .445), elective imaging/ surgical ($F_{34,239}$ = 4.183; P = .382), type of tissue injured ($F_{4,240}$ = 1.102; P=.333), lower extremity-joint/ muscle ($F_{10,234}$ = 0.810; P = .620)/ ($F_{3,231}$ = 0.331; P = .857). Post hoc analyses indicated significant IIRs (P =.05 =.001) across first degree, second degree, 0.0 (95% CI, 0.0-0.0) vs 0.1 (95% CI, 0.1-0.1); no precipitation/ dry field, 0.2 (95% CI, 0.2-0.3) vs 0.3 (95% CI, 0.2-0.3); center back/ sweeper/ libero, 0.0 (95% CI, 0.0-0.1) vs 0.1 (95% CI, 0.0-0.1); dual/ deep-lying striker, 0.0 (95% CI, 0.0-0.0) vs 0.0 (95% CI, 0.0-0.1); turf age of 1-3 yrs, 0.1 (95% CI, 0.1-0.1) vs 0.1 (95% CI, 0.1-0.1); and turf age of 8+ yrs 0.0, (95% CI 0.0-0.0) vs 0.1 (95% CI, 0.0-0.1). **CONCLUSION:** Although similarities existed between artificial turf and natural grass during competitive play, artificial turf is a practical alternative for natural grass when comparing this specific artificial surface and level of play.

Head Impacts In Female Professional Mixed Martial Arts

Mark Jesunathadas, Elizabeth D. Edwards, Trenton E. Gould, Scott G. Piland. *University of Southern Mississippi, Hattiesburg, MS.*

(No relevant relationships reported)

Mixed martial arts (MMA) is a full-contact combat sport, which in recent years has experienced an increase in participation of female athletes. Previous research has indicated knockouts (KO) and technical knockouts (TKO), which are typically associated with head trauma, are frequent occurrences (46.2% of match outcomes are determined by KO and TKO) in male MMA competitions. However, the occurrences and context of KOs and TKOs have not been investigated in female MMA competitions. **PURPOSE**: To characterize the occurrences and context of KOs and TKOs in female professional MMA competition. **METHODS**: Publicly available score card and video data of female Ultimate Fighting Championship (UFC) competitions that occurred between November 2014 (UFC 180) and July 2016 (UFC 200) were analyzed. Score card information from www.ufc.com and www.sherdog.com was used to determine the occurrences of KOs and TKOs of female UFC fights. The MMA Knockout Tool was used to analyze video of the female UFC fights that ended in KO or TKO. The MMA Knockout Tool allows for coding of the context of a KO and TKO as well as coding the number of head and body strikes sustained by the loser in the 30 s prior to the KO or TKO. **RESULTS**: Two out of a total 29 matches ended in KO while 4 ended in TKO due to repetitive strikes. One other TKO was due to a musculoskeletal injury and was not included in the analysis. The combined incidence of KOs and TKOs from head trauma was 103.4 per 1000 athlete exposures (AEs). Video analysis of the KOs and TKOs revealed that in 5 of the 6 KO/TKOs the loser was standing and not clinched with the winner, and in 1 fight the loser was on the ground. In the 30 s prior to TKO the loser sustained a mean of 15.5 ± 7.6 impacts to the head with a mean 8.0 ± 3.6 strikes to the head occurring in the final 10 s. The head regions that sustained the greatest number of strikes within the 30 s prior to KO or TKO were the mandibular and temporal regions, which received 34.7 and 30.7 % of all head strikes, respectively. **CONCLUSIONS**: KO and TKO events may represent a conservative estimate of concussive events in MMA competition. The incidence of 103.4 TKO/KOs per 1000 AEs is less than that observed for professional female boxing and male MMA competitions. Furthermore, our data suggest that engaging in a standup versus ground fight is associated with greater incidences of KO/TKOs.

Injuries Resulting From Checking In United States High School Boy's Lacrosse, 2008/09-2015/16 School Years

E. Paige Harrell[1], Zachary Y. Kerr[1], Andrew E. Lincoln[2], Lauren A. Pierpoint[3], Margot Putukian, FACSM[4], Shane V. Caswell[5]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC. [2]MedStar Sports Medicine Research Center, Baltimore, MD. [3]University of Colorado Anschutz, Aurora, CO. [4]Princeton University, Princeton, NJ. [5]George Mason University, Manassas, VA.* (Sponsor: Margot Putukian, FACSM)

(No relevant relationships reported)

High school boys' lacrosse allows for intentional contact through body and stick checking. Recently, rules further limiting body checking were implemented to reduce injury risk. Yet, there is limited research focused on the epidemiology of injuries resulting from being checked.**PURPOSE:** Describe the epidemiology of injuries resulting from being body and stick checked in high school boys' lacrosse during the 2008/09-2015/16 school years. **METHODS:** Athletic Trainers (ATs) collected injury and athlete-exposure (AE) data via the High School Reporting Information Online system. Injury was defined as: (1) occurring from participation in a school-sanctioned completion or practice; (2) requiring medical attention by an AT or physician; and (3) resulting in time loss of at least 24 hours (although all concussions, dental injuries, fractures were included). Analyses were restricted to injuries occurring from being

body and stick checked. Injury counts, rates per 10,000AE, and injury rate ratios (IRR) with 95% confidence intervals (CI) were reported. Linear regression estimated annual average changes in injury rates. **RESULTS**: ATs reported 160 "body checked" and 137 "stick checked" injuries. These injuries occurred during 933,165AE, leading to injury rates of 1.71 and 1.47/10,000AE, respectively. A decrease in injury rate was found for "body checked" injuries (annual average change of -0.18/10,000AE; 95%CI: -0.23, -0.13; P<0.001) but not for "stick checked" injuries (annual average change of 0.02/10,000AE; 95%CI: -0.07, 0.11; P=0.68). The injury rate was higher in competitions than practices for both "body checked" (4.35 vs. 0.56/10,000AE; IRR=7.82; 95%CI: 5.40, 11.34) and "stick checked" injuries (3.40 vs. 0.62/10,000AE; IRR=5.51; 95%CI: 3.81, 7.96). Most "body checked" injuries were to the head/face (47.5%) and shoulder (16.9%), and diagnosed as concussions (43.8%). In contrast, most "stick checked" injuries were to the hand/wrist (29.2%) and head/face (21.2%), and diagnosed as fractures (32.8%) and contusions (27.7%). **CONCLUSION:** "Body checked" and "stick checked" injuries occurred at higher rates in competitions than practices, but varied in body part and diagnosis distributions. Reductions in the "body checked" injury rate across time may be associated with rule changes limiting body checking.

2344   Board #180   June 1 9:30 AM - 11:00 AM

The Epidemiology Of Dii Baseball, Basketball, And Soccer Injuries And Potential Preventive Strategies

Christopher P. Holdren, Andrea Fradkin, FACSM. *Bloomsburg University of Pennsylvania, Bloomsburg, PA.*

(No relevant relationships reported)

Baseball (B), basketball (K), and soccer (S) are among the top-five sports causing injury in males. To date, no published studies have prospectively investigated the epidemiology of sporting injuries. **PURPOSE:** To design and implement a prospective injury surveillance system to describe B, K, and S injuries, and devise potential preventive measures to help reduce injury risk. **METHODS:** Participants were recruited from Bloomsburg University's B, K, and S teams. Sport-specific injury reporting forms were developed, and injury details were recorded by athletic trainers. Information was collected on the injury and circumstances surrounding the injury, with injury defined as "damage to the body that occurs as a result of competing, practicing and/or participating in an athletic activity". **RESULTS:** The B, K, and S teams consisted of 32, 11, and 25 players respectively. There were 73 injuries sustained (B = 34, K = 12, S = 27), with significant differences (p ≤ 0.001) in all injury parameters between sports. Excluding those who were unsure, in all sports, soft tissue injuries were most common (66.6%), with B having more non-contact injuries, and K and S having more contact injuries (p ≤ 0.001). There were similar numbers of head and torso injuries among sports, however B had more upper extremity injuries (p ≤ 0.05), while K and S had more lower extremity injuries (p ≤ 0.001). B and K had more competition injuries (p ≤ 0.05), while S had more training injuries (p ≤ 0.001). **CONCLUSION:** Due to the high injury prevalence, this study reinforces the need for injury prevention strategies, and further highlights that all sports require unique injury prevention strategies, as well as tailoring these strategies to players' positions. For all sports, undertaking a suitable warm-up, evaluating and correcting improper mechanics, and enforcing competition rules may reduce injury risk. Proper conditioning to provide strength and flexibility to the lower extremities in K and S, and upper extremities in B also seems warranted. In S specifically, modifying training intensities and investigating footwear worn and surfaces where games and trainings are conducted might be useful. Whereas in K, plyometric training could be used to improve landing techniques. Lastly, in B, proper preseason conditioning, particularly in pitchers should be investigated.

2345   Board #181   June 1 9:30 AM - 11:00 AM

Descriptive Epidemiology of Injuries AmongRecreational Mountain Bikers

Lauren Samuels[1], Julia Kammel[1], Jonathan Finnoff, FACSM[2], Masaru Teramoto[1], Stuart Willick, FACSM[1]. *[1]University of Utah, Salt Lake City, UT. [2]Mayo Clinic, Rochester, MN.*

(No relevant relationships reported)

Introduction:
Although mountain biking is an inherently dangerous activity, participation in the sport is steadily rising. To date, there are very few publications on mountain biking injuries. Further investigation of mountain biking injuries can improve medical care and lead to the development of safety initiatives.
Purpose:
The aim of this study was to describe injury patterns among recreational mountain bikers in the United States.
Methods:
Mountain biking injury data between the years 1996-2016 were gathered from the National Electronic Injury Surveillance System (NEISS). Any injury sustained while mountain biking that resulted in an emergency department visit to one of the 96 NEISS

participating facilities was included in this study. The NEISS database is designed to represent a probability sampling of emergency departments nationwide. Data analysis was performed using descriptive statistics, a χ^2 test, and a logistic regression model. **Results:**
A total of 2,621 mountain biking injury cases were identified in the NEISS database in the past 11 years. Fracture was the leading diagnosis (26.86%), followed by contusion/abrasion (19.11%), strain/sprain (14.88%), laceration (14.42%), internal injury (6.87%), dislocation (3.97%), and concussion (3.93%). The most commonly injured body part was the shoulder (17.44%), followed by head (11.10%), upper trunk (10.07%), and knee (6.64%). Males had a significantly higher proportion of shoulder injuries than did females (20.3% of males vs. 8.7% of females, Rao-Scott χ^2 = 30.66, p < 0.001). On the other hand, a significantly higher proportion of females than males sustained elbow injuries (4.7% of males vs. 11.0% of females, Rao-Scott χ^2 =25.46, p < 0.001) and wrist injuries (4.8% of males vs. 8.5% of females, Rao-Scott χ^2 = 9.55, p < 0.011). The logistic regression model showed that these results held true even after adjusting for age.
Conclusion:
The results of this study suggest mountain biking injuries are commonly seen in emergency departments, and injuries are often severe. The shoulder is the most commonly injured anatomic location, with different injury patterns seen among males and females. Further research is needed to determine specific mechanisms of injury that might inform injury prevention strategies.

2346   Board #182   June 1 9:30 AM - 11:00 AM

Incidence and Severity of College Football Hand and Wrist Injuries on Artificial versus Natural Grass

Marissa R. Chase, Michael C. Meyers, FACSM, Shad K. Robinson. *Idaho State University, Pocatello, ID.*

Reported Relationships: M.R. Chase: *Contracted Research - Including Principle Investigator; Partial support by FieldTurf USA.*

Over the past two decades, newer generations of artificial turf have been developed to duplicate the playing characteristics of natural grass. Few turf-related studies have been published comparing hand and wrist trauma. **PURPOSE:** To quantify incidence and severity of game-related collegiate football hand and wrist injuries on artificial turf vs natural grass. **METHODS:** 24 universities were evaluated over 8 competitive seasons for injury incidence rates (IIRs) across injury severity, injury category, injury mechanism and situation, primary type of injury, anatomical location, type of tissue injured, elective imaging/surgery, field conditions, and turf age. **RESULTS:** Of the 1,237 collegiate games documented, 628 (50.8%) were played on artificial turf vs 609 (49.2%) played on natural grass. A total of 536 hand and wrist injuries were reported with 212 (39.6%) occurring on artificial turf, and 324 (60.4%) on natural grass. MANOVAs (Wilks' λ) indicated a significant playing surface effect by injury severity ($F_{2,533}$ = 8.053; P < .0001), primary type of injury ($F_{11,524}$ = 5.254; P < .0001), body part injured ($F_{4,531}$ = 3.294; P = .006), tissue type ($F_{3,532}$ = 12.421; P < .0001), elective imaging/surgery ($F_{4,531}$ = 2.798; P = .039), field conditions ($F_{3,532}$ = 13.991; P < .0001) and turf age ($F_{3,532}$ = 90.901; P < .0001), but not by injury category, position played, injury mechanism, or situation. Post hoc analyses indicated significantly lower IIRs (P < .05 to .0001) observed across 2nd degree trauma, 0.2 (95% CI, 0.1-0.3) vs 0.6 (0.4-0.8); ligament sprains, 1.4 (95% CI, 1.2-1.7) vs 2.0 (1.7-2.3), and subluxations, 0.4 (95% CI, 0.3-0.6) vs 0.3 (0.3-0.5); joint, 2.1 (95% CI, 1.8-2.4) vs 2.5 (2.2-2.9), and muscle trauma, 0.6 (95% CI, 0.5-0.9) vs 2.0 (1.7-2.3); MRIs, 0.0 (95% CI, 0.0-0.1) vs 0.2 (0.1-0.3), and x-rays ordered, 1.7 (95% CI, 1.4-2.0) vs 2.2 (1.8-2.5); during adverse weather conditions, 0.3 (95% CI, 0.2-0.6) vs 1.2 (0.8-1.6); and turf lasting 4-7 yrs, 0.9 (95% CI, 0.7-1.2) vs 1.3 (1.1-1.6), and 8+ yrs, 0.1 (95% CI, 0.1-0.2) vs 0.8 (0.7-1.1) when comparing artificial turf to natural grass, respectively. **CONCLUSION:** Although similarities existed between both surfaces over an 8-year period of competitive play, artificial turf is in many cases safer than natural grass when comparing hand and wrist trauma in college football.

2347   Board #183   June 1 9:30 AM - 11:00 AM

Medical Attention Injury Rates in U.S. Women Rugby-7s Players by Positions

Christian Victoria[1], Victor Lopez Jr[2], Richard Ma[3], Meryle G. Weinstein[4], James L. Chen[5], Arun T. Gupta[6], Samuel Y. Haleem[7], Answorth A. Allen[8]. *[1]New York University, New York, NY. [2]Rugby Research and Injury Prevention Group, Inc, Hospital for Special Surgery, New York, NY. [3]University of Missouri, Missouri Orthopaedic Institute & Thompson Laboratory for Regenerative Orthopaedics, Columbia, MO. [4]New York University, Steinhardt School of Culture, Education and Human Development, New York, NY. [5]University of California, San Francisco, San Francisco, CA. [6]University of Calgary, Calgary, AB, Canada. [7]City College of New York of the City University of New York, New York, NY. [8]Hospital for Special Surgery, New York, NY.*
(Sponsor: Robert Cantu, FACSM)
(No relevant relationships reported)

PURPOSE: There is a lack of injury data on women's rugby, and less on the Olympic format of Rugby-7s. Reporting medical-attention injuries may provide a more complete picture of the true burden of injury and illness in sport. The aim was to determine medical attention (no time-loss) injury incidence in U.S. women's Rugby-7s. **METHODS**: A prospective epidemiology study of U.S. women Rugby-7s (6,768 players; 564 teams), in multi-level *USA Rugby* and *USA Sevens LLC* tournaments (2010-2014). Incidence (per 1000 player-hour (ph)) and biomechanism of medical attention injuries were captured via the Rugby Injury Survey & Evaluation (RISE) Report methodology. **RESULTS**: Medical attention injury rate was found at 84.4/1000 ph (n=356). Amongst positions, injuries were found at similar rates (backs: 60%, 59.3/1000ph, n=143; forwards: 40%, 53.6/1000ph, n=97; RR=1.11; P=0.447). Most injuries were acute (95%) occurring during the tackle (67%). Most match injuries were from a shoulder tackle (70%) (backs 72%; forwards 62%; RR=1.32; P=0.113). Recurrent injuries occurred at 25%. Lower extremity ligament sprains (53%) were most common, among injury types, muscle/tendon injuries were most common overall at 41% (backs 41/1000ph; forwards 42/1000ph; P=0.998). Knee injuries occurred more frequently in forwards (23%) than backs (16%; P<0.213). Head/neck injury rates, were 22% of all injuries. The sub-acute head contusion rate, where players were physician-cleared to return to sport was 6% (3.5/1000ph). **CONCLUSIONS**: Documentation of medical-attention incidents is recommended in the literature, as this is likely to capture a far greater number of ailments, than time loss injuries alone and will therefore, provide a more inclusive picture of the true burden of injury and illness in a population. A panoptic view of rugby-7s injury rates, provides fundamental gender injury data, to guide injury prevention protocols by stakeholders to guide player welfare. Head/neck and upper extremity injury rates (both at 21%) support an emphasis on tackling techniques for injury reduction. A program, including contact-based-awareness, for women newly introduced to this collision-sport, would nurture injury prevention. Furthermore, adherence on return to play protocols would decrease recurrent injury rates seen in this gender-specific cohort.

2348   Board #184   June 1 9:30 AM - 11:00 AM

The Epidemiology of Female Golfing Injuries

Andrea Fradkin, FACSM. *Bloomsburg University, Bloomsburg, PA.*
(No relevant relationships reported)

Golf is a popular sport worldwide, however, the tendency of players to be older and in poor physical condition contributes to its injury risk. Although golf has a moderate injury incidence, few studies have illustrated the extent of golfing injuries, and only one study has focused on female golf injuries. **PURPOSE:** To examine the injury profile of female golfers and investigate differences in injury epidemiology by age, handicap, experience, and participation. **METHODS:** Female golfers over 18 years with a registered handicap documented their 12-month injury status and associated golfing demographics. **RESULTS:** 1803 female golfers (median age: 51.3 years; handicap: 12.4; experience: 13.7 years) reported 671 injuries (37.2%) over a 12-month period, with the majority of injuries sustained during play (72.9%). The most common injury sites were the shoulder (23.2%), lower back (22.9%), and elbow (18.1%). Strains were the most frequent type of injury (43.0%), with overuse injuries most prevalent (32.2%), followed by a technical error (24.8%). Over half of all injuries required treatment from a healthcare professional (57.8%), and 1358 (75.3%) of the injured golfers reported an impact on their performance or participation. Over two-thirds of the injured golfers missed participation time due to their injury, and 187 of the injured golfers (10.4%) needed time off school or work. Chi-square analysis showed golfers' handicap (χ^2_4 = 23.747, p ≤ 0.001), hours of play (χ^2_8 = 35.735, p ≤ 0.001), hours of practice (χ^2_8 = 30.137, p ≤ 0.001), and experience (χ^2_9 = 28.003, p ≤ 0.001) were significantly associated with their injury status. Handicap, hours of play, and experience level were also significant independent predictors of injury. The Hosmer and Lemeshow test indicated acceptable goodness of fit (p = 0.905).

CONCLUSION: This study confirms the common occurrence of, and impact injuries have on golfers. Lower handicap golfers were more likely sustain an injury than higher handicap golfers, potentially due to increased exposure time required to obtain lower handicaps. This is further supported as exposure time and experience level were found to be significant predictors of injury. Before suggesting limits to golf participation, other prevention avenues focusing on specific female golfer characteristics must be investigated.

A Cross-sectional Look At Injuries Among Individuals Engaged In Crossfit Training: A Four-year Study.

Yuri Feito, FACSM[1], Evanette K. Burrows[2], Loni P. Tabb[2]. [1]*Kennesaw State University, Kennesaw, GA.* [2]*Drexel University, Philadelphia, PA.*
(No relevant relationships reported)

Little epidemiological data exist to describe the incidence of injury among individuals engaged in CrossFit training. **PURPOSE**: To examine the prevalence and incidence of injury among individuals engaged in CrossFit training over a four-year period. **METHODS**: Between 2013-2017, individuals (Females = F; Males = M) engaged in CrossFit training were asked to complete a survey designed to examine variables related to their participation in CrossFit training and their injury history over the previous 12 months (survey was distributed at the end of each year). **RESULTS**: A total of 3,079 individuals responded to the online survey. Data was only analyzed for the cases that had complete data (N = 3,049; F = 48.6%, M = 51.4%). Overall, 30.5% (n = 931) of individuals reported experiencing an injury, with no difference between F and M [14% (n = 436); 16.2% (n = 495), respectively; $\chi2$= 1.65, $p = 0.1989$]. Of those who experienced an injury, 62.4% (n = 581) reported an injury to a single body part, while 37.6% (n = 350) reported injuries to multiple body parts; in addition, there were significant differences between males and females ($\chi2$=8.43, p=0.0037) in the number of body parts injured. The shoulders (39%), back (36%), knees (15%), elbows (12%), and wrists (11%) recorded the highest prevalence of injury. Based on the assumed maximum number of workout hours per week, the injury rate was 0.27 per 1,000 hours (F = 0.28, M = 0.26); whereas, the assumed minimum number of workout hours per week resulted in an injury rate of 0.74 per 1,000 hours (F = 0.78, M = 0.70). **CONCLUSIONS**: To our knowledge, this is the first study to examine the prevalence and incidence of injury in a multi-year large sample of individuals participating in CrossFit training. Our findings support the notion that CrossFit training has similar rates of injury than other forms of exercise training.

2351   Board #187   June 1 9:30 AM - 11:00 AM
Incidence And Severity Of Collegiate Men's Soccer Lower Leg Injuries On Artificial Versus Natural Grass

Shianne M. Blessing, Michael C. Meyers, FACSM, Shad K. Robinson. *Idaho State University, Pocatello, ID.*
Reported Relationships: S.M. Blessing: *Contracted Research - Including Principle Investigator; Partial support by FieldTurf USA.*

Recently, artificial turf has been developed to duplicate the playing characteristics of natural grass. No long-term studies have compared match-related, collegiate men's soccer lower leg trauma between the two surfaces. **PURPOSE:** To quantify incidence, mechanisms, and severity of match-related lower leg collegiate men's soccer injuries on artificial turf versus natural grass. **METHODS:** 11 universities were evaluated over 6 seasons for injury incidence rate (IIR) across injury severity, lower leg joint/muscle, elective imaging/surgery, type of tissue injured, injury mechanism/situation, player position, injury category, field conditions, cleat design, and turf age. **RESULTS:** Overall, 380 games (49.7%) were played on artificial turf versus 385 games (50.3%) played on natural grass. A total of 256 injuries were documented, with 109 occurring on artificial turf and 147 on natural grass. MANOVAs per 10 games indicated a significant playing surface effect by lower leg trauma-joint/muscle ($F_{11,256} = 5.668$; $P < .0001$/$F_{4,256} = 17.931$; $P < .001$), elective imaging/surgery ($F_{3,256} = 18.129$; $P < .0001$), type of tissue injured ($F_{5,256} = 12.413$; $P < .0001$), injury mechanism/situation ($F_{16,256} = 2.305$; $P < .001$/$F_{8,256} = 5.592$; $P < .0001$), injury category ($F_{6,256} = 40.251$; $P < .0001$), and cleat design ($F_{3,256} = 2.258$; $P < .047$), but none observed by severity injury, player position, and field conditions. Significantly lower IIRs (P = .05-.0001) across distal tibiofibular joint, 0.3 (95% CI, 0.2-0.5) vs 0.5 (95% CI, 0.3-0.8); lower leg muscles combined, 1.4 (95% CI, 1.1-1.8) vs 2.2 (95% CI, 1.8-2.6); total medical procedures combined, 0.8 (95% CI, 0.6-1.1) vs 1.2 (95% CI, 0.9-1.6); ligament sprains, 1.4 (95% CI, 1.1-1.8) vs 1.5 (95% CI, 1.2-1.9); muscle-tendon strain/spasm/tears, 0.6 (95% CI, 0.4-0.9) vs 0.3 (95% CI, 0.2-0.5); tackled from the side/behind, 0.7 (95% CI, 0.5-1.0) vs 1.2 (95% CI, 0.9-1.5); player-turf impacts, 0.2 (95% CI, 0.1-0.3) vs 0.4 (95% CI, 0.2-0.6); adverse weather conditions combined, 0.5 (95% CI, 0.3-0.8) vs 1.3 (95% CI, 1.0-1.7) between artificial turf and natural grass, respectively. **CONCLUSION:**

Although similarities exist between both surfaces during competitive play, artificial turf is in many cases safer than natural grass when comparing this specific artificial surface and level of play.

Epidemiology Of Sports-related Facial Injuries Treated In The United States Emergency Departments Between 1997-2016.

Natalie Ronshaugen, Morteza Khodaee, FACSM. *University of Colorado, Aurora, CO.*
(No relevant relationships reported)

Purpose: Worldwide, facial injuries in sports make up a large number of emergency room visits each year. The purpose of this study was to describe the epidemiology of sports related facial injuries that presented to the United States emergency departments (EDs). **Methods:** This was a retrospective analysis of the data of facial injuries in the ED related to sports from the National Electronic Injury Surveillance System (NEISS) from 1997-2016. **Results:** A total of 183,985 people presented to US EDs for sports related facial injuries from 1997-2016. The average age was 19 years. About three quarters of patients were male. The most common injury was facial laceration (50%), followed by contusion/abrasion (27%), fracture (12%), followed by eyeball injuries (10%). The majority did not require admission and were discharged from the ED (97%). The most common sports associated with facial injuries were biking (19%), basketball (16%), baseball (11%), football (6%), softball (4%), and soccer (4%). The most common sport associated with male facial injuries was biking (19%), followed by basketball (18%), baseball (12%), football (8%), and soccer (4%). The most common sport associated with female facial injuries was biking (21%), followed by softball (10%), basketball (8%), baseball (7%), and soccer (5%). **Conclusion:** This study identifies common facial injuries in sports and which sports are more likely to cause them. Biking and basketball have the highest incidence of facial injuries overall though softball is the second most common sport associated with female injuries. Most injuries occurred in males. Most injuries were minor in nature and did not require hospitalization. <!--EndFragment-->

Profile Of Non-time-loss Conditions/injuries In U.s. Men'S Rugby-7s Players

Richard Ma[1], Victor Lopez Jr[2], Meryle G. Weinstein[3], Christian Victoria[4], James L. Chen[5], Arun T. Gupta[6], Martena T. Mettry[7], Answorth A. Allen[8]. [1]*University of Missouri, Missouri Orthopaedic Institute & Thompson Laboratory for Regenerative Orthopaedics, Columbia, MO.* [2]*Rugby Research and Injury Prevention Group, Inc., Hospital for Special Surgery, New York, NY.* [3]*New York University, Steinhardt School of Culture, Education and Human Development, New York, NY.* [4]*New York University, New York, NY.* [5]*University of California, San Francisco, San Francisco, CA.* [6]*University of Calgary, Calgary, AB, Canada.* [7]*City College of New York of the City University of New York, New York, NY.* [8]*Hospital for Special Surgery, New York, NY.* (Sponsor: Robert C. Cantu, FACSM)

Reported Relationships: R. Ma: *Contracted Research - Including Principle Investigator; USA Rugby New England and Empire GU Rugby Football Unions and the National Operating Committee on Standards for Athletic Equipment grant (ID 44-16), Chapel Hill, NC, USA.*

PURPOSE: Rugby-7s, on the Olympic program, over the next decade, has a dearth of injury data, limiting injury prevention. Most injury reporting focuses on time-loss injuries with little or no data on medical attention injuries. The aim was to determine the match non-time-loss injury incidence in U.S. men's Rugby-7s. **METHODS**: A prospective epidemiology study of 17,770 U.S. men Rugby-7s players (1,474 teams), in multi-level *USA Rugby* and *USA Sevens LLC* tournaments (2010-2014). Incidence (per 1000 player-hour (ph)) and biomechanism of non-time-loss injuries were captured via the Rugby Injury Survey & Evaluation (RISE) Report methodology. **RESULTS**: Non-time-loss injuries were found at 66.1/1000 ph (n=686). Positionally, backs encountered more injuries (63%; 67.4/1000ph; n=400) than forwards (36%; 52.4/1000ph; n=233; RR=1.3; P=0.002). Most injuries were acute (93%), occurring in the tackle (67%). Shoulder tackles resulted in most non-time-loss injuries (63%) (backs 65%; forwards 58%; RR=1.7; P<0.001). Recurrent injuries (23%) occurred frequently. Main injuries were lower extremity ligament sprains (14.2%). Overall head/neck injury rates were 23%, and found higher with incorporation of tackles (26%). The sub-acute head trauma/contusion rate, where players were physician-cleared to return to sport (non-time loss) was 4.9% (3.2/1000ph). **CONCLUSIONS**: Recording non-time-loss (medical attention) injuries will provide a true burden of injury and illness among the growing U.S. Rugby-7s population. Most injuries occur to the lower extremity (41%), reflective of the greater amount running, acceleration and deceleration in the Rugby-7s format. Head/neck non-time-loss injury rates were found lower than the "all medical attention injuries (30%)" in community international male Rugby-15s. Most injuries

---

were related to tackling amongst the upper extremity (35%), and head/neck (26%), making these areas a focus to reduce risk in the U.S. and support tackle-technique evaluations especially with head positional focusing and its target area (lateral hip). Proper medical assessments, need to scrutinize return to play post-tournaments to reduce recurrent injury risk in the U.S. men's cohort. Investigations such as this will aid in understanding the current needs and allocation of medical resources for Rugby-7s.

2354   Board #190   June 1 9:30 AM - 11:00 AM

Perfectionist Concerns Predict Injury Risk In Collegiate Distance Runners - Preliminary Findings From A Prospective Study

Lace E. Luedke[1], Brian J. Wallace[1], Maya L. Puleo[1], Mitchell J. Rauh, FACSM[2]. [1]University of Wisconsin - Oshkosh, Oshkosh, WI. [2]San Diego State University, San Diego, CA. (Sponsor: Mitchell J Rauh, FACSM)
(No relevant relationships reported)

Distance runners have a high incidence of running-related injury (RRI). While anatomical, biomechanical, and training load have been associated with RRIs, psychological factors like perfectionism may also contribute to injury risk. Perfectionist strivings (high personal standards [PS]) can be adaptive, but perfectionist concerns (concerns over mistakes [COM] and doubts about actions [DAA]) are considered maladaptive. The combination of high PS with high COM and DAA is considered unhealthy perfectionism and may increase a runner's risk of RRI. **PURPOSE:** To determine whether perfectionist concerns were associated with RRI occurrence in distance runners. We hypothesized that runners with higher PS and COM and/or DAA would have a higher incidence of RRI during the season. **METHODS:** Thirty-four NCAA Division III collegiate cross country runners (18 males, 16 females; mean age of 19.6±1.2 years; BMI of 20.6±1.8) completed the Sport Multidimensional Perfectionism Scale-2 (Sport-MPS-2) on the first day of their competitive season. Runners were followed prospectively during the first 8 weeks of their season for any RRIs resulting in limited or missed practices or competitions. Fifteen runners (44.1%) experienced a time loss RRI. Independent t-tests were used to compare mean differences of PS, COM and DAA scores between runners who experienced a RRI and runners without RRI. Odds ratios (OR) and 95% confidence intervals (CI) assessed the risk of RRI between runners with and without perfectionist concerns. **RESULTS:** Injured runners rated their COM higher (23.5±4.9 points) than uninjured runners (19.9±5.3 points) (p=0.05). Injured runners also rated their DAA higher (14.5±4.2 points) higher than uninjured runners (11.4±3.6 points) (p=0.03). Runners with perfectionist concerns (high PS and high COM and/or DAA) were 17 times more likely to experience a RRI during the season (OR=17.0, 95% CI 2.8-104.5, p=0.001). **CONCLUSIONS:** Runners reporting Sport-MPS-2 scores classifying them as having unhealthy perfectionism were more likely to incur a RRI than runners with lower Sport-MPS-2 scores. Further study is needed to determine whether interventions can modify perfectionist concerns and whether training load modifications for those with unhealthy perfectionism affect injury rates.

2355   Board #191   June 1 9:30 AM - 11:00 AM

Video Corroboration Of Player Incurred Impacts Using Trunk Worn Sensors Among National Ice-hockey Team Members

Aaron Pilotti-Riley, Davor Stoyanov, Muhammad Sohaib Arif, Stephen J. McGregor. *Eastern Michigan University, Ypsilanti, MI.* (Sponsor: Mark Peterson, FACSM)
(No relevant relationships reported)

Wearable sensors (WS) have been increasingly used to quantify training loads in team sports but can also be used to identify impacts. Helmet worn sensors have been used to identify head impacts, but there is currently no data with regard to whole-body impacts incurred by players in ice hockey using trunk-worn sensors.
PURPOSE: To use video to corroborate impacts identified by trunk-worn WS and determine validity of player incurred impacts (PII) among elite national ice hockey team members.
METHODS: 23 players on the U.S. National Team Development Program (NTDP) U18 team consented to procedures approved by EMU Human Subjects Committee. Players wore a BH-3 (Zephyr, MD) WS to measure occurrences of PII during games. Of the 23 players, 8 with the top activity levels each game determined by WS, were observed using video. Game video was collected by NTDP staff and synchronized with accelerometer data. Previous pilot work determined only impacts of > 6 g were relevant, so, impacts identified by WS of 6 - 7.9 g (Z3), 8 - 9.9 g (Z4) and 10+ g (Z5) were used to corroborate PII. Magnitude and duration of each identified impact were compared by category using MANOVA with Tukey *post hoc* (α= 0.05; SPSS 22.0, IBM, NY).
RESULTS: WS logged 419 on-ice impacts, 358 were confirmed true PII (85.5%), 60 were confirmed as other non-PII (14.3%) and 1 false positive (0.2%). For 358 PII, 17 (4.1%) were categorized as 1) Board contact/no check, 74 (17.7%) as 2) Board contact/

check, 202 (48.2%) as 3) Open ice check, 65 (15.5%) as 4) Player fall. For the 60 Non-PII, 19 (4.5%) as 5) other form of player to player event, 16 (3.8%) as 6) Hard Stop, 19 (4.5%) as 7) Slapshots and 6 (1.4%) as 8) other identifiable player events. 140 of the 200 Z3 events were confirmed PII (80%), 103 of 110 Z4 events (93.6%) and 95 of 109 Z5 events were PII (92.2%). The magnitude of impacts was not different by category, but the duration of category 6 (Hard stop; .058 s) was lower than categories 2, 4 and 7 (.112, .112, .133 s, respectively, p<.05).
CONCLUSION: These data show that using some limited criteria (e.g. impact magnitude and duration), PII can be identified with relatively high accuracy in ice hockey using trunk-worn wearable sensors. Use of these devices should allow a more complete understanding of the whole-body impacts incurred by players participating in ice hockey.

2356   Board #192   June 1 9:30 AM - 11:00 AM

Pain and Overuse in High School Baseball Pitchers During a Season

Michael P. McNally[1], James A. Onate[1], Jingzhen G. Yang[2], Kevin E. Klingele[2], Ajit MW Chaudhari, FACSM[1]. [1]Ohio State University College of Medicine, Columbus, OH. [2]Nationwide Children's Hospital, Columbus, OH. (Sponsor: Ajit Chaudhari, FACSM)
(No relevant relationships reported)

Over half of adolescent baseball pitchers retrospectively recall throwing arm pain during a baseball season, leading to the institution of pitch count regulations across high school baseball; however, how pain varies throughout the season is unknown. PURPOSE: The purpose of this study was to determine the prevalence of pain and overuse symptoms occurring in high school baseball pitchers throughout a high school baseball season. METHODS: 97 pitchers were enrolled in the research study from eight central and southern Ohio high schools. Weekly surveys were sent via text message to assess overuse and pain using a validated questionnaire throughout the season (11 weeks). 44 of the 60 participants who met all inclusion criteria responded a minimum of 80% of the time and were included in the analysis. Descriptive statistics and prevalence of overuse and pain were calculated weekly throughout the season. RESULTS: The final participant pool maintained an average weekly completion rate of 91.8±0.2%. 34.8±7.9% of participants reported symptoms of overuse each week, with peak prevalence occurring in the 4th week of practice (45.5%), and trending downwards with 26.2% reporting overuse in the final week of the season. Prevalence of severe overuse, determined by a report of moderate or greater effect on training or performance, was low throughout the season (4.0±1.8%). Of those who did experience any symptom of overuse, the mean weekly overuse score was 22.0±3.1 out of 100 (mild overuse). Pain prevalence showed similar trends, with 28.5±7.6% of participants reporting pain during the season, with the peak occurring in week 4 of practice (40.9%), and trending down with 19.0% experiencing pain in the final week. The majority who experienced pain reported mild pain (81.3±7.1%), with few experiencing moderate pain (18.0±7.1%), and only one report of severe pain occurring in week 3. CONCLUSION: Prevalence of pain and overuse symptoms varies over the course of a high school baseball season, peaking within the first five weeks of the season, though most pain is mild. Further research is needed to determine whether increases in pain at this time are preceded by an initial period of chronic overuse or more acute changes in workload.

Evaluating Methods For Utilizing Time-loss Data In Sports Settings Using A Sample Of US Collegiate Soccer-related Injury Observations

Avinash S. Chandran, Angelo Elmi, Heather Young, Loretta DiPietro, FACSM. *The George Washington University, Washington DC, DC.* (Sponsor: Dr. Loretta DiPietro, FACSM)
(No relevant relationships reported)

Time-loss has featured heavily in assessments of sports-related injury severity, and has been helpful in identifying sport-specific injury severity patterns.
PURPOSE: To compare inferences from distinct approaches for conditional, multifactorial modeling of time-loss due to injury in sports settings.
METHODS: Data from the NCAA-ISS for the 2004/05-2013/14 years, were used for this analysis. For unadjusted analyses, time-loss was considered a count outcome, following a Poisson distribution with some underlying intensity λ_j. Time-loss was examined across categories of potential time-loss determinants, by assuming a distribution-free random effect that accounted for the heterogeneity introduced by latent 'injury severity.' Then, the random effect was incorporated into multifactorial Poisson models. A second approach was considered for building multifactorial models of time-loss, where time-loss was considered a continuous outcome and Accelerated Failure Time (AFT) models were built with frailties to capture latent 'injury severity.' Both approaches for regression modeling were used to derive conditional parameter estimates. **RESULTS:** In both modeling approaches, injury site, injury mechanism

---

and injury history had the strongest overall associations with time lost due to injury. The direction and magnitudes of conditional estimates obtained from both regression approaches were also comparable. For example, in the Poisson approach, time-loss due to a contact injury was significantly lower than time-loss due to a 'similarly severe' non-contact injury (Adj. TLR= 0.835, 95% CI= [0.787, 0.885]). Similarly, in the AFT approach, a non-contact injury seemed more (~17%) deleterious (in terms of time spent injured) than a 'similarly severe' contact injury (β= -0.1906, p<0.0001). Importantly, post-hoc residual analyses (for the Poisson approach), and examinations of AICs (for the AFT approach) revealed that the random-effects based models fit these time-loss data better than models with only fixed-effects. **CONCLUSIONS:** Although using time-loss as an indicator to define 'injury severity' may be justifiable, comparing time lost due to 'similarly severe' injuries to 2 different sites, or resultant of 2 different mechanisms using the approaches described here, may be more scientifically salient.

2358   Board #194   June 1 9:30 AM - 11:00 AM
Perception about Running and Knee Joint Health among the Public and Healthcare Practitioners

Jean-Francois Esculier, Natasha M. Krowchuk, Linda L. Li, Jack E. Taunton, FACSM, Michael A. Hunt. *University of British Columbia, Vancouver, BC, Canada.* (Sponsor: Jack Taunton, FACSM)

(No relevant relationships reported)

PURPOSE: There is conflicting evidence surrounding the effect of running on knee joint health, particularly as it relates to knee osteoarthritis (KOA). The perception about running and knee joint health could affect choices of activities, but remains undocumented in the population. Given the uncertainty in the literature, the objective of this study was to evaluate the perception of the public and healthcare practitioners (HCP) with respect to running and KOA.
METHODS: A total of 397 public respondents (mean age=53.1 years, 163 females; 79 non-runners [NRUN]; 318 runners [RUN]) and 176 HCP (mean age=39.2 years, 68 females) completed an online cross-sectional survey. The survey included multiple-choice questions about perceptions of running as it relates to knee joint health, and about the appropriateness of maintaining running by individuals with KOA. The HCP subgroup was also asked about clinical recommendations to runners with KOA. Proportions (agree, uncertain, disagree) were compared between subgroups using chi-squared tests.
RESULTS: In general, 11% of respondents perceived running as detrimental for knee joint health (NRUN=43.0%, RUN=5.0%, HCP=6.3%; *p*<0.001) while 21.1% were uncertain. Frequent running was perceived as a risk factor for KOA by 6.3% of respondents (NRUN=24.1%, RUN=2.2%, HCP=5.7%; *p*<0.001) and 26.5% were uncertain. Running long distances (marathons, ultra-marathons) was perceived by 15.5% as a risk factor (NRUN=32.9%, RUN=9.1%, HCP=19.3%; *p*<0.001), but 38.7% were uncertain. As for continuation of running in the presence of KOA, 14.7% of respondents agreed that it would lead to greater cartilage damage (NRUN=40.5%, RUN=10.2%, HCP=11.1%; *p*<0.001). However, 31.3% were uncertain about the appropriateness of running in the absence of symptoms (NRUN=34.2%, RUN=38.7%, HCP=16.4%; *p*<0.001). The subgroup of HCP reported having recommended to 76.1% and 30.7% of runners with KOA to modify training parameters and to quit running, respectively.
CONCLUSION: These results suggest that many non-runners perceive running as detrimental to knee joint health. High rates of uncertainty warrant further studies to guide the population and HCP about the appropriateness of running for individuals with KOA, as it may influence choices of physical activity and clinical recommendations.

2359   Board #195   June 1 9:30 AM - 11:00 AM
Concussion and Mental Health among United States Service Academy Cadets

Jonathan C. Jackson[1], C. Dain Allred[1], Bonnie M. Anderson[1], Kevin J. Baldovich[1], Darren E. Campbell[1], Christopher J. D'Lauro[1], Megan N. Houston[2], Brian R. Johnson[1], Tim Kelly[2], Gerald T. McGinty[1], Kathryn L. O'Connor[3], Patrick G. O'Donnell[4], Karen Y. Peck[2], Joel B. Robb[1], Steven J. Svoboda[2], Michael F. Zupan[1], Paul Pasquina[5], Thomas McAllister[6], Michael McCrea[7], Steven P. Broglio, FACSM[3]. *[1]United States Air Force Academy, Colorado Springs, CO. [2]United States Military Academy, West Point, NY. [3]University of Michigan, Ann Arbor, MI. [4]United States Coast Guard Academy, New London, CT. [5]Uniformed Services University of the Health Sciences, Bethesda, MD. [6]Indiana University, Indianapolis, IN. [7]Medical College of Wisconsin, Milwaukee, WI.* (Sponsor: Steven P Broglio, FACSM)

(No relevant relationships reported)

Purpose: Few studies have evaluated the association between pre-participation psychological symptoms and concussion. The purpose of the current analysis was to evaluate the relationship between previous concussions, incident concussions, and Brief Symptom Inventory-18 (BSI-18) among U.S. military service academy cadets.
Methods: Data were analyzed from the Concussion Assessment, Research and Education (CARE) Consortium at three U.S. Service Academy sites. Between August 2014 and June 2017, 10,603 participants were enrolled and completed the BSI-18 assessing three psychological domains: somatization, depression, and anxiety. The total number of previous concussions (diagnosed or undiagnosed) was extracted from participant self-reports at baseline screening. Incident concussions were captured prospectively via the CARE protocol. Pearson correlations assessed associations between total number of prior concussions and BSI-18 scores. Analyses controlling for sex, age, service academy, previous concussions, and freshman status evaluated the association between baseline BSI-18 total score and odds of incident concussion.
Results: Total concussions and "diagnosed" prior concussions did not have a significant correlation with baseline BSI-18 scores. Statistical but not clinically significant correlations were observed between the total prior undiagnosed concussions and somatization (r = 0.05, p < 0.01), depression (r = 0.05, p < 0.01), anxiety (r = 0.04, p < 0.01), and total BSI-18 score(r = 0.06, p < 0.01). While significant, each of the correlations are small. Multivariable analyses estimating the odds of incident concussion based on BSI-18 total score were significant (X^2(7) = 271.68; p < 0.01). BSI-18 total score was a significant estimator of incident concussion odds (p = 0.02) even after controlling for all covariates (all p's < 0.01). For each point increase in BSI-18 score, the odds for incident concussion increased 2% (OR = 1.02; 95% CI: 1.01-1.03).
Conclusions: Univariate analyses demonstrate a limited association between previous self-reported undiagnosed concussions and BSI-18 scores. Pre-participation BSI-18 scores may be predictive of subsequent concussion likelihood. These results highlight the interaction between the functional concussive and psychological health.

Classification Accuracy Of A Moderate Intensity Cadence (steps/min) Threshold During Overground Walking

Zachary R. Gould[1], Elroy J. Aguiar[1], Scott W. Ducharme[1], Christopher C. Moore[1], John M. Schuna[2], Tiago V. Barreira[3], Stuart R. Chipkin[1], Catrine Tudor-Locke, FACSM[1]. *[1]University of Massachusetts Amherst, Amherst, MA. [2]Oregon State University, Corvallis, OR. [3]Syracuse University, Syracuse, NY.* (Sponsor: Dr. Catrine Tudor-Locke, FACSM)

(No relevant relationships reported)

A walking cadence of 100 steps/min has been established as a heuristic (evidence-based, rounded) threshold for absolutely defined moderate intensity (3 Metabolic Equivalents, METs). This threshold was calibrated during treadmill (TM) walking, however few studies have assessed its classification accuracy during overground (OG) walking. **PURPOSE:** To evaluate the classification accuracy of the 100 steps/min cadence threshold originally established during TM walking to OG walking. **METHODS:** Participants (n=75, 50.7 % men, 21-40 years of age, mean±SD age:

30.3±5.8 years, BMI: 24.8±3.4 kg/m^2) performed a 13 m overground corridor walk back and forth at a self-selected pace for 5-min. Cadence was hand-tallied and METs were obtained using indirect calorimetry. Receiver Operating Characteristic curves were used to determine the optimal OG cadence threshold associated with moderate intensity (Youden's index). Classification accuracies (counts and percentages for true positives and negatives, false positives and negatives) for the optimal OG and original TM heuristic (100 steps/min) thresholds were compared. **RESULTS:** Table 1 reports the classification accuracies of optimal OG and original TM heuristic cadence thresholds for identifying moderate intensity. The optimal OG threshold displayed an overall accuracy (i.e., correctly classified bouts; true positives and negatives) of 74.6%, compared to 73.3% for the TM heuristic threshold. The positive predictive value (i.e., probability of achieving ≥3 METs at ≥100 steps/min) was 80.3%. **CONCLUSION:** Optimal OG and original TM heuristic thresholds produced similar classification accuracies. The probability of achieving a moderate intensity when walking at a cadence ≥100 steps/min was >80%. The original TM heuristic (100 steps/min) threshold remains a valid heuristic threshold for achieving moderate intensity during overground walking.

Table 1: Classification accuracy of optimal OG and original TM heuristic cadence thresholds for corr					
	Cadence (steps/min)	True Negative	False Negative	True Positive	False Positive
Optimal OG	103	10 (13.3%)	11 (14.7%)	46 (61.3%)	8 (10.7%)
Heuristic (TM-based)	100	6 (8.0%)	8 (10.7%)	49 (65.3%)	12 (16.0%)

Aerobic Physical Activity Does Not Mediate the Association of Neighborhood Walkability with Overweight/Obesity in Latino Adults

Rosenda Murillo, Layton M. Reesor, Daphne C. Hernandez, Ezemenari M. Obasi. *University of Houston, Houston, TX.*

(No relevant relationships reported)

PURPOSE: To examine whether aerobic physical activity mediates the association between neighborhood walkability and overweight/obesity among Latino adults. **METHODS:** We used cross-sectional 2015 National Health Interview Survey data on Latino participants 18 years of age and older (n=4,765). Neighborhood walkability was assessed based on self-reported measures of built environment (e.g., presence of sidewalks, presence of paths/trails) and neighborhood safety (e.g., presence of traffic, crime). A neighborhood walkability score was created by combining the built environment and neighborhood safety items, with a higher score indicating higher walkability. Self-reported height and weight were used calculate body mass index categories (overweight/obesity versus normal weight). Aerobic physical activity was measured continuously based on self-reported total minutes of moderate-to-vigorous aerobic activity per week. Multivariate logistic regression models, accounting for the complex survey design, were used to estimate the association between neighborhood walkability and overweight/obesity, with covariates adjusting for age, sex, education, and acculturation. Indirect effects were assessed using bootstrap methods outlined by Preacher and Hayes, to quantify the extent to which aerobic physical activity mediates the association of neighborhood walkability with overweight/obesity (BMI≥25 kg/m^2). **RESULTS:** On average the sample was 44 years old, 56% were female, 36% had less than a high school education, and 58% were foreign-born. After adjusting for covariates, a one-unit higher neighborhood walkability score was associated with significantly lower odds of overweight/obesity (OR: 0.98; 95% CI: 0.93, 0.99), relative to normal weight. Results indicated that aerobic physical activity accounted for 0.7% of the total effect of neighborhood walkability on overweight/obesity among Latino adults, but was not significant (p=0.46). **CONCLUSION:** These findings suggest neighborhood walkability contributes to overweight/obesity among Latino adults. However, mediation results indicate aerobic physical activity does not account for the impact of neighborhood walkability on overweight/obesity, suggesting other factors may play a role.

2362 Board #198 June 1 9:30 AM - 11:00 AM

Physical Activity Levels of Students Walking Shelter Dogs in anActivity Course: A Pilot Study

Melanie Sartore-Baldwin, Bhibha M. Das, Lacey Schwab, Katrina DuBose, FACSM. *East Carolina University, Greenville, NC.* (Sponsor: Katrina DuBose, FACSM)

(No relevant relationships reported)

While it is becoming less and less common for four-year colleges and universities to require physical activity courses as part of student curricula, many schools continue to offer elective physical activity courses. These elective courses are important given the benefits associated with physical activity and the low levels of physical activity found within the college student population. College and universities also stress the importance of community engagement within their courses, suggesting that addressing the physical activity needs of others, such as shelter dogs, within activity-based courses may benefit multiple entities. **PURPOSE:** The purpose of this study was to assess the physical activity levels of students enrolled in a service-learning fitness walking course in which students walk local shelter dogs. **METHODS:** Ten college students (age = 20.8 years (SD = 1.23); 80% female; 90% White), enrolled in a fitness walking course that met at the county animal shelter, were asked to wear NL-1000 pedometers twice a week for 50 minutes for a duration of 10 weeks. Students will complete a survey about their experience at the end of the semester. **RESULTS:** Preliminary results indicate that, on average, students acquired approximately 4726.5 steps (SD = 299.14; range 2167-6212 steps) per walking session and walk an average of 2.26 miles (SD = .14; range 1.06-3.23 miles). Of the time spent on these walks, approximately 28.5 minutes (SD = 2.4; range 11.32-43.44 minutes) was moderate physical activity. **CONCLUSIONS:** Students enrolled in this course are currently reaching approximately 40% of their recommended daily physical activity requirements during class time. To date, student perceptions of the course have been overwhelmingly positive suggesting that incorporating shelter dogs into a physical activity elective course at a college or university can promote physical activity amongst college students. The local shelter dogs also benefitted from being physically active demonstrating the utility of community engagement when seeking new and fun ways to promote physical activity among college students.

The Effect ofa Web-based Physical Activity Promotion Program on Sedentary Behavior: The Walk 2.0 Trial

Gregory S. Kolt, FACSM[1], Tanya Wood[1], Mitch J. Duncan[2], Cristina M. Caperchione[3], Anthony J. Maeder[4], Richard R. Rosenkranz, FACSM[5], Trevor N. Savage[6], Anetta Van Italie[7], W Kerry Mummery[8], Corneel Vandelanotte[7], Emma S. George[1]. [1]*Western Sydney University, Sydney, Australia.* [2]*University of Newcastle, Newcastle, Australia.* [3]*University of British Columbia, Kelowna, BC, Canada.* [4]*Flinders University, Adelaide, Australia.* [5]*Kansas State University, Manhattan, KS.* [6]*Griffith University, Gold Coast, Australia.* [7]*Central Queensland University, Rockhampton, Australia.* [8]*University of Alberta, Edmonton, AB, Canada.*

(No relevant relationships reported)

Time spent engaging in sedentary behavior represents a growing public health concern, with many national physical activity guidelines now also including recommendations on reducing sedentary time. Sedentary behavior contributes to a range of poor health outcomes. Web-based interventions are increasingly used in health promotion given their broad reach and ability to engage participants through Web 2.0 technologies. The WALK 2.0 intervention (a Web 2.0-based physical activity intervention) has demonstrated effectiveness in increasing physical activity, yet its impact on sedentary behaviour is unknown. **PURPOSE:** To investigate the effectiveness of the WALK 2.0 intervention on sedentary behaviour. **METHODS:** Participants were 504 (328 female and 176 male, mean age 50.8±13.1 years) adults randomised to one of two web-based interventions or a paper-based Logbook group. Those in the Web 1.0 group participated in the existing 10,000 Steps program and those in the Web 2.0 group participated in a Web 2.0-enabled physical activity intervention that included social networking capabilities. Sedentary behaviour was assessed using ActiGraph GT3X activity monitors and was recorded in terms of total minutes of sedentary time per day and number of bouts (> 10 minutes) of sedentary time per day. **RESULTS:** For total daily minutes of sedentary behaviour, repeated measures analysis showed no significant group x time interactions in either the unadjusted model (p=0.46) or the model adjusted for gender, age at baseline, BMI, education, and accelerometer wear time (p=0.58). No significant group x time interactions were shown for daily bouts of sedentary time in either the unadjusted (p=0.21) or adjusted (p=0.21) models. There were no significant changes in total minutes or number of bouts of sedentary behaviour within groups or across time. **CONCLUSIONS:** The WALK 2.0 intervention is not effective in reducing sedentary behavior. Specific behavior strategies targeting both sedentary behaviour and physical activity are necessary and their implementation requires careful consideration in the design phase.

Effects of One Session of Treadmill Desk Walking on Free-Living Physical Activity

Rebecca R. Rogers, Erica Disbrow, Kendra Skenderi, John K. Petrella, FACSM, Mallory R. Marshall, Christopher G. Ballmann. *Samford University, Birmingham, AL.*

(No relevant relationships reported)

PURPOSE: Treadmill desks are being implemented in office and classroom settings to counteract long durations of sedentary behavior. The purpose of this study was to examine the effects of one treadmill desk walking session on daily physical activity patterns outside of work or school in healthy individuals. **METHODS**: Male and female participants (age = 38 yrs ± 8.0, weight = 166.2 lbs ± 47.5, height = 62.0 in ± 71.5) were recruited for this study. To assess baseline free-living physical activity patterns, all participants wore an Actigraph GT9X link accelerometer for one week during waking hours. Participants completed one session of treadmill desk walking at a speed of 2.0 mph for a total of 3 hours. During the 3 hours, participants performed typical office or school related tasks. Physical activity patterns were then recorded via accelerometer for 2 additional days following the treadmill workstation bout. **RESULTS**: Participants classified as "low active" (mean steps/day = 7368.0 steps ± 540.4) did not show a significant difference in average steps/day (p=0.190) or activity counts (p=0.204) between the 2 days prior and after the treadmill desk session. No significant differences in average steps/day (p=0.233) or activity counts (p=0.119) were observed pre and post treadmill desk session in participants classified as "somewhat active" to "active" (mean steps/day = 9538.5 steps ± 578.7) indicating there was no change in daily physical activity levels. **CONCLUSIONS**: This study suggests that treadmill desk walking does not influence free-living physical activity regardless of activity classification.

2365   Board #201   June 1 9:30 AM - 11:00 AM

Obesity and Walking Efficiency in Survivors of Acute Lymphoblastic Leukemia: Report from St. Jude Life

Matthew D. Wogksch, Carrie R. Howell, Robyn E. Partin, Heather Chambliss, FACSM, Hiroto Inaba, Ching-Hon Pui, Melissa M. Hudson, Leslie L. Robison, Kirsten K. Ness. *St. Jude Children's Research Hospital, Memphis, TN.*

(No relevant relationships reported)

Treatment for childhood acute lymphoblastic leukemia (ALL) is associated with an increased risk of being overweight/obese, having neuromusculoskeletal impairment and mobility limitations. Obesity may contribute to mobility limitations by increasing the physiologic cost/effort associated with movement. **PURPOSE:** To evaluate associations between obesity and walking efficiency in adult survivors of childhood ALL. **METHODS**: ALL survivors (N=351, mean±SD age: 28.5±6.0 years, 51.6% male) and 342 age-, sex- and race-matched controls (N=342, 29.0±7.5 years, 51.2% male) were assessed for body mass index (BMI: kg/m^2), body fat percentage (%BF) using dual x-ray absorptiometry, and completed the six minute walk test. Walking efficiency was characterized with the physiological cost index (PCI). PCI is calculated using the formula: (Maximal heart rate (HR) during walking – HR at rest)/distance walked; expressed as beats per meter (normal range 0.13-0.49 in adults). **RESULTS:** ALL survivors with BMI ≥40 kg/m^2 had higher PCI values compared with normal weight survivors (0.63±.040 vs. 0.50±0.019, p<.01), adjusting for age, sex, physical activity, and cranial radiation exposure. ALL survivors with excess %BF (defined as > 25% for men and > 33% for women) also had higher PCI values compared to survivors with normal %BF (0.54±.013 vs. 0.47±0.017, p<.01). No associations between obesity and PCI were evident among controls. **CONCLUSIONS:** Obesity is associated with reduced walking efficiency in ALL survivors but not in healthy controls, suggesting that ALL survivors do not have the same capacity to compensate for excess body weight as their peers with no cancer history. Weight loss interventions may have a significant impact on daily activity in this population.

2366   Board #202   June 1 9:30 AM - 11:00 AM

Evaluation of Step Rate of Walking Corresponding to Moderate Intensity

Woo Ram Bae[1], So Mi Yun[1], Yun Bin Lee[1], Min Gi Jung[1], Da Hye Lim[1], Ah Reum Jung[1], Woong Hee Lee[1], Eun Jin Hwang[1], Ik Jin Kwon[2], Dae Taek Lee[1]. *[1]Kookmin University, Seoul, Korea, Republic of. [2]Chung-Ang University, Seoul, Korea, Republic of.*

(No relevant relationships reported)

PURPOSE: Walking at 100 steps per min is assumed to be the moderate exercise intensity in most cases. But it may not be universally accepted. This study evaluated how the overground walking at different step rates would elicit exercise intensities, and aimed to provide a cut-point of step rate which corresponds to a moderate walking intensity.

METHODS: Twenty-three young men (25±2 yrs, 175±6 cm, 76±14 kg) completed four overground walking trials. At the first trial, participants were asked to walk freely for 6-min at an intensity they felt moderate. Subsequently, they walked another 3 occasions for 6-min of each at 100, 120, and 140 beat/min while matching to a metronome beat. During the walking, oxygen consumption (VO_2), walking speed (WS), step rate (SR), and ratings of perceived exertion (RPE) were measured. On a separate occasion, their resting VO_2 and maximal aerobic capacity (VO_2max 41±6 ml·O_2/kg/min) on a treadmill using Bruce Protocol were measured. **RESULTS**: The actual SR at free walking and 100, 120, and 140 beat/min was 117±9, 101±2, 120±1, and 138±4 step/min, respectively (p<0.01). SR they felt moderate during free walking was higher than 100 step/min (p<0.01). Based on the intensity parameters such as WS (4.9±0.5, 3.9±0.3, 5.2±0.4, and 6.4±0.5 km/h), %VO_2 reserve (31±8, 24±6, 33±9, and 45±9 %), and RPE (7.6±1.5, 7.4±1.5, 9.4±2.0, and 12.3±1.9 at free walking and, 100, 120, and 140 beat/min, respectively), the criteria of a moderate intensity of walking (100 step/min) was not satisfied. Regression analysis revealed that a cut-point of SR representing a moderate intensity (about 40%VO_2 reserve) was 128 step/min based on %VO_2 reserve, while it was 88.2 step/min based on metabolic equivalents. When grouped by aerobic fitness level, the less fit participant (VO_2max 32±3 ml·O_2/kg/min) met the moderate intensity at SR of 120 step/min while the more fit (VO_2max 50±2 ml·O_2/kg/min) did at 140 step/min. **CONCLUSIONS**: Based on the relative intensity index (%VO_2 reserve), the cut-point corresponding to a moderate intensity was 128.9 step/min. But this estimation also has to be widened by the aerobic fitness level of the walkers. In general, approximately 120-140 step/min of overground walking can be considered as a moderate walking intensity for those of healthy population.

2367   Board #203   June 1 9:30 AM - 11:00 AM

Process Evaluation of a Multi-Component "Sit Less, Walk More" Workplace Intervention for Office Workers

Yun-Ping Lin[1], Shu-Hua Lu[1], Wei-Fen Ma[1], Kwo-Chen Lee[1], Chiu-Chu Lin[2], Meei-Maan Chen[3]. *[1]China Medical University, Taichung, Taiwan. [2]Kaohsiung Medical University, Kaohsiung, Taiwan. [3]National Taipei University of Nursing and Health Sciences, Taipei, Taiwan.*

(No relevant relationships reported)

Sit Less, Walk More (SLWM) workplace intervention was designed for office workers with demonstrated efficacy in improving walking and some cardiometabolic biomarkers. However, little is known about the participants' perceptions of the program and each program component's contribution to observed program effects. **PURPOSE:** To evaluate participants' perceptions of and engagement with the program components in the SLWM to understand program effects. **METHOD:** Process evaluation data were collected during and immediately after the 12-week intervention period. The SLWM included multi-components: three monthly newsletters, six biweekly motivational tools, a team-based 10,000 steps challenge, environmental prompts, and walking routes and resources. A survey contained both closed and open-ended questions assessing frequency of use and perceptions of program components; factors that hindered the use of program components; and recommendations for improving program components. Qualitative data were analyzed using content analysis. **RESULTS:** Fifty-one (100%) intervention participants completed the post-intervention survey. Their ages ranged from 30 to 62 (mean = 52.1, SD = 6.57). The majority of participants were married (92.2%) and highly educated (60.8% had a college or graduate degree). Most participants were satisfied with the SLWM program (84.3%) and thought the program to be beneficial (78.4%) and effective (74.5%) to them in increasing physical activity and decreasing sitting behavior. Participants reported the 10,000 steps challenge to be the most helpful component because of the motivation and encouragement elicited by the pedometer and Step Log (79.6%), goal setting (45.5%), and the use of the support group approach as well as rewards and recognition for group competition (29.6%). The walking route was not received well by the participants. The reasons for this included time constraints due to work or family obligations (54.1%), physical environment issues primarily due to weather (21.6%), and using their own preferred methods of exercise or walking routes (13.5%). **CONCLUSIONS:** The findings provide a better understanding of the use and preference for different program components and how future SLWM workplace intervention for office workers could be provided.

Application Of The ActiGraph GT9X IMU For The Assessment Of Turning During Walking And Running

Robert T. Marcotte[1], David R. Bassett, Jr, FACSM[2], Joshua T. Weinhandl[2], Scott E. Crouter, FACSM[2]. [1]University of Massachusetts Amherst, Amherst, MA. [2]University of Tennessee Knoxville, Knoxville, TN.
(No relevant relationships reported)

Rotational movements, such as turning, can significantly increase energy expenditure (EE) during ambulatory activity. Gyroscope and magnetometer sensors can quantify rotational motion, which provides additional information on movement beyond linear acceleration that is provided by only using an accelerometer. **PURPOSE:** The purpose of this study was to examine the use of the ActiGraph GT9X gyroscope and magnetometer for detecting turns and quantifying turn degree during walking and running. **METHODS:** Participants (N=17) completed pivot trials, treadmill walking and running (TM; 3 to 6 mph) and four turn conditions (i.e. 45°, 90°, 135°, and 180°) during over-ground walking and running (OG). Pivot and TM trials were completed for 1-min and 6-min, respectively. Turn frequency was constant (10 turns/min) for all OG trials. A GT9X was placed on the left hip and a Cosmed K4b[2] was used to measure EE. Raw GT9X gyroscope and magnetometer data were processed through various low-pass filter frequencies (0.25 Hz to 2.0 Hz). TM and pivot trials were used to develop thresholds for turn detection using the gyroscope and magnetometer data and the OG trials were used for cross-validation. K4b[2] data (VO_2) were averaged over 30-s periods and converted to relative VO_2 (ml/kg·min). Linear mixed models were used to compare actual and predicted number of turns, measured and predicted turn degree, and differences in VO_2 across OG conditions. **RESULTS:** There were no main effects for speed or turn condition on turn detection when filtering the gyroscope at 0.25 Hz (p>0.05). A speed main effect was present when filtering the magnetometer at 0.75 Hz (p<0.001). 0.25 Hz (gyroscope) and 0.75 Hz (magnetometer) filters resulted in 100.5%±4.4% and 96.9%±45.4% of turns detected, respectively. Using the gyroscope, turn degree was estimated to within approximately 2.2° for all turn conditions (p<0.001). In general, the VO_2 of walking and running was significantly greater during 135° and 180° turn conditions compared to 0-90° turn conditions (p<0.05). **CONCLUSION:** The GT9X gyroscope, when low-pass filtered at 0.25 Hz, can be used to detect the number of turns and estimate turn degree. The magnetometer was only useful for detecting the number of turns. Future work should explore the gyroscope use for turn detection during activities other than walking and running.

Peak Torque, Rate Of Velocity Development And Walking Performance: The Baltimore Longitudinal Study Of Aging

Yusuke Osawa, Stephanie A. Studenski, Luigi Ferrucci. National Institute on Aging/ NIH, Baltimore, MD.
(No relevant relationships reported)

PURPOSE: Efficiency of movements depends on both muscle strength and movement velocity. Men have higher muscle strength than women but whether strength and velocity contribute differently to walking performance in men and women remains unclear. Using data from the Baltimore Longitudinal Study of Aging, we investigated whether knee extension rate of velocity development (RVD) and peak torque differently contribute to walking performance measures in men and women. **METHODS**: We assessed the effect of sex on associations of RVD and peak torque with physical performance independent of demographics, body composition and subjective knee pain in 868 BLSA participants (48.2% women; aged 26 to 96 years; women, 64.1 ± 13.6 years; men, 68.6 ±14.4 years). We measured peak torque and RVD by isokinetic, concentric knee extension at 180 deg/sec. RVD was determined from the slope of the velocity-time relationship from the onset of movement to the time point that angular velocity first reached target velocity. Walking performance tests included gait speed during a 6m walk at usual and fast pace (6m-usual and fast) and during a 400m walk at fast pace (400m), and the distance covered in a 2.5-minute walk at normal pace (2.5min). Sex-specific generalized linear regression models were adjusted for age, race, body height, appendicular lean mass, whole body fat mass, and knee pain. A term testing whether the interaction between RVD and peak torque significantly improves the model fit was also included. **RESULTS**: In men, RVD was associated with 6m-usual (p<0.0001), while higher peak torque was significantly associated with better performances in 2.5min walk, 6m-fast, and 6m-fast (p<0.05). A significant interaction between RVD and peak torque was observed in 6m-usual (p<0.0001). In women, higher RVD was significantly associated with better performances in all measures independent of peak torque, and a significant interaction between RVD and peak torque was observed in all measures (p<0.05). **CONCLUSIONS**: RVD predicts walking performance in women but less in men. These results suggest that sex-specific strategies to accomplish motor tasks exist. Future studies are needed to identify the mechanisms underlying this sex difference.

Comparison of Physical Activity Levels of College Students after a Five Week Walking Class

Julio Morales. Lamar University, Beaumont, TX.
(No relevant relationships reported)

Physical Activity (PA) of college students has been the focus of much study because of its decline when students enter college. Efforts are consistently made to provide strategies to foment college students' engagement in PA**.**
PURPOSE: To compare the level of PA of college students before and after participation in a walking class containing information on PA and exercise.
METHODS: Participants in the study were sixty nine (25 males, 44 females; ages 19 to 26) college students enrolled in three different five week summer walking classes held during the same period over three different summers. Participants were administered the International Physical Activity Questionnaire-Short Form during the first and last class meeting to assess their leisure time physical activity. An experienced investigator read the questions and answered any questions during the administration of the questionnaire. He also made clear during the second administration that students should only report the PA done outside class. Walking (WMET), Moderate (MMET), Vigorous (VMET) and Total (TMET) METS levels were calculated following the IPAQ scoring guidelines. Paired samples t tests were conducted by gender for the pre and post administration for all MET levels. Independent samples t tests were conducted between genders to examine differences pre and post class.
RESULTS:Females showed a significant increase in TMET form pre (M = 5665.01, SD = 5580.14) to post (M = 8229.76, SD =7121.46), $t(31)$ = -2.21, p<.034 (two tailed). In the gender post comparison, females had significantly higher MMET values (M = 2584.38, SD = 3542.06) than males (M = 724.44, SD = 843.81), $t(37$ = 2.83, p <007 (two tailed).
CONCLUSIONS: Findings may suggest that there are possibilities for the use of content driven college activity courses could offer another avenue to foment participation in physical activity.

Association Between the National Walkability Index and Sidewalk Features

Kathleen B. Watson, Susan A. Carlson, Kristine Day, Janet E. Fulton, FACSM. Centers for Disease Control and Prevention, Atlanta, GA. (Sponsor: Janet E. Fulton, FACSM)
(No relevant relationships reported)

Step It Up! The Surgeon General's Call to Action to Promote Walking and Walkable Communities calls on Americans to work together to increase walking and improve walkability. Well-connected, safe, and attractive sidewalks is one common feature of walkability. The Environmental Protection Agency National Walkability Index (NWI) provides a composite index of walkability at the block group level but does not include a direct measure of sidewalks. Knowing the associations between the NWI and sidewalk presence and quality may help assess the utility of the NWI to facilitate the planning of walkable communities. **PURPOSE** To determine the association between a nationwide geographic measure of walkability and features of sidewalks. **METHODS** We surveyed adults from 20 Community Transformation Grant sites. Respondents (n=20,918) reported on the presence of individual sidewalk features in their neighborhood (present; well maintained; separated from traffic by parked cars; separated from streets by grass/dirt strips). Sidewalk data were merged with the NWI - a nationwide geographic measure of walkability that encompasses density, land use mix, and proximity to transit. Associations of the NWI score with sidewalk presence and features were assessed by correlations and by comparing NWI mean scores by individual sidewalk features, tested with pairwise comparisons. **RESULTS** The correlation between the NWI and sidewalk presence was moderate (r=0.52) while correlations between NWI and individual sidewalk features were weak (r=0.04-0.19). Among adults who reported sidewalks present (73%), the mean (± standard deviation) NWI scores were higher (p<0.05) for those reporting (versus not reporting) sidewalks on most streets (11.6±0.1 vs. 9.6±0.1), well-maintained sidewalks (11.5±0.1 vs. 11.1±0.1), and sidewalks separated from traffic by parked cars (11.9±0.1 vs. 10.3±0.1). The NWI was lower (p<0.05) for sidewalks separated from street by grass/dirt (11.2±0.1 vs. 11.8±0.1). **CONCLUSIONS** The NWI was moderately associated with sidewalk presence; however, associations with individual sidewalk features were weak. The NWI may be not be useful to identify individual features of sidewalk quality or locations where sidewalks are lacking. Future studies may want to assess its utility to facilitate planning in other locations.

Creatine Hcl In Elite Gymnastic Athletes

Caroline Ayme Yoshioka[1], Renata Furlan Viebig[2], Paulo Carrara[3], Jeferson Oliveira Santana[1], Diana Madureira[1], Elias de França[1], Iris Callado Sanches[1], Erico Caperuto[1]. [1]*São Judas Tadeu University, São Paulo, Brazil.* [2]*Mackenzie Presbiterian University, São Paulo, Brazil.* [3]*São Paulo University, São Paulo, Brazil.*

(No relevant relationships reported)

PURPOSE: The objective of this study was to compare the effects of creatine HCl and monohydrate supplementation on performance and body composition markers in weight-dependent elite athletes. **METHODS**: Elite athletes from the Artistic Gymnastics Brazilian top team (11 males, 15 to 25 years old), were randomly divided into the randomized cross-over model into two conditions: Placebo (PG), Creatine Monohydrate Supplement (CMG) and Creatine HCl Supplement (HClG). In a 30-day period (Pre and Post), including experimental protocols and gymnastics training, variables related to body composition were measured (IN BODY Bioimpedance), maximum strength (1RM test), and RPE (Physical Self-Efficacy Scale (RPE)). **RESULTS**: The results showed that lean mass increased in both moments when intragroup values were compared (CMG Pre 53.81 ± 6.67 and Post 54.98 ± 6.28 p=0.000025; HClG Pre 54.81 ± 5.96 and Post 55.29 ± 6.07; p=0.002). Regarding fat percentage, creatine hydrochloride supplementation showed significant decrease (HClG Pre 5.28 ± 1.44 and Post 4.37 ± 1.32; p=0.0001). There were similar strength gains between the two supplements in the post-period (CMG Pre 93.09 ± 16.86 and Post 96.64 ± 16.20 p=0.00014; HClG Pre 96.91 ± 15.35 and Post 102.00 ± 14.94; p=0.0018). Finally, the psychophysiological analysis (RPE) showed changes in the athletes' perception regarding the training only at the end of the creatine hydrochloride period (HClG Pre 3.27 ± 0.90 and Post 2.18 ± 0.75; p=0.003). **CONCLUSIONS**: We concluded that both creatines were effective in relation to muscle mass gains (p<0.05), but only HCl creatine was able to promote body composition and self efficacy perception changes.

Preliminary Analysis - Moderating the Stress Perception of Collegiate Distance Runners Using Branched-Chain Amino Acids

Tara K. Whiton, Kimitake Sato, Asher Flynn, Joseph Walters, Caleb Bazyler, Michael H. Stone, Brad DeWeese. *East Tennessee State University, Johnson City, TN.*

(No relevant relationships reported)

Exercise-induced fatigue may be caused by increases in cerebral serotonin resulting in symptoms of central fatigue (i.e. decreased mood, and increased stress and sleepiness). Branched-chain amino acid (BCAA) supplementation is one intervention that can reduce symptoms of central fatigue by competing for the tryptophan transporter reducing serotonin synthesis. Psychological monitoring tools such as The Daily Analysis of Life Demands for Athletes (DALDA) Questionnaire can be used to study symptoms of central fatigue by identifying sources of general and sport-specific stress as well as an athlete's reaction to stressors. **PURPOSE:** To examine the response of BCAA on stress perception of trained collegiate distance runners using DALDA. **METHODS:** 8 collegiate distance runners (men n=4, women n=4) took BCAA supplement (SUP) (0.08g/kg) or placebo (PLA) daily for 6 weeks, alternating conditions week to week. Each morning athletes filled out the 34-item DALDA prior to training by selecting one of 3 answers corresponding to stress symptoms: A = "feel worse than normal", B= "feel normal", C= "feel better than normal". Response ratios were generated for each of the 3 answers for each condition (SUP or PLA) by taking total number of responses for each answer over number of answers overall. Response ratios were calculated as weekly mean ± SD and MANOVA was used for analysis. The alpha criterion was set to p<0.05. **RESULTS:** Statistical significance was found (p<0.01), and further analyses were done to examine changes from week to week. On average, athletes reported fewer 'A' responses in SUP weeks than PLA weeks (SUP: $9.27\% \pm 2.21\%$; PLA: $13.46\% \pm 7.29\%$), while response percentage for 'C' was the same between both conditions (SUP: $11.78 \pm 2.12\%$; PLA: $11.24\% \pm 2.32\%$). Changes from SUP weeks to PLA weeks produced noticeable changes in 'A' responses (e.g.: 14.36% SUP week to PLA week; -9.95% from PLA week to SUP week). **CONCLUSIONS:** Results from DALDA revealed a noticeable change in the stress response of the athletes from condition to condition. The athletes reported higher instances of feeling "worse than normal" during PLA weeks and fewer instances of

feeling "worse than normal" during SUP weeks. These results indicate that BCAA supplementation seems to be an effective means of reducing the stress perception in these collegiate distance runners.

2374   Board #210   June 1 11:00 AM - 12:30 PM

Effect Of B-Hydroxy B-Methylbutyrate Supplementation On Sprint Kinetics Across A Collegiate Rugby Season

Jennifer M. Julian, Katy L. Hayes, Trisha A. VanDusseldorp, Garrett M. Hester, Yuri Feito, FACSM, Gerald T. Mangine. *Kennesaw State University, Kennesaw, GA.* (Sponsor: Dr. Yuri Feito, FACSM)

(No relevant relationships reported)

During a collegiate rugby season, players practice and compete for 1-2 hours on multiple days per week for 3-4 months per year. Practices and matches consist of multiple activities (e.g. sprinting, hitting, etc.) that could result in accumulated damage and affect performance. β-Hydroxy β-Methylbutyrate (HMB) is thought to speed protein synthesis which in turn could maintain performance. **PURPOSE:** To determine the effect of HMB supplementation on sprint kinetics throughout a rugby season. **METHODS:** In this cross-over design investigation, 13 collegiate male rugby players were assigned to consume one of two supplementation regimens: 5 g HMB + 5 g creatine per day (HMB) or 5 g creatine + 5 g placebo per day (PLB) for six weeks. During the fall season, players were matched for lean body mass and randomly assigned to HMB (n = 7; 21.1 ± 1.1 y; 88.2 ± 16.5 kg; 176.3 ± 7.9 cm) or PLB (n = 6; 21.5 ± 2.4 y; 88.8 ± 15.4 kg; 179.3 ± 5.2 cm). The supplementation regimen was switched for athletes who returned and completed the spring season (n = 7; 22.5 ± 1.3 y; 96.4 ± 14.7 kg; 179.6 ± 4.5 cm). Prior to and following each supplementation period (i.e., fall or spring), 40-m sprinting kinetics were assessed in all athletes while tethered to a robotic sprinting device. Peak ($_{PK}$) and mean sprinting power (P), force (F), and velocity were assessed against minimal (1 kg) and heavy (15 kg) resistance. Since only 7 of the original 13 athletes returned and completed the spring season, separate 2×2 repeated measures analyses of variance (RMANOVA) with Bonferroni adjustments were used to assess group differences in each variable during the fall, while a 2×4 RMANOVA was used to assess the cross-over sub-sample throughout the fall and spring. **RESULTS:** While no group differences were observed in sprint kinetics during the fall, a significant group × time interaction was observed for P_{PK} at 1kg (F = 4.85, p = 0.020, n_p^2 = 0.55) across the fall and spring seasons, where during the spring, P_{PK} at 1kg decreased for PLB_{SPRING} ($-6.9 \pm 1.2\%$, p = 0.020) but not for HMB_{SPRING} ($+7.5 \pm 10.7\%$). No other differences were observed. **CONCLUSION**: Our data suggest a potential benefit from HMB supplementation for maintaining sprinting power in rugby players.

Effect Of β-hydroxy-β-methylbutyrate And Creatine Supplementation On Muscle Recovery In Elite Rowers As Measured By Anabolic And Catabolic Hormones.

Calleja-González Julio[1], Ana Martha Espinosa-Uribe[2], Juan Mielgo-Ayuso[2], Jeffrey Mjaanes, FACSM[3]. [1]*Faculty of Sports Sciences.University of the Basque Country, Vitoria, Spain.* [2]*Kaiarriba Donostiarra, San Sebastian, Spain.* [3]*Northwestern University, Chicago, IL.* (Sponsor: Dr. Jeffrey Mjaanes,MD, FACSM)

(No relevant relationships reported)

PURPOSE: The aim of the present study was to experimentally investigate the effect of supplementation with creatine (Cr) and / or β-hydroxymethyl-β-hydroxy (HMB) on muscle recovery in elite rowers using anabolic and catabolic hormones. The hypothesis was that supplementation with both HMB + Cr for 10 weeks would improve muscle recovery, as measured by testosterone and T/C ratio, to a greater degree than would each individual supplements alone.
METHODS:
Twenty-four elite rowers (27.0 ± 5.6 years) who participated in the 10-week non-placebo-controlled trial were randomized to one of the following 4 groups: GC: Control group; GCR: Group supplemented with Cr (0.04 g / kg / day); GHMB: Group supplemented with HMB (3 g / day); and, GCR + HMB (supplemented with the same doses as individual).
RESULTS:
There were significant differences in testosterone behavior, as well as in the Testosterone / Cortisol ratio (T/C) between groups. Higher testosterone levels were observed in GCR + HMB than in the others (p <0.05). A smaller decrease in the T / C ratio in the GCR + HMB than in the others was also observed (p <0.05).
CONCLUSIONS:
This study indicates that combined supplementation with Cr (0.04 mg / kg) together with β-hydroxymethyl-βutyrate (HMB) (3 g / kg) in elite rowers favors endogenous recovery through an increase in total testosterone and maintenance of the T / C ratio.

Effect of Preand Post-Exercise Creatine Supplementation on Bone Mineral in Aging Adults

Darren Glenn Candow, Sarah Johannsmeyer. *University of Regina, Regina, SK, Canada.*

(No relevant relationships reported)

PURPOSE: Creatine supplementation before and after resistance training may be an important strategy for increasing aging muscle health; however, it is unknown whether the timing of creatine ingestion influences aging bone health.
METHODS: Using a double-blind, repeated measures design, aging adults were randomized to one of two groups: Creatine-Before (CR-B: n=15; 53.2 ± 2.5 yrs, 170.1 ± 9.9 cm, 77.1 ± 15.6 kg; creatine [0.1g·kg^{-1}] immediately before resistance training and placebo [0.1g·kg^{-1} corn-starch maltodextrin] immediately after resistance training) or Creatine-After (CR-A: n=12; 55.2 ± 3.5 yrs, 173.4 ± 8.2 cm, 86.8 ± 20.1 kg; placebo immediately before resistance training and creatine immediately after resistance training). Resistance training (11 exercises) was performed 3 days/week for 8 months. Prior to and following training and supplementation, bone mineral content (BMC) and density (BMD) of the whole-body, femoral neck, lumbar spine, and hip was measured by dual energy x-ray absorptiometry.
RESULTS: There was a time main effect (p=0.04) for femoral neck BMD (CR-B: pre 0.80 ± 0.11g, post 0.79 ± 0.11g; CR-A: pre 0.87 ± 0.15g, post 0.86 ± 0.13g) and a group x time interaction for hip BMD (p=0.02). Hip BMD was preserved in the CR-A group over time (pre 1.01 ± 0.15g/cm², post 1.01 ± 0.15g/cm²) whereas the CR-B experienced a slight reduction (pre 0.98 ± 0.12g/cm², post 0.96 ± 0.12g/cm²). There were no other differences (p>0.05).
CONCLUSIONS: Creatine supplementation immediately following resistance training helps preserve hip BMD. Creatine supplementation only on training days has no effect on bone mineral in aging adults.

No Impact of HMB Supplementation on Muscle or Strength Gains During an Undulating Periodized Resistance Training Program in Trained, Young Men

Josie S. Jakubowski[1], Edwin P. Wong[1], Everson A. Nunes[2], Josh Vandeweerd[1], Kenneth S. Noguchi[1], Kevin T. Murphy[1], Robert W. Morton[1], Steven K. Baker[1], Stuart M. Phillips, FACSM[1]. *[1]McMaster Univeristy, Hamilton, ON, Canada. [2]Federal University of Santa Catarina, Florianoplóis, SC, Brazil.* (Sponsor: Stuart Phillips, FACSM)

(No relevant relationships reported)

PURPOSE: We examined the effect of whey protein enriched with leucine compared to whey protein plus calcium-β-hydroxy, β-methylbutyrate (HMB) on skeletal muscle strength, mass, and recovery during 12 weeks of an undulating periodized resistance training (RT) program in young men. **METHODS:** Twenty-six recreationally trained men (≥2x/wk RT, aged 23±2y, lean mass 63.0±7.2kg) performed 12 weeks of a 3-phase RT program. Participants underwent 8 weeks of undulating periodized RT (Phase 1), followed by a 2-week overreaching period (Phase 2), and a 2-week taper (Phase 3). During the 12-week RT program, participants were randomized to ingest: whey protein (25g) with added HMB (1.5g) (Whey+HMB;n=13) or whey protein (25g) with added leucine (1.5g) (Whey+LEU;n=13), twice daily. One-repetition maximum (1-RM) strength tests were conducted throughout Phase 1, Phase 2 and upon completion of Phase 3. Fat and bone-free mass (FBFM) was measured with dual-energy X-ray absorptiometry (DXA) scans at weeks 0,4,8,10,12. B-mode ultrasound was preformed to assess muscle thickness (MT) and cross sectional area (CSA) at weeks 0,8,12. Systemic hormone concentrations were measured at weeks 0,4,8,9,10,12. **RESULTS:** In response to RT, participants increased their 1-RM for squat, bench-press and deadlift (p≤ 0.01), with no significant differences between groups. FBFM increased similarly in Whey+HMB and Whey+LEU (2.3±1.2kg and 2.6±1.9kg, respectively; p=0.59). Following RT, *Vastus lateralis* MT increased by 5±6% and 5±6%, with no difference (p>0.05) between groups. Both groups exhibited comparable changes in CSA, Whey+HMB; 2.2±1.4cm2 (6±4% increase) and Whey+LEU; 2.3±1.4cm2 (7±4% increase). Following overreaching, both groups experienced similar changes (p>0.05) in 1-RM strength for squat (HMB 2±4%, LEU -1±5%) bench-press (HMB -1±4%, LEU -1±3%) and deadlift (HMB -2±5%, LEU -3±7%). Circulating creatine kinase and cortisol concentrations increased significantly (p≤0.05) from week 0 at phase 2, in both groups. There were no between-group differences in these blood markers during any phase of the study. **CONCLUSION**: These data demonstrate that there are no additional effects of Whey+HMB supplementation on muscle strength or size following 12 weeks of RT in young healthy men when compared to a leucine-fortified supplement Whey+LEU.

2378   Board #214   June 1 11:00 AM - 12:30 PM

Body Composition And Muscular Performance Following 8-weeks Of Resistance-training And Protein Supplementation: Pilot Study

Matthew S. Stone, Michelle Gray, Austin Toups, Jordan Rezac, Dominique Blake, Jake Blalock. *University of Arkansas, Fayetteville, AR.*

(No relevant relationships reported)

Increased protein intake in the diet decreases fat mass (FM) and increases lean mass (LM). Resistance training increases LM, as well as increases muscular strength. Together, protein supplementation and resistance exercise work synergistically when taken prior to or following exercise. **PURPOSE**: The purpose of this pilot study was to investigate the effects 8 weeks of protein supplementation and Autoregulatory Progressive Resistance Exercise (APRE) training had on measures of body composition and muscular performance. **METHODS**: Untrained males (*n* = 22; 42.1 ± 7.1 years) participated in this pilot study. LM and FM were measured via Dual Energy X-ray Absorptiometry (DEXA), while strength was measured utilizing one repetition maximum (1RM), and endurance measured using maximum repetitions completed (REPS) at 75% 1RM for the bench and leg press. Subjects were randomly placed into one of four groups: control (CON), protein (PO), APRE, or protein plus APRE (PAPRE). Subjects repeated testing for the DEXA, 1RM, and REPS every four weeks for 8 weeks. Both PO and PAPRE groups ingested 25g of supplemental protein twice daily. Subjects in the exercise groups completed a resistance training program, 3 days per week, for 8 weeks, or 24 training sessions. **RESULTS:** Repeated measures ANOVA indicated a significant group by time interaction for LM, bench press 1RM, and leg press 1RM (*p* < .05). LM increased by 4% (+2.3 ± 0.2kg) in the PAPRE group, while increases in bench and leg press 1RM were 23% (+14.7 ± 0.7kg) and 50% (+132.1 ± 13.9 kg), respectively. There were no other group by time interactions for any of the variables assessed (*p* > .05). LM (*p* < .05), bench press 1RM (*p* < .001), and leg press 1RM (*p* < .001) indicated a significant time effect (+0.93 ± 0.02kg, +6.3 ± 0.9kg, and +68.2 ± 2.5kg, respectively). Body fat percentage showed a trend for decreasing over time (*p* = .05), while FM was significantly reduced over the 8-week training period (*p* < .05). Bench press increased 20% (+13.0 ± 2.0kg) from baseline for the APRE group, while leg press increased 13% (+32.9 ± 7.3kg), 18% (+43.1 ± 8.5kg), and 20% (+64.6 ± 28.8kg) for CON, PO, and APRE groups, respectively. **CONCLUSION**: The synergistic effects of protein plus exercise can be seen with the PAPRE group out-performing all other groups given the significant increases in LM and muscular strength over 8 weeks.

(No relevant relationships reported)

Branched-chain Amino Acid Supplementation May Produce Marginal Reductions Muscular Soreness in Collegiate Distance Runners
Asher Flynn, Tara Whiton, Kimitake Sato
East Tennessee State University
INTRODUCTION: A normal response to a rigorous training program is delayed onset muscle soreness (DOMS) often characterized by painful, tender, and swollen muscles with reduced range of motion and strength loss. These symptoms can take 24-48 hours to appear and dissipate within 5 to 7 days. Ingesting branched-chain amino acids (BCAA) has been shown to mitigate symptoms of DOMS by reducing muscle damage factors, sparing protein, and increasing muscle protein synthesis. **PURPOSE:** The purpose of this study was to investigate the influence of BCAA on perception of muscular soreness in collegiate distance runners. **METHODS:** 8 collegiate distance runners (men n=4, women n=4) took BCAA supplement (SUP) (0.08g/kg) or placebo (PLA) daily for 6 weeks, alternating conditions each week. Each morning prior to training, athletes filled out a 10-point scale Soreness Chart in which they rated soreness levels for each major muscle group on both anterior (ANT) and posterior (POST) body segments (1= no pain at all and 10= excruciating pain). Responses were totaled for each condition (SUP or PLA) and body segment (ANT or POST). After preliminary analyses for data, upper extremity data were excluded. Data were analyzed using paired-samples T-test to compare soreness levels between PLA and SUP weeks. **RESULTS:** Statistical significance ranged from p=0.09 – 0.89 depending on lower extremity segments. Based on descriptive analyses, athletes reported higher ratings of soreness in the ANT segment of the lower body. Overall soreness ratings were lower in SUP weeks vs PLA in both ANT and POST (SUP: ANT= 98.01% ± 34.86%; POST= 97.18% ± 39.72% and PLA: ANT= 108.52% ± 38.41%; POST = 110.32% ± 38.60%) but did not reach statistical significance. **CONCLUSION:** Although significance was not met, some note-worthy changes were captured. For instance, leg muscles, the primary movers involved in running, had a greater tendency to be less sore while

on the supplement. Since gains in athletic performance can often be marginal, it is possible that marginal reductions of DOMS can eventually lead to an improvement training experiences.

The Effects of Creatine Loading on Dynamic Balance, Mobility and Strength in Older Adults

Joseph Reale, John Petrizzo, John Wygand, FACSM, Melhaney Reichelt, Glen Reid, Robert M. Otto, FACSM. *Adelphi University, Garden City, NY.* (Sponsor: Robert M. Otto, FACSM)

(No relevant relationships reported)

Aging often attenuates balance and strength regardless of activity profile, thus resulting in an increased risk of falling. Older populations taking part in a resistance training program tend to minimize the loss of lean body mass, but still may suffer decrements. Creatine (Cr) supplementation has been studied extensively for almost 20 years and is a popular supplement of choice by athletes. Cr purportedly provides an enhancement of the phosphocreatine energy system allowing users to maintain a greater work intensity for an extended time. **Purpose:** To determine if acute Cr supplementation (20g of Cr/day for 5 days) improves balance, mobility, and strength in older adult populations. **Methods:** Ten subjects (age 64.4 ± 5.2 yr, ht. 168 ± 5.6 cm, body mass 76.3 ± 8.1 kg, ♀6) participated in familiarization trials conducted on the Biodex Balance SD [four conditions: normal stance w/ eyes open (NEO), N w/ eyes closed (NEC): and closed stance w/ eyes open (CEO), and C w/ eyes closed (CEC)], isokinetic knee extension (KE) and knee flexion (KF) peak torque (ft/lbs) and the Timed Up and Go Test (TUG) expressed in seconds. The battery of tests were conducted in the same sequence for each of the four assessments (pre control [PC], post control [PoC], pre Cr [PCr], and post Cr [PoCr]). Subjects were randomly assigned to 5 days of either 20 g of Cr or a matched placebo in a double blind protocol with a washout period of 14 days between treatments. Cr and placebo were indistinguishable in volume, taste, flavor, texture and color. **Results:** Statistical analysis by ANOVA revealed NSD (p>.05) between treatments.

	KE	KF	TUG	NEO	NEC	CEO	CEC
PC	30.3±20	47.1±22	8.8±1.5	15.9±24	40.0±83	27.7±30	83.7±114
PoC	30.2±17	61.6±43	8.2±1.1	11.5±15	21.9±33	23.1±30	68.6±99
PCr	30.5±14	64.7±34	8.2±1.2	23.9±26	46.3±79	46.4±38	102.6±90
PoCr	27.9±12	55.0±21	8.1±1.1	21.8±21	38.5±36	43.0±40	101.1±100

Conclusion: The acute use of Cr loading for individuals aged ≥60 was ineffective in altering muscular strength, balance or mobility for moderately active adults. It may require a longer period of loading or larger doses for creatine to be effective in older populations.

The Effect of Pre-sleep Protein Supplementation After Resistance Exercise on Next Day Performance and Recovery

Margaret Morrissey[1], Jaymie Donaldson[2], Andrew McKune[3], Michael Ormsbee, FACSM[1]. *[1]Florida State University, Tallahassee, FL. [2]University of KwaZulu-Natal, Durban 4000, South Africa. [3]University of Canberra, Bruce, Canberra ACT 2601, Australia.* (Sponsor: Michael Ormsbee, FACSM)

(No relevant relationships reported)

PURPOSE: To evaluate the effect of pre-sleep protein supplementation after an acute bout of resistance training on performance and post-exercise recovery the following day. **METHODS:** Eighteen athletic men performed a single bout of eight sets of eight repetitions of weighted barbell squats and weighted barbell chest press immediately followed by an exercise recovery drink (60g carbohydrate, 20g whey protein). The participants received either a pre-sleep protein supplement (PRO) containing 40g of casein protein (n=10; mean ± SD; age = 24.00 ± 3.86yrs; height = 1.81 ± 0.08m; weight = 84.91 ± 9.45kg) or a non-caloric, flavor matched placebo (PLA; n=8; age = 28.38 ± 9.97yrs; height = 1.81 ± 0.07m; weight = 86.68 ± 10.93kg) 30 min before sleep (1 hour after recovery drink). Blood samples were obtained at baseline (BL), pre- and post-exercise, prior to pre-sleep supplementation, and the following day to assess creatine kinase and C-reactive protein. Visual analog scales were utilized to assess perceived pain, hunger, and recovery. One-RM tests for bench and squat were performed at BL and the day following resistance exercise. Jump performance was assessed at BL, immediately post-exercise, and the day following resistance exercise. Statistical analyses were performed using SPSS (V.23) and p ≤ 0.05 was considered statistically significant; values reported as mean ± SD. **RESULTS:** PRO reported significantly less hunger the following day compared to PLA, which represented a moderate and probably beneficial effect (PRO:4.21 ± 2.85, PLA: 6.94 ± 2.22; 95% C.I. = 0.1, 2.0; p=0.04; d = 1.1; 95% C.I. = 0.1, 2.0). Although perceived recovery was not significantly different (p=0.14), the effect of PRO was interpreted as moderate and possibly beneficial (PRO:7.36 ± 1.71, PLA: 5.76 ± 2.13; d = 0.8; 95% C.I.=

-0.1, 1.8). There were no significant differences between groups in post-exercise recovery biomarkers or muscular performance assessments. Jump squat power was significantly higher in PLA immediately post exercise compared to PRO (29.7 ± 16.4 W.kg^{-1}, 22.9 ± 18.4 W.kg^{-1}, respectively; p=0.02). **CONCLUSIONS:** Pre-sleep protein supplementation after resistance exercise may improve perceived rate of recovery and hunger the following day with no effect on next day performance. This study was supported by Dymatize Nutrition.

The Effects Of Leucine-enriched Branched-chain Amino Acid Supplementation On Exercise-induced Muscle Damage

Gabriela Juache, Adam Osmond, Dean Directo, Michael Wong, Edward Jo. *Cal Poly Pomona, Pomona, CA.*

(No relevant relationships reported)

A significant degree of efficacy of branched-chain amino acid (BCAA) supplements in attenuating the symptoms of exercise-induced muscle damage (EIMD) and accelerating recovery from intense exercise have been demonstrated. Of the BCAA, leucine is evidently most contributory to the anabolic and anti-catabolic properties of BCAA in skeletal muscle. The speculation that supplementary leucine alone would likewise attenuate the symptoms of EIMD is within scientific reason. However, whether a leucine-enriched BCAA supplement (LBCAA) or a free-form leucine supplement (LEU) further attenuates EIMD when compared to a conventional BCAA supplement remains of significant debate. PURPOSE: To examine the effects of LBCAA and LEU supplementation on select markers of EIMD elicited by a bout of damaging exercise. MEHODS: Participants completed a bout of damaging eccentric-based resistance exercise (ECRE) following a 7-day supplementation period with either a conventional BCAA supplement (BCAA), LBCAA, or LEU. Muscle soreness, mean average power (MAP), mean peak power (MPP), lower body flexibility, and pressure-pain threshold were measured immediately before ECRE (0 hours) and at 24, 48, and 72 hours following ECRE. RESULTS: MAP ($45 \pm 56\%$, p=0.01) and MPP ($41 \pm 20\%$, p<0.05) decreased at 48 hours post-ECRE in LEU only. Additionally, at 48 hours post-ECRE, MPP in LEU was significantly lower than BCAA ($41 \pm 20\%$ vs. $98 \pm 15\%$, p=0.05). During resting conditions, LBCAA reported increased soreness from 0 to 48 hours post-ECRE (p<0.05), while LEU reported increased soreness from 0 to 24 hours post-ECRE (p<0.05), and BCAA exhibited no changes from 0 hours. During a contracted state, both LBCAA and LEU demonstrated increased soreness from 0 to 24 and 48 hours post-ECRE (p<0.05) while BCAA only exhibited an increase from 0 to 48 hours post-ECRE (p<0.05). All groups returned to baseline soreness levels at 72 hours post-ECRE. There were no other differences in lower body flexibility and pressure-pain threshold among supplementation groups. CONCLUSION: LBCAA and LEU failed to afford any discernible advantages to recovery from a bout of damaging exercise over BCAA.

BCAA Supplementation Improves Mental Performance Following a Soccer-Specific Conditioning Session

Beau K. Greer, Matthew S. Manzo. *Sacred Heart University, Fairfield, CT.*

(No relevant relationships reported)

The efficacy of branched-chain amino acid (BCAA) supplementation on exercise performance has been researched extensively, but influence on post-exercise mental performance remains understudied. **PURPOSE**: The present study sought to determine the efficacy of BCAA supplementation on cognitive and psychomotor performance after a high-intensity conditioning session, as well as on post-exercise rating of perceived exertion (RPE). **METHODS**: In a double-blind manner, 14 male Division I collegiate soccer players performed a smartphone-based Stroop test (EncephalApp) immediately before and after a conditioning-heavy, 80-minute soccer practice. Before and during practice, subjects ingested a water-based solution containing either BCAAs (SUPP; n=7) or an isocaloric amount of maltodextrin (PLAC; n=7) at fixed time intervals. The SUPP treatment beverage contained a total of 18 grams of BCAA, with a 3:1:1 ratio of leucine, isoleucine, and valine, respectively. Paired t-tests were used to assess within-group differences. Session RPE was assessed 30 minutes post-exercise, and between-group comparisons were made via a Mann-Whitney U test. **RESULTS**: Subjects in the SUPP group had significantly ($p < 0.05$) improved performance on the EncephalApp following exercise (11.1 ± 1.5 s) as compared to before exercise (13.4 ± 3.6 s). There was not a significant difference ($p > 0.05$) between pre-exercise (12.5 ± 2.2 s) and post-exercise (11.0 ± 1.4 s) performance in the PLAC group. No between-group difference was found for session RPE ($p > 0.05$). **CONCLUSIONS**: This evidence suggests that BCAA supplementation before and during exercise may improve certain aspects of post-exercise cognitive and psychomotor performance, but without influencing session RPE.

Effects of Creatine Monohydrate Timing Supplementation on Isometric Strength In Male College Soccer Players

Clara Yunnuen Rodriguez-Ramirez, Alejandro Gaytan-Gonzalez, Eduardo Pinedo-Ruan, Andrea Patricia Rohan-Lopez, Roberto Gabriel Gonzalez-Mendoza, Sayra Nataly Muñoz-Rodriguez, Ana Gabriela Gutierrez-Muñiz, Marisol Villegas-Balcazar, Juan R. Lopez-Taylor. *Universidad de Guadalajara, Guadalajara, Mexico.*

(No relevant relationships reported)

PURPOSE: To compare the effects of timing supplementation with creatine monohydrate in isometric strength in male college soccer players.
METHODS: Fifteen male college soccer players were supplemented with creatine monohydrate for 26 days with a load phase (5 days 20 g creatine/d) and a maintenance phase (21 days 5 g creatine/d). In the maintenance phase subjects were assigned, in a randomized and double blind form, to either consume 5 g of creatine before training and 5 g of maltodextrin after training (CRB) or 5 g of maltodextrin before training and 5 g of creatine after training (CRA) diluted in flavored water. At the same time a physical conditioning program was carried out (resistance training + soccer training 2 d/week; soccer training only 3 d/week). Before and after intervention, isometric strength in biceps, back, legs and forearms. were evaluated through dynamometry. Similarly, nutritional intake was evaluated (before and after) through 24-h dietary recalls. The strength and nutritional variables were compared by group (CRB vs CRA) and by time (PRE vs POST).
RESULTS: There were no significant differences in strength variables between groups at the beginning nor at the end of the study. However, CRB group had a significant increase in leg strength at the end of the study. The CRA group also had significant changes at the end of the study; an increase in back strength and leg strength were observed (Table 1). No other strength variable had significant changes. In the nutritional variables, there were no significant differences between groups at the beginning nor at the end of the study. Nonetheless, CRA group showed a significant decrease in energy and total protein intake (Table 1).
CONCLUSIONS: Both CRA and CRB showed similar strength gains in legs but CRA helped to increase strength in back, considering that energy and protein intake for players in CRA group decreased and they still had a significant increase in strength.

Table 1. Strength and nutritional variables compared by group (CRB vs CRA) and by time (PRE vs POST)								
		PRE			POST			p CRB by time	p CRA by time
		CRB	CRA	p group	CRB	CRA	p group

Chronic (24 weeks) Beta-alanine Supplementation Does Not Affect Muscle Taurine Or Blood Clinical Chemistry

Bryan Saunders[1], Mariana Franchi[1], Luana F. Oliveira[1], Vitor S. Painelli[1], Vinicius E. Silva[1], Rafael P. Silva[1], Luiz A.R. Costa[1], Craig Sale, FACSM[2], Roger C. Harris[3], Hamilton Roschel[1], Guilherme G. Artioli[1], Bruno Gualano[1]. *[1]University of Sao Paulo, Sao Paulo, Brazil. [2]Nottingham Trent University, Nottingham, United Kingdom. [3]Junipa Ltd, Newmarket, United Kingdom.*

Reported Relationships: B. Saunders: *Salary; Natural Alternative Inc..*

PURPOSE: To investigate the effects of chronic beta-alanine (BA) supplementation on muscle taurine content, blood clinical markers and sensory side-effects.
METHODS: Twenty-five healthy male participants (age 27 ± 4 y, height 1.75 ± 0.09 m, body mass 78.9 ± 11.7 kg) were supplemented with 6.4 g·day^{-1} of sustained release BA (N = 16; CarnoSyn™, NAI, USA) or placebo (PL; N = 9; maltodextrin) for 24 weeks. Muscle biopsies of the *m. vastus lateralis* were taken at 0, 12 and 24 weeks and analysed for taurine content using high-performance liquid chromatography. Resting venous blood samples were taken in the supine position every 4 weeks and analysed for markers of renal, hepatic and muscle function (aspartate transaminase; alanine aminotransferase; alkaline phosphatase; lactate dehydrogenase; albumin; globulin; creatinine; estimated glomerular filtration rate and creatine kinase). Data were analysed using mixed model ANOVA. **RESULTS:** There were no significant differences in taurine content at Week 0 (BA: 33.67 ± 8.18 mmol·kg^{-1}dm, PL: 27.75 ± 4.86 mmol·kg^{-1}dm; $p = 0.21$). There was a significant main effect of group ($p = 0.04$) on muscle taurine, with overall lower values in PL, although there was no main effect of time or interaction effect (both $p > 0.05$; BA, Week 12: 35.93 ± 8.79 mmol·kg^{-1}dm and Week 24: 35.42 ± 6.16 mmol·kg^{-1}dm; PL, Week 12: 27.67 ± 4.75 mmol·kg^{-1}dm and Week 24: 31.99 ± 5.60 mmol·kg^{-1}dm). There was no effect of treatment, time or any interaction effects on any blood marker (all $p > 0.05$) and no self-reported side effects in these participants throughout the study. **CONCLUSION:** The current study showed that twenty-four weeks of BA supplementation at 6.4 g·day^{-1} did not affect muscle taurine content, clinical markers of renal, hepatic and muscle function, nor did it result in chronic sensory side-effects, in these healthy individuals. Since athletes are likely to engage in chronic supplementation, these data provide important evidence to suggest that supplementation with BA at these doses for up to 24 weeks do not adversely affect these markers in healthy individuals.

E-38   Free Communication/Poster - Ergogenic Aids II - Beetroot and Nitrates

Sucrose But Not Nitrate Ingestion Reduces High-intensity Exercise-induced Gut Injury

Kristin L. Jonvik[1], Kaatje Lenaerts[1], Joey SJ Smeets[1], Jeroen Kolkman[2], Luc JC van Loon[1], Lex B. Verdijk[1]. *[1]Maastricht University, Maastricht, Netherlands. [2]Medisch Spectrum Twente and University Medical Center, Groningen, Netherlands.*
(Sponsor: Professor Janice L Thompson, PhD, FACSM)

(No relevant relationships reported)

Purpose: During high-intensity exercise many athletes suffer from gastrointestinal (GI)complaints, which are likely related to splanchnic hypoperfusion, resulting in intestinal injury. Intestinal perfusion may be improved by increasing circulating nitric oxide (NO) levels or inducing postprandial hyperemia, potentially attenuating intestinal injury during exercise. Therefore we investigated the effects of both dietary nitrate and sucrose ingestion on splanchnic perfusion and intestinal injury induced by high-intensity exercise.
Methods: In a randomized cross-over manner, 16 well-trained male athletes (age: 28 ± 7 y; W_{max}: 5.0 ± 0.3 W·kg^{-1}) cycled 60 min at 70% W_{max} following acute ingestion of: sodium nitrate (NIT; 800 mg NO_3), sucrose (SUC; 40 g) or water placebo (PLA). Splanchnic perfusion was assessed using gastric air tonometry. Plasma intestinal fatty-acid binding protein (I-FABP) concentrations, reflecting enterocyte damage, were assessed every 20 min during and up to 60 min post-exercise.
Results: The exercise protocol resulted in hypoperfusion, as gap$_{g-a}$pCO$_2$ levels increased during exercise ($P<0.001$), with no differences between treatments ($P=0.47$ for time x treatment interaction). Although plasma I-FABP concentrations increased during and post-exercise for all treatments ($P<0.001$), the increase was attenuated following SUC ($P=0.007$ for time x treatment interaction). In accordance, total I-FABP

area under curve (AUC) tended to be different between treatments (P=0.061), and I-FABP AUC was significantly different in the post-exercise period (P=0.006). Post hoc testing showed significantly lower I-FABP AUC in SUC vs PLA (1096±2182% vs 3900±3731%, P=0.022). No differences were observed between NIT and PLA (P=1.0).
Conclusions: Sucrose but not nitrate ingestion lowers gut injury evoked during high-intensity exercise. These results suggest that sucrose, but not nitrate, may prevent hypoperfusion-induced GI damage during exercise and, as such, may prevent or lower exercise-related GI complaints.

The Effect Of Nitrate Supplementation Through Powdered Beetroot Juice In Endurance Athletes Over The Time Required To Complete A 10-km Bicycle Time-trial.

Alexia Wiegandt Rohde. *Universidad Iberoamericana Mexico City, Mexico City, Mexico.*
(No relevant relationships reported)

It has been found that nitrate supplementation in the diet of athletes may have ergogenic effects, such as a decrease in the cost of oxygen when exercising at low or moderate intensity. Significant improvement has also been observed in the results of several time trials or incremental exercise tests after nitrate supplementation. Nitrate supplementation is achieved through beetroot consumption, since it is one of the nitrate-richest foods, containing over 250 mg. of nitrate per 100 g gross weight.
PURPOSE: Analyze if a group of amateur endurance athletes reduce their time to complete a 10Km time-trial on a stationary bicycle after a 5-day supplementation period with powdered beetroot juice.
METHODS: Amateur runners, cyclists and triathletes who participate regularly in sports events in any of the disciplines mentioned before participated in this study. Two tests were performed, the subjects arrived at the laboratory having taken the last dose of either placebo or supplement 2 hours earlier. This supplement should have been taken daily during the previous four days. After remaining seated for 10 minutes blood pressure and cardiac rhythm was be measured. A 10 kilometer time-trial on the stationary bicycle was performed, during which oxygen volume, cardiac rhythm and pedaling power was measured. Subjects were asked periodically at what level in the Scale of Perceived Exertion they felt to be. At the end the time taken for their cardiac frequency to be restored to its initial value was measured. **RESULTS**: Participants were able to increase their power significantly after supplementation with beetroot juice 159.2 (27,3-287.3) Watts, as compared to the placebo 130.85 (26.7-260.3) Watts (p=0.041). A significant reduction of approximately 56 (15:12-22:34) seconds was also achieved in the time the participants required to cover 10 Km on the stationary bicycle (p=0.41).
CONCLUSIONS: Beetroot juice in powder or liquid form may improve athlete's performance, since it increases considerably the power that may be exerted during a sub maximal exercise test, such as that of 10 Km by bicycle. It still remains to be determined whether these effects are consistent with those in professional athletes, since there are no studies to prove it, and whether these effects are just as efficient in longer distances.

2388   Board #224   June 1 11:00 AM - 12:30 PM

The Effects of Beetroot Juice Supplementation on Cycling Time-Trial Performance in Normoxia and Moderate Hypoxia

Samantha Fessler. *East Stroudsburg University, East Stroudsburg, PA.* (Sponsor: Shala Davis, FACSM)
(No relevant relationships reported)

Recent research has shown that Beetroot Juice (BR) ingestion assists in Nitric Oxide (NO) production and may increase exercise efficiency, decrease muscular fatigue, increase mitochondrial respiration, increase calcium handling, elevate glucose uptake, and aid vasodilatation. Also, given evidence for the detrimental effects of environmental hypoxia on exercise due to decreases in partial pressure of arterial oxygen (P_aO_2), as well as hypoxia-induced reductions in NO, increases in NO production via dietary nitrate supplementation may serve to enhance performance in hypoxia. **PURPOSE:** To investigate the effects of 3 day supplementation of beetroot juice on oxygen consumption (VO_2), arterial oxygen saturation (SpO_2), and average workload (W) during 15 minute time trial (TT) in both normoxic and simulated hypoxic (F_iO_2 = 15.3%) conditions in active males, aged 18-24. **METHODS:** Ten recreationally active healthy males participated in the study. Subjects were assigned in a double-blind randomized, crossover design consuming 140 mL of beetroot juice (2 shots) containing ~8.4mmol of nitrate (NO_3^-) and nitrate depleted placebo (PL) for 2 days prior to testing and 2.5 hours prior to testing in both normoxic and hypoxic conditions. A 72 hour washout was utilized during the crossover. Prior to testing all subjects completed a maximal effort protocol to determine Maximal Power Output (W_{max}).During testing, subjects completed a 5 minute warmup, a 15 minute steady state normoxic preload at 50% W_{max}, and finished with a 15 minute cycling time trial (TT) at

70% W_{max}, in either normoxia or simulated hypoxia (F_iO_2=15.3% O_2). **RESULTS:** No significant difference was found for BR or PL group by condition in mean workload (164.5±20.7 vs. 166.5±18.7 watts in normoxia and 162.6±13.9 vs. 161.0±22.1 watts in hypoxia, p=.769). **CONCLUSION:** The present research found no significant differences in average workloads during a 15 minute cycling TT performed in either normoxia or moderate simulated hypoxia after chronic supplementation of beetroot juice (1.4 mL X 3 days) vs. placebo. A 3-day chronic dosing protocol of 8.4 mmol NO_3^- per day in the form of BR may not be beneficial to athletes competing in cycling time trials of ~15 minutes in duration at either sea level, or following acute altitude exposure at ~2500m.

2389   Board #225   June 1 11:00 AM - 12:30 PM

Effect Of Inorganic Nitrate Supplementation On O_2 Uptake And Quadriceps Deoxygenation During The Onset And Offset Of Exercise.

Brynmor Breese[1], David Poole, FACSM[2], Dai Okushima[3], Stephen Bailey[4], Andrew Jones, FACSM[5], Narihiko Kondo[6], Tatsuro Amano[7], Shunsaku Koga[3]. [1]*Plymouth University, Plymouth, United Kingdom.* [2]*Kansas State University, Manhattan, KS.* [3]*Kobe Design University, Kobe, Japan.* [4]*Loughborough University, Loughborough, United Kingdom.* [5]*Exeter University, Exeter, United Kingdom.* [6]*Kobe University, Kobe, Japan.* [7]*Niigata University, Niigata, Japan.*
(No relevant relationships reported)

PURPOSE: To investigate the effect of inorganic nitrate (NO_3^-) supplementation on O_2 uptake (VO_2) and deoxyhemoglobin/myoglobin (i.e. deoxy-[Hb + Mb]) kinetics at contrasting muscle depths during the onset and offset of submaximal cycle exercise.
METHODS: In a randomized, cross-over study, eight males completed step cycle tests at a work rate equivalent to 50% of the difference (Δ) between the gas exchange threshold and peak VO_2 over 4-day supplementation periods with NO_3^--rich beetroot juice (BR; providing 8.4 mmol NO_3^-·day⁻¹) and NO_3^--depleted (placebo; PLA) beetroot juice. Pulmonary VO_2 was measured and absolute deoxy-[Hb + Mb] was determined in the superficial and deep vastus lateralis (i.e. VL-s and VL-d, respectively).
RESULTS: Whereas primary VO_2 kinetics (i.e. on versus off) were symmetrical, the primary deoxy-[Hb + Mb] mean response time (MRT_p) slowed within the VL-s during the off- compared to on- transient ($P < 0.05$). There were no significant differences ($P > 0.05$) between the PLA and BR trials in the deoxy-[Hb + Mb] MRT_p within the VL-s at exercise onset (PLA: 21 ± 5 vs. BR: 22 ± 5 s) or offset (PLA: 32 ± 4 vs. BR: 32 ± 9 s). Likewise, whilst the primary deoxy-[Hb + Mb] amplitude was asymmetrical within the VL-d (i.e. off > on, $P < 0.05$), there were no significant differences ($P > 0.05$) between supplement conditions at exercise onset (PLA: 27 ± 34 vs. BR: 16 ± 20 μM) or offset (PLA: 37 ± 44 vs. BR: 24 ± 26 μM).
CONCLUSIONS: Dietary NO_3^- supplementation does not affect the dynamic asymmetry of muscle deoxy-[Hb + Mb] kinetics (and by extension the matching between O_2 delivery to O_2 utilization) within deep and superficial sites during intense submaximal exercise.

Beetroot Juice Supplementation Lowers Oxygen Cost of Vigorous Intensity Aerobic Exercise in Trained Endurance Athletes

Ryan E. Fiddler[1], Erik Lind[1], Nathaniel S. Ashton[1], Joanna L. Fiddler[2]. [1]*SUNY-Cortland, Cortland, NY.* [2]*Cornell University, Ithaca, NY.*
(No relevant relationships reported)

Nitric oxide (NO) plays a critical role in regulating blood flow to skeletal muscle. NO production in humans is 1) oxygen-dependent via NO-synthases that convert L-arginine to NO and 2) oxygen-independent via the nitrate-nitrite-NO pathway. The latter can be augmented via beetroot juice supplementation (BR). **Purpose**: The purpose of this study was to investigate the effect of BR during vigorous intensity aerobic exercise. **Methods**: Using a double-blind, repeated measures crossover design, 11 Division III collegiate distance runners (mean ± SD: age = 20.3 ± 1.1 yr; VO_2peak = 55.5 ± 8.1 ml·kg⁻¹·min⁻¹) consumed either 120 mL·day⁻¹ of BR or placebo (PL) for 4 days. On day 5 of each 4-day supplementation period, subjects completed an exercise trial on a motorized treadmill consisting of five minutes of running at 65%, 85%, and 100% of volume of oxygen uptake reserve (VO_2R) separated by 2 minutes each. BR and PL supplementation protocols were separated by a 7-day washout period. Two-way repeated measures ANOVAs were used to determine the effect of treatment (BR or PL) and exercise intensity (65%, 85%, and 100% VO_2R) on VO_2, heart rate (HR), respiratory exchange ratio (RER), and rating of perceived exertion (RPE). **Results**: There were no statistically significant interactions between treatment and exercise intensity for VO_2, HR, RER, or RPE. The main effect of treatment was not statistically significant for HR, $F(1, 10) = 0.514$, $p = 0.490$; RER, $F(1, 9) = 0.590$, $p = 0.462$; or RPE $F(1, 10) = 0.562$, $p = 0.471$. However, the main effect of treatment was statistically significant for VO_2, where BR (2.43±0.18 L·min⁻¹) was lower compared

to PL (2.49±0.17 L·min⁻¹), *p* = 0.029. **Conclusions**: These results suggest that a 4-day protocol of 120 mL·day⁻¹ of BR reduces VO₂ during vigorous intensity aerobic exercise in trained endurance athletes.

Acute Dietary Nitrate Supplementation has no Significant Effect on Wasted Left Ventricular Energy in Young Healthy Individuals

Jozelyn Rascon[1], Francisco J. Morales[1], Brycen J. Ratcliffe[2], Caleb D. Harrison[2], Evan J. Bockover[2], Sierra Crowe[2], Colin R. Carriker[3], Alvaro N. Gurovich, FACSM[1]. *[1]The University of Texas at El Paso, El Paso, TX. [2]Indiana State University, Terre Haute, IN. [3]High Point University, High Point, NC.*
(No relevant relationships reported)

Cardiovascular disease is the leading cause of death worldwide and is associated with low levels of Nitric Oxide (NO) bioavailability. NO is a vascular protective agent, which bioavailability could increase through dietary nitrate supplementation. Wasted left ventricular energy (LVEw) represents the added workload the ventricle must produce during the duration of the reflecting pressure wave within a cardiac cycle. This energy is wasted because there is no blood flow gain produced by the extra work being exerted by the ventricle. LVEw is associated with arterial stiffness, left ventricular hypertrophy, and refractory angina syndrome. Higher levels of NO are associated with lower cardiovascular disease risks. Therefore, an increase in NO through dietary nitrates might reduce LVEw.
Purpose: To determine the response of an acute dietary nitrate supplement in LVEw via noninvasive pulse wave analysis (PWA).
Methods: A double-blind, cross-over study design was performed in 17 young, healthy subjects (18 to 24 years old). Four lab visits were schedule within 10 days; the first 2 visits in back to back days and the last 2 visits one week after. Subjects were asked to follow a low-nitrate diet for 3 days (NHLBI: 7 East Low-Nitrate Diet), starting two days prior to the first and third lab visits. Two hours before visits 2 and 4, subjects were asked to drink 800 mg of nitrate or placebo (solutions randomly assigned). LVEw was calculated using LVEw $=((\pi/4) \times (Ps-Pi) \times (ED - \Delta Tp) \times 1.333)$ where ED is ejection duration, Ps and Pi represent central systolic pressure and the central incident pressure from reflecting pressure wave, respectively, and ΔTp is the round trip travel time of the reflecting pressure wave. PWA was measured non-invasively with a cuff-based PWA device (SphygmoCor Xcel®). A two-way repeated measurements ANOVA (time x sex) was performed and significance was set at alpha=0.05.
Results: LVEw ranged from 736 ± 644 dyne•s•cm⁻² at baseline in males to 997 ± 917 dyne•s•cm⁻² after placebo, also in males and there was no significant interaction (time x sex).
Conclusions: These results show that an acute dose of dietary nitrate supplement has no effect on LVEw in young healthy individuals. Further studies including the elderly or patients with hypertension should be performed to assess more clinical effects of dietary nitrates.

Changes in Oxidative Stress and Resting Metabolic Rate after Acute Dietary Nitrate Supplementation

Brycen J. Ratcliffe[1], Caleb D. Harrison[1], Evan J. Bockover[1], Sierra Crowe[1], Alberto Friedmann[1], Francisco J. Morales[2], Colin R. Carriker[3], Alvaro N. Gurovich, FACSM[2]. *[1]Indiana State University, Terre Haute, IN. [2]The University of Texas at El Paso, El Paso, TX. [3]High Point University, High Point, NC.*
(No relevant relationships reported)

BACKGROUND: Cardiovascular disease is the leading cause of preventable death in the United States and the Western world. A major component of cardiovascular disease is the deterioration of the cardiovascular system by increased oxidative stress. Dietary nitrate supplementation could increase nitric oxide bioavailability, decreasing oxidative stress.
PURPOSE: The purpose of the present study is twofold: 1) to determine the impact of an acute dietary nitrate supplementation on oxidative stress and 2) to assess the oxygen dependent nature of a dietary nitrate supplementation.
METHODS: Eighteen (7 females and 11 males) apparently healthy subjects, aged 18-30 years of age, participated in a randomized, double blind, placebo-controlled crossover study. Following a 12-hour fast and adherence to an NIH-approved low-nitrate diet for 48 hours, subjects visited the lab on 4 occasions (identical procedures) within 2 weeks. A resting blood draw preceded 15 minutes of supine rest followed by a 20-minute period of metabolic gas analysis for determination of resting metabolic rate; RMR (True One, ParvoMedics, Sandy, Utah, USA). Visits 2 and 4 served as baseline controls for the placebo or dietary nitrate treatments (negligible and 800mg nitrate, respectively) which were consumed 2.5 hours prior to visits 3 and 5. The resting concentration of the oxidative stress marker 8-isoprostane (8-ISO) was determined by

ELISA testing using a commercial available kit (Cayman Chemical, USA). A 2-way repeated measures ANOVA was used to determine differences between protocols and over time, with an alpha of 0.05.
RESULTS: There was no significant difference between placebo and dietary nitrate supplementation in oxidative stress (Placebo: 158±59 vs. 181±62 pg/ml; Active: 176±74 vs. 171±59 pg/ml, p=0.84) or in RMR (Placebo: 1839±308 vs. 1790±307 kcal/day; Active: 1828±318 vs. 1859±324 kcal/day, p=0.20).
CONCLUSION: These data showed that acute dietary nitrate supplementation does not decrease resting oxidative stress. The conversion of nitrate to nitrite to nitric oxide has been previously described to be oxygen-independent. Our data supported this statement, as RMR did not change following the dietary nitrate supplementation.

2393   Board #229   June 1 11:00 AM - 12:30 PM

Effect of Increased Nitric Oxide Bioavailability on Endothelial Function and Pulse Wave Velocity

Evan J. Bockover[1], Sierra Crowe[1], Brycen J. Ratcliffe[1], Caleb D. Harrison[1], Alberto Friedmann[1], Francisco J. Morales[2], Colin R. Carriker[3], Alvaro N. Gurovich, FACSM[2]. *[1]Indiana State University, Terre Haute, IN. [2]The University of Texas at El Paso, El Paso, TX. [3]High Point University, High Point, NC.*
(No relevant relationships reported)

BACKGROUND: Dietary nitrate supplementation is believed to increase the long-term bioavailability of nitric oxide (NO) within the body. This increase in NO bioavailability should lead to a decrease in arterial stiffness and an increase in endothelial function due to the vasodilator characteristics of NO.
PURPOSE: The purpose of this experiment was to evaluate whether an increased NO bioavailability, achieved through dietary nitrate supplementation, improves pulse wave velocity (PWV) and flow-mediated dilation (FMD).
METHODS: In a randomized double blind, placebo-controlled crossover design, eighteen (7 females, 11 males) apparently healthy subjects aged 18-30 years old visited the lab 4 times within 2 weeks. All subjects were required to fast for 10 to 12 hours prior to testing and each visit consisted of a resting blood draw followed by peripheral blood pressure acquisition, PWV and assessment of brachial FMD. Visits 2 and 4 (separated by a 1-week washout) were baseline controls and, 24 hours after, on visits 3 and 5 participants consumed a concentrate nitrate beverage or placebo (800mg and negligible nitrate, respectively) 2.5 hours prior to testing. Plasma nitrate/nitrite (NOx) concentration was determine by ELISA testing using a commercially available kit (Cayman, USA). A 2-way repeated measures ANOVA was used to determine differences between conditions and over time, with an alpha of 0.05.
RESULTS: There was an acute increase in NOx concentration after dietary nitrate supplementation compared to the baseline control (1.2±1.3 vs. 27.1±10.8 μmol/l, p<0.01) while no difference was seen following consumption of the placebo: 1.7±1.5 vs. 1.7±1.1 μmol/l, p=0.311). No changes were observed for PWV (Placebo: 6.2±0.6 vs. 6.2±0.7 m/s; Active: 6.1±0.6 vs. 6.1±0.8 m/s, p=0.81), or FMD (Placebo: 9.7±6.6 vs. 9.0±10.2 %; Active: 10.4±5.0 vs. 9.9±7.3 %, p=0.96) between nitrate and placebo conditions.
CONCLUSION: The data from this experiment illustrates that the dietary nitrate supplementation did provide an acute increase of NO bioavailability. However, this acute increase in NO bioavailability did not result in acute benefits to arterial stiffness or endothelial function measured via PWV and FMD, respectively.

Effects of Beet Juice on Anaerobic Exercise Performance

Clare Zamzow[1], Matthew E. Darnell[2], Philip Ford[1], Scott A. Conger[1]. *[1]Boise State University, Boise, ID. [2]University of Pittsburgh, Pittsburgh, PA.* (Sponsor: Dawn P. Coe, FACSM)
(No relevant relationships reported)

Research suggests dietary nitrate contained in beet juice is beneficial during aerobic exercise. Its impact during anaerobic (i.e. short duration, high power) exercise has received much less attention. **PURPOSE:** To determine the effects of acute beet juice supplementation on anaerobic performance during 30-s and 60-s maximal effort cycling sprints. **METHODS:** Fourteen male hockey players participated in this study. The exercise protocol included maximal effort 30-s and 60-s tests (Wingate), on a stationary bike with a fixed amount of resistance applied relative to body weight. In addition to two familiarization trials, each participant completed in random order 30-s placebo and beet juice trials and 60-s placebo and beet juice trials. The beet juice supplement contained ~8mmol/496 mg of dietary nitrate. Apple-cherry-cranberry juice served as the placebo, containing a negligible amount of dietary nitrate. Paired t-tests were run to compare performance in both the 30-s and 60-s trials, analyzing peak and mean power (W), peak and mean RPM, relative power (W/kg), total work (J), and fatigue index (FI, %). A one-way ANOVA was utilized to compare the change between the beet juice and placebo trials of the 30-s test, to the change between beet juice and placebo trials of the 60-s test. **RESULTS:** Beet juice supplementation yielded no statistical differences in any of the measured variables during the 30-s or 60-s tests

($p > 0.05$). A trend occurred during the 30-s test ($p = 0.059$), showing a decreased FI (53.44 vs. 56.01%), suggesting less fatigue occurred after beet supplementation, while there was no statistical difference in FI during the 60-s trials. The percent change for FI was significantly different between the 30 and 60-s tests (30-s: -5.24 9.70, 60-s: 0.50 5.94, $p = 0.032$). No other significant differences emerged between the 30-s and 60-s tests. **CONCLUSIONS:** A dose of ~8 mmol of beet juice did not improve anaerobic exercise performance during a 30-s or 60-s maximal effort cycling sprint. The performance differences were similar when comparing the 30-s and 60-s bouts after beet juice supplementation. Beet juice supplementation during high power, anaerobic exercise does not produce similar improvements in performance that have been reported during aerobic exercise.

Effect of Beet Root Juice on Delayed Onset Muscle Soreness Following Eccentric Loading.

Charles R. Jedlicka, Hailey M. Richter, Abigail E. Geislinger, Gianna E. Scala, Adrienne T. Tryan, Katelyn D. Olson, Shannon M. Bodily, Kaitlyn A. Anderson, Kent C. Hansen. *winona state university, Winona, MN.*

(No relevant relationships reported)

The increase in prevalence of super foods, such as beet root, in popular culture has necessitated research into their effectiveness. Betalains, a prominent phytonutrient in beet root, have proven to have both antioxidant and anti-inflammatory properties. Due to these qualities, betalains have the potential to augment the natural process of healing delayed onset muscle soreness (DOMS) from eccentric loading. **Purpose**: To determine if beet root juice provides benefit in DOMS recovery. **Methods:** 13 healthy college aged males were recruited into a double-blind crossover design study using a beet root concentrate. Participants were randomly assigned to a beet root juice (BRJ) or a placebo (PLA) group. Prior to eccentric loading, participants were dosed twice daily (2x70mL) for six days. They were then subjected to an eccentric only load protocol (5 sets of 10 repetitions) on the biceps brachii using a Biodex Dyanamometer. Several variables reflective of DOMS were measured including: maximal isometric voluntary contraction (MIVC), flexed arm angle (FAA), relaxed arm angle (RAA), subjective pain, point tenderness, and maximal contractile force. The indicators were measured at baseline and three time points following eccentric loading (24, 48, and 72 hrs). Dosing continued through the 72hr time point. **Results:** A significant treatment effect (p=0.03) was seen in reducing the angle at the elbow while being flexed (FAA) at all post exercise timepoints (24, 48, and 72 hrs) while being dosed with beet root juice concentrate. A trend toward a significant treatment effect (p=0.09) was observed in increasing isometric biceps brachii strength (MIVC). A significant time effect was observed (p<.001) for all measured variables. **Conclusion**: This evidence suggests that BRJ has the potential to provide improvement in recovering from exercise induced muscle damage.

Nitrate Supplementation Influences Contraction-Relaxation Rates During Ischemic Exercise in Post-Menopausal Women

Swapan Mookerjee[1], Jin-Kwang Kim[2], Kristina Neely[2], Jacqueline Tucker[2], Yasina Somani[2], Michael P. Flanagan[2], Daniel B. Kim-Shapiro[3], Swati Basu[3], David N. Proctor, FACSM[2]. [1]*Bloomsburg University, Bloomsburg, PA.* [2]*Penn State University, University Park, PA.* [3]*Wake Forest University, Winston-Salem, NC.* (Sponsor: David Nathan Proctor, FACSM)

(No relevant relationships reported)

Purpose:
Recent studies suggest that dietary nitrate supplementation can increase contractile force development and relaxation rates in electrically-stimulated human and rodent muscles, particularly at low stimulation frequencies (i.e., conditions associated with enhanced SR Ca^{++} release). In the present study we retrospectively examined handgrip force recordings from a prior study in which we observed a nitrate-associated enhancement of ischemic exercise tolerance in older women. We hypothesized that rates of handgrip force development and relaxation would be increased during their nitrate supplement visit relative to their placebo visit.
Methods:
Nine healthy, normotensive, post-menopausal women (57-64 years) performed intermittent handgrip exercise (10% of MVC, 30 per min) during progressive upper arm cuff inflation (+20 mmHg per min) on 3 study visits, with 7 to 10 days between visits. Approximately one week following visit 1, participants randomly consumed 140 ml of nitrate-concentrated (0.6 g of nitrate; $BrJ_{nitrate}$) or nitrate-depleted ($BrJ_{placebo}$) beetroot juice (James White Beet-It Organic; IND#119978), with handgrip exercise beginning two hours post-consumption. Grip force recordings (1,000 Hz sampling rate) were subsequently analyzed and time to 90% peak force (t90%) as well as half relaxation time (hrt) were determined.
Results:

Compared to responses observed during the $BrJ_{placebo}$ visit, $BrJ_{nitrate}$ consumption increased time to volitional fatigue (526±46 vs. 567±50 sec) (p<0.05). Significant Δ (BRJplacebo - BRJnitrate) effects were noted for Δ t90% (mean 27.7 ± 31.8 msec, p <0.03) as well as Δ hrt (27.8 ± 31.6 msec, p<0.03), indicating a faster rate of force development as well as a faster relaxation rate with $BrJ_{nitrate}$ consumption. Visit order (i.e., practice) did not influence exercise tolerance. **Conclusion:** Acute dietary nitrate supplementation increases rates of muscle force development and relaxation during ischemic, voluntary exercise in older women, possibly implicating improved calcium handling as a mechanism underlying their enhanced fatigue resistance under these conditions.

The Integrative Benefits Of Oral Nitrate Supplementation On Supra-Maximal Cycling Work Demands

Craig E. Broeder, FACSM[1], Victoria Flores[1], Bill Julian[1], Frank Wojan[2], Rachel Tauber[2], Laurie Schubert[1], Amanda Salacinski[3]. [1]*Exercising Nutritionally, LLC, Naperville, IL.* [2]*Northern Illinois University, DeKalb, IL.* [3]*University of Masschusetts, Lowell, MA.*

Reported Relationships:　C.E. Broeder: *Contracted Research - Including Principle Investigator; Corporate grant.*

PURPOSE: This study investigated the effects beet nitrate supplementation had on cycling performance (power, force, cadence (Cad) speed (Spd), distance, time to fatigue, kJ expended) during repeated high intensity intervals (HIIT). **METHODS:** Eight cyclists participated (Age: 41.4 ± 9.1; WT: 83.3 ± 9.6 kg; BF%: 21.7 ± 0.1; VO2 max: 4.20 ± 0.58 L/min, functional threshold power (FTP): 245.4 ± 43.6 watts). This study was a randomized, double-blind, crossover, matched pair design. Prior to the HIIT sessions, subjects consumed for 7-days placebo (PL) or an oral beet nitrate (BN) supplement. On the day of testing, after completing baseline measurements & 45-mins prior to the HIIT session, 10g of the treatment week's supplement was consumed by each rider. The HIIT workload was set at a wattage 1.5 times greater than a cyclist's baseline FTP, e.g., FTP = 200 watts; HIIT work interval = 300 watts. Each HIIT segment was 75-secs and followed by a 2-min recovery at 50% of FTP. Cyclists were instructed to do as many intervals as possible. A matched paired t-test was used to compare each treatment for the summary data (i.e., total secs completed under the placebo versus beet supplementation conditions), HIIT trial total work data, and HIIT trial total recovery data. When a significant difference was observed, Cohen's d effect size (ES) procedures were used to determine the magnitude. **RESULTS:** BN supplementation improved time to exhaustion (PL: 1,251 ± 562 secs, BN: 1,475 ± 504 secs; p = 0.02; ES = 0.423) and total energy expended (PL: 251.3 ± 48.6 secs, BN: 306.6 ± 55.2 kJ; p = 0.01; ES = 1.079) compared to PL. Subjects during the BN trials completed more intervals (BN = 8.14 ± 2.4, PL = 7.00 ± 2.5, p = 0.03, ES = 0.42) and cycled 23.9% further (BN = 13.5 ± 3.9 km, PL = 10.9 ± 4.0 km, p = 0.01, ES = 0.65). During the work segments, BN enhanced cadence and speed by 2.0% at the same force compared to PL (Cad: p = 0.02; ES = 0.20; Spd; p = 0.02; ES = 0.20). During recovery, comparing BN to PL, force was lower (PL: 68.2 ± 15.6 N, BN: 65.5 ± 13.7 N, p = 0.01, ES = 0.23), Cad was higher (PL: 91.8 ± 10.9 rpm, BN: 93.9 ± 7.4 rpm, p = 0.01, ES = 0.23), Spd was greater (PL: 30.7 ± 3.3 kph, BN: 31.4 ± 1.9 kph, p = 0.02, ES = 0.27). **CONCLUSIONS:** BN enhanced HIIT work and recovery performance allowing a more efficient maintenance of Cad, force, & Spd.

Nitrate and Nitrite Content of Beet Juice Products Marketed to Athletes

Edgar J. Gallardo, Andrew R. Coggan, FACSM. *Indiana University Purdue University Indianapolis, Indianapolis, IN.*

(No relevant relationships reported)

The consumption of beet juice has become particularly popular among athletes, due to the fact that dietary nitrate has been shown to enhance exercise capacity. This has resulted in many companies creating and marketing beet-based products to meet consumer demand. Depending on growing conditions, however, the nitrate content of beets can vary significantly. This makes it difficult for athletes to know how much nitrate they are actually ingesting. **PURPOSE**: To determine the quantity of nitrate (and nitrite) present in beet juice products marketed towards, or easily available to, athletes. **METHODS**: Samples from 26 different lots of 11 different beet juice products produced by 10 different companies were purchased locally or via the internet. After reconstituting (if necessary) and diluting each sample 1000x in water, nitrate and nitrite concentrations were measured using a dedicated high performance liquid chromatography system. The amount of nitrate and nitrite per serving was then calculated based on the measured concentrations and either 1) the manufacturer's recommended serving size (for prepackaged/single dose products) or 2) a volume of 500 mL (for beet juice sold in bulk containers). **RESULTS:** There was moderate-to-large variability in nitrate content between samples of the same product, with a mean coefficient of variation of 14.9±21.2% (range 2.3 to 60.6%). However, there was even

greater variability between products, with nearly a 20-fold range in nitrate content between the lowest (1.0±0.6 mmol/serving) and highest (17.9±0.8 mmol/serving). The amount of nitrite in all products was very low (i.e., <0.5% compared to nitrate), except for one that contained 10.2±1.1%. Over half of the products contained less nitrate (or nitrite) per serving than appears necessary to enhance exercise capacity in most individuals. Interestingly, among bulk juices there was no difference between certified organic and non-organic products in terms of nitrate content (i.e., 9.2±6.0 vs. 8.4±3.4 mmol/serving). **CONCLUSIONS:** The present results may be useful to athletes or coaches contemplating which (if any) beet juice product to utilize. These data may also offer some insight into variability in the literature with the respect to the effects of beet juice on exercise performance.

Effects Of Tetrahydrobiopterin On Limb Blood Flow And Muscle Metabolism In Patients With COPD

Stephen Decker[1], Oh Sung Kwon[1], Taylor S. Thurston[1], Yann Le Fur[1], Eun-Kee Jeong[1], Gwenael Layec[1]. *[1]University of Utah, Salt Lake City, UT. [2]Centre de Resonance Magnetique Biologique et Medicale, Marseille, France.*
(No relevant relationships reported)

Exercise intolerance is a frequent complaint and an important predictor of mortality in patients with Chronic Obstructive Pulmonary Disease (COPD). Though several factors have been implicated in the development of muscle dysfunction with COPD, chronic oxidative stress and reduced nitric oxide (NO) bioavailability have been previously suggested to be key factors involved in impaired muscular function. Thus, restoration of the redox balance and NO bioavailability using tetrahydrobiopterin (BH_4), an essential cofactor involved in the production of NO and free-radicals, appears to represent a novel therapeutic target for improving muscle oxygenation and metabolism in patients with COPD. **PURPOSE:** The aim of this study was to determine the effects of an acute BH_4 supplementation (10 mg·kg^{-1}) on peripheral O_2 delivery and muscle metabolism in the plantar flexor muscles of patients with COPD. **METHODS:** 5 patients with clinically diagnosed COPD performed dynamic plantar flexion exercise at 40% of maximal work rate with phosphorus magnetic resonance spectroscopy (^{31}P-MRS), near-infrared spectroscopy (NIRS), and vascular Doppler ultrasound assessments following oral supplementation of BH_4 or placebo (PL). **RESULTS:** Following BH_4 supplementation, exercise-induced changes in Phosphocreatine (PL: 35.4% ± 11.7%; BH_4: 26.8% ± 10.7%, P<0.01), inorganic phosphate (PL: 8.4% ± 2.2%; BH_4: 6.1% ± 1.4%, P<0.05), and pH (PL: 6.89 ± 0.12; BH_4: 6.97 ± 0.04, P=0.10) showed attenuated responses. In contrast, end-exercise limb blood flow was not significantly different between BH_4 and PL. **CONCLUSION:** Acute oral BH_4 supplementation in patients with COPD appears a promising therapy to, at least partially, restore skeletal muscle metabolism, thus potentially contributing to improved exercise tolerance and quality of life.

E-39   Free Communication/Poster - **Ergogenic Aids III - Bicarbonate and Caffeine**

The Acute Effect of Energy Shots on 5K Run Performance

Aashaun Khedaru, Matthew Marra, John Petrizzo, Lauren Yanni, Jessica Machaby, John Wygand, FACSM, Robert M. Otto, FACSM. *Adelphi University, Garden City, NY.* (Sponsor: Robert M. Otto, FACSM)
(No relevant relationships reported)

Caffeine (CF) is the most widely used psychotropic drug in the world and has wide spread use in sport performance. The benefit in short, powerful activities may be questionable, but the benefit to endurance performance is well studied. Generally this central nervous system stimulant is believed to delay the perception of fatigue and may improve performance. CF can be ingested in isolation or in combination with other substances. Energy shots (60-90 mL volume) with less sugar, carbohydrates, and carbonated water than traditional energy drinks are gaining popularity for CF delivery with less gastrointestinal distress. **Purpose:** The purpose of this study was to determine the effect of an acute ingestion of two types of energy shots on 5K treadmill time-trial run performance. **Methods:** In a double-blind crossover study, 17 recreational or intercollegiate runners (body mass 64.3 ± 16 kg, height 172.9 ± 4 cm, age 23.9 ± 3.6 yr, run 40 ± 8 km/wk, 10♂) performed three randomly assigned 5K trials preceded by abstaining from CF for 48 hrs and ingesting a matched fluid from an opaque container, 30 minutes pre-trial. Trials A and B both contained 5 mg CF/kg, but A contained a popular energy shot, while Trial B contained naturally occurring CF derived from

plants with additional minerals, vitamins, and anti-oxidants. Trial C (placebo) contained only the same lemon-lime taste in water absent of CF. Subjects performed their own consistent warm-up, controlled their pace throughout each trial, and were informed of splits at each mile. Statistical analysis by ANOVA (p<.05) was applied to these data. **Results:** Time trial performance for Trials A, B, and C were 1393 ± 274 sec, 1368 ± 287 sec, and 1403 ± 295 sec, respectively with NSD among all trials. The analysis of mile split times revealed NSD among each mile of the 5K distance, as well. **Conclusion:** The use of CF at 5 mg/kg was insufficient to improve run performance in moderate duration endurance activity during self-modulated treadmill running for recreational through intercollegiate runners. CF tolerance, initiated by the chronic ingestion of CF, is acquired gradually and dissipates over a similar time course. It may be possible that the 48 hour abstinence from CF was insufficient for some of the runners to reduce their CF tolerance, and thus the acute effect of CF was attenuated.

Optimising Sodium Bicarbonate Supplementation: Are Gastro-resistant Capsules The Answer?

Luana F. Oliveira, Bryan Saunders, Guilherme Yamaguchi, Bruno Gualano, Hamilton Roschel, Guilherme G. Artioli. *University of São Paulo, Sao Paulo, Brazil.*
(No relevant relationships reported)

PURPOSE: To investigate the effects of sodium bicarbonate (SB) delivery method (gastro-resistance or gelatin capsules) and dosage on bicarbonate increase and side-effects incidence. **METHODS**: Fourteen healthy men (age 27 ± 5 y; body mass [BM] 76.1 ± 11.4 kg; height 1.75 ± 0.06 m) participated in a double-blind and crossover study, composed of five laboratory visits. During each visit they received a different treatment: 0.3 g•kg^{-1} BM of SB in gastro-resistent (RES3) and gelatine capsules (GEL3); 0.1 g•kg^{-1} BM of SB in gastro-resistent (RES1) and gelatine capsules (GEL1); and 0.3 g•kg^{-1} BM of corn flour (PLA). Following an overnight fast, participants consumed a standardised breakfast one hour before ingesting the supplements. Blood samples were taken before and every 10-min following supplement ingestion for 3 h and then every 20 min for a further 1h and were analysed for bicarbonate concentration (RAPIDLab 348, Siemens). Area under the curve (AUC), and peak bicarbonate were recorded. Side-effects were assessed using a modified questionnaire. Data were analysed using mixed-model ANOVA for blood variables and Friedman test for side-effects. **RESULTS**: There was a significant main effect of treatment on AUC and peak bicarbonate (both p < 0.001), with greater values in RES3 (AUC: 1594.5; peak: 36.4 mmol•L^{-1}) and GEL3 (AUC: 1641.6; peak: 35.1 mmol•L^{-1}) compared to RES1 (AUC: 1069.6; peak: 31.8 mmol•L^{-1}), GEL1 (AUC: 888.7; peak: 31.5 mmol•L^{-1}) and PLA (AUC: 849.3; peak: 29.7 mmol•L^{-1}); there were no differences between types of capsules. Side-effects were significantly different between treatments (X^2=13.545; p=0.009), with higher incidence in RES3 and GEL3 than RES1, GEL1 and PLA, with no differences between capsule types. **CONCLUSIONS**: The current study showed thatblood variables were not different when SB was delivered in gastro-resistant and gelatine capsules, nor were any associated side-effects. The only differences shown were due to dose and not the type of capsule. SB supplementation in gastro-resistent capsules did not lead to greater increases in circulating bicarbonate or less side-side effects compared to gelatine capsules.

Double-blind, Placebo Controlled, Randomized Crossover Pilot Study Evaluating The Impacts Of Sodium Bicarbonate in a Transdermal Delivery System on Physiological Parameters and Exercise Performance

Mark Kern[1], Lisa M. Misell[2], Andrew Ordille[1], Madeline Alm[1], Brookell Salewske[1]. *[1]San Diego State University, San Diego, CA. [2]Ampersand Biopharmaceuticals, LLC, Thousand Oaks, CA.* (Sponsor: Michael Buono, FACSM)
Reported Relationships: M. Kern: *Contracted Research - Including Principle Investigator; Ampersand.*

Oral sodium bicarbonate has been used for decades as an ergogenic aid by buffering muscle acid production during exercise and subsequently delaying the onset of fatigue in athletes. However, gastrointestinal side effects limit the use of sodium bicarbonate. **PURPOSE**: This study evaluated the efficacy of a commercially available topical transdermal sodium bicarbonate (TSB) lotion (Topical Edge™) which is claimed to be delivered through the skin using a novel patent-pending transdermal delivery system for impacting exercise metabolism and performance.
METHODS: 20 trained cyclists (Category 1-3) and a professional triathlete participated in this randomized, cross-over, double-blinded, placebo-controlled study. After application of TSB or placebo lotions, subjects completed a variety of exercise and performance tests. On one day subjects completed a high-intensity series of exercise tests which included a ramped protocol until reaching a rating of perceived exertion (RPE) of 17 out of 20, a 30-second sprint performance test, and a 5-minute

time trial performance test, with 5 minutes of recovery between tests. On a separate day subjects completed a 1-hour time trial. Heart rate, RPE, blood lactate and pH were assessed before, during, and after performance testing.
RESULTS: Heart rate and RPE were significantly (p<0.05) lower for TSB compared to placebo at the 15-min mark of the 1-hour time trial, but not at other time points. When TSB was applied, lactate was higher (p<0.05) after the high-intensity ramp, sprint and 5-min time trial series (10.8±3.2 mmol/L versus 9.7±3.1 mmol/L for TSB and placebo, respectively). Similar effects were not observed after the 1-hour time trial. Significance was not reached when examining performance differences (p>0.05).
CONCLUSIONS: Overall, the findings from this study provide evidence that TSB can significantly impact blood lactate, heart rate and RPE during performance tests of varying intensity/length. These significant findings support the ability of this lotion to tradermally deliver sodium bicarbonate, which could allows athletes to avoid the side-effects of oral bicarbonate use. Further research is warranted to substantiate these findings and determine the most effective use for this commercially available transdermal sodium bicarbonate lotion.

Double-blind, Placebo Controlled, Randomized Crossover Pilot Study Evaluating the Impacts of Sodium Bicarbonate in a Transdermal Delivery System on Delayed Muscle Onset Soreness

Lisa Misell[1], Mark Kern[2], Andrew Ordille[2], Madeline Alm[2], Brookell Salewske[2]. [1]*Ampersand Biopharmaceuticals, LLC, Thousand Oaks, CA.* [2]*San Diego State University, San Diego, CA.* (Sponsor: Michael Buono, FACSM)
Reported Relationships: M. Kern: *Contracted Research - Including Principle Investigator; Ampersand.*

Sodium bicarbonate/alkalinization may reduce muscle mitochondrial damage caused by reactive oxygen species during intense exercise. Such damage can induce post-exercise inflammation and pain, which may be linked to delayed onset muscle soreness, or DOMS. However gastrointestinal side effects limit the use of oral sodium bicarbonate. **PURPOSE**: This study evaluated the efficacy of a commercially available, topical transdermal sodium bicarbonate (TSB) lotion (Topical Edge™), which is claimed to be delivered through the skin using a novel patent-pending transdermal delivery system for impacting DOMS.
METHODS: 20 trained cyclists (Category 1-3) and professional triathletes participated in this randomized, cross-over, double-blinded, placebo-controlled study. After application of TSB or a placebo, subjects completed a variety of exercise and performance tests varying in duration. On one day subjects completed a series of high-intensity exercises which included a ramped protocol to a rating of perceived exertion (RPE) of 17 out of 20, a 30-sec sprint performance test, and a 5-min time trial with 5 minutes of recovery between tests. On a separate day subjects completed a 1-hr time trial. Subjects completed DOMS questionnaires 24- and 48-hours after exercise sessions. Muscle soreness was rated on a scale of 0-100 where 0 = "no soreness", 25 = "mild pain", 50 = "moderate pain", 75 = "severe pain" and 100 = "the worst pain you can imagine".
RESULTS: DOMS was reduced following the high-intensity series with TSB compared to placebo. Similar effects were not observed following the 1-hr exercise bout. From the first to second day following the high-intensity exercise series, subjects using TSB experienced a 54% reduction in DOMS versus an increase in DOMS of 34% with placebo (p=0.007). **CONCLUSIONS**: Findings from this study suggest that TSB can significantly shorten recovery from DOMS following high-intensity exercise. Findings also support the effectiveness of the transdermal system in delivering sodium bicarbonate topically and may allow athletes to achieve these results while avoiding the side-effects of oral bicarbonate. Furthermore, we believe this study is the first to provide a direct link between sodium bicarbonate use and DOMS in athletes. Additional research is underway to further substantiate these findings.

Effects of a Thermogenic Pre-Workout Supplement on Fat Oxidation Rates During Moderate-Intensity Running in Females

Jamie Erickson[1], Andrew Jagim[2], Glenn Wright[1], Carl Foster, FACSM[1], Clayton Camic[3]. [1]*University of Wisconsin-La Crosse, La Crosse, WI.* [2]*Lindenwood University, St. Charles, MO.* [3]*Northern Illinois University, DeKalb, IL.* (Sponsor: Carl Foster, FACSM)
(No relevant relationships reported)

PURPOSE: The purpose of the present study was to examine the effects of acute doses of a thermogenic, pre-workout supplement on fat oxidation rates during moderate-intensity treadmill running in females.
METHODS: Twelve aerobically-trained females (mean ± SD: age = 25.3 ± 9.4 years; body mass = 61.2 ± 6.8 kg) volunteered to visit the laboratory on four occasions. For the first visit, each subject completed an incremental treadmill test to exhaustion to determine their ventilatory threshold (VT) using a metabolic cart. On the second visit, each subject consumed a standardized meal following overnight fasting (8 hours) 30 minutes prior to ingestion of one (S1) or two servings (S2) of the supplement or placebo (P). One serving of the supplement contained caffeine anhydrous (150 mg), beta alanine (1600 mg), arginine AKG (1000 mg), as well as tyrosine, L-carnitine, green coffee bean extract, and velvet bean extract at unspecified quantities. The placebo was a non-caloric mix that was matched for flavor and consistency. Thirty minutes post-ingestion, the subjects performed a 30-minute constant-velocity treadmill run at 90% of their VT with ventilatory parameters expressed as 5-min averages. The subjects then returned to the laboratory for their third and fourth visits to ingest the remaining conditions (S1, S2, or P) and underwent the same testing procedures (including time of day) as the second visit. A two-way ANOVA with repeated-measures was used to compare the rates of fat oxidation among the conditions (S1, S2, P) at the common time points (5, 10, 15, 20, 25, 30 min) of the 30-minute run.
RESULTS: For the rates of fat oxidation, there was no significant ($P > 0.05$) condition x time interaction or main effect for condition, but there was a main effect for time. Specifically, the marginal means (collapsed across conditions) for fat oxidation rates were significantly ($P < 0.05$) greater at 5-min (0.35 ± 0.20 g·min[-1]) and 30-min (0.35 ± 0.16 g·min[-1]) than 10-min (0.28 ± 0.13 g·min[-1]), 15-min (0.29 ± 0.13 g·min[-1]), 20-min (0.28 ± 0.14 g·min[-1]), and 25-min (0.31 ± 0.15 g·min[-1]).
CONCLUSIONS: The present findings indicated that one or two servings of the pre-workout supplement had no significant effect on rates of fat oxidation during 30 minutes of moderate-intensity treadmill running in aerobically-trained females when compared to placebo.

The Effects Of Caffeine On Time-trial Performance And Associated Physiological Responses: a Meta-analysis

Mark Glaister, FACSM. *St Mary's University, Twickenham, United Kingdom.*
(No relevant relationships reported)

PURPOSE: The aim of this study was to carry out a systematic review and meta-analysis of the effects of caffeine supplementation on moderate to high-intensity closed-loop time-trial performance and associated physiological responses. METHODS: 32 studies met the inclusion criteria of adopting double-blind, randomized, crossover designs that included a closed-loop time-trial of moderate to high-intensity aerobic exercise performed under a standard caffeine dose of 3-6 mg·kg[-1] administered 30 – 90 minutes prior to performance. Meta-analyses were completed using a random-effects model, with effects on time-trial performance presented as standardized mean difference (δ) and with physiological responses presented as raw mean difference (D). 95% confidence limits (CL_{95}) were calculated for all estimates. RESULTS: Relative to placebo, caffeine had a significant positive effect on time-trial performance ($\delta = 0.43$; CL_{95} [0.26,0.60]; $p < 0.00001$; $n = 329$). Moreover, the effects of caffeine on time-trial performance corresponded with significant increases in heart rate ($D = +3.1$ b·min[-1]; CL_{95} [+1.6, +4.6]; $p < 0.0001$; $n = 164$), blood lactate ($D = +1.53$ mmol·L[-1]; CL_{95} [+1.21, +1.84]; $p < 0.00001$; $n = 209$), and blood glucose ($D = +1.12$ mmol·L[-1]; CL_{95} [+0.80, +1.43]; $p < 0.00001$; $n = 95$). In contrast, caffeine had no effect on time-trial measures of oxygen uptake ($D = +0.07$ L·min[-1]; CL_{95} [-0.02, +0.15]; $p = 0.13$; $n = 96$), respiratory exchange ratio ($D = +0.01$; CL_{95} [-0.01, +0.03]; $p = 0.37$; $n = 78$), or ratings of perceived exertion ($D = +0.06$; CL_{95} [-0.14, +0.26]; $p = 0.54$; $n = 196$). CONCLUSION: The results of this analysis reveal a clear effect of caffeine on moderate to high-intensity time-trial performance; an effect which is accompanied by significant increases in heart rate, blood lactate, and blood glucose. When considered in conjunction with research using fixed-intensity exercise, the caffeine-induced increase in time-trial intensity likely explains all of the associated increase in heart rate, and part of the increase in blood lactate and blood glucose.

2406   Board #242   June 1 11:00 AM - 12:30 PM
Caffeine Mouth Rinsing in the Fed State Does Not Enhance 3-km Cycling Performance

Michael J. Saunders, FACSM, Kayla A. Sweeney, Nicholas D. Luden, Christopher J. Womack, FACSM. *James Madison University, Harrisonburg, VA.*
(No relevant relationships reported)

PURPOSE: A prior investigation from our laboratory reported that a caffeine mouth-rinse (CMR) enhanced 3-km cycling performance during trials conducted in the early morning (before 10:00), but not in the late-morning. However, interpretation of these findings was complicated by the fact that early-morning trials were predominantly completed after an overnight fast, whereas late-morning trials were all post-prandial. Thus, the purpose of the present study was to assess the effects of a CMR on cycling performance in the fed-state, at different times of day. **METHODS**: 12 recreational cyclists (VO_{2peak} = 51 ± 8 ml/kg/min) completed a simulated 3-km time trial on four occasions; twice in the morning (before 10:00) and twice in the afternoon (after 16:00). 25 ml of a mouth-rinse solution, containing either 300 mg of caffeine (CMR), or a placebo (PL) was swirled in the mouth for 5 s on three occasions during a 10 min

period prior to each time-trial. All trials were completed two hours after ingestion of a standardized meal (~ 500 kcal, consisting of cereal with milk, yogurt, and juice). A randomly counterbalanced, double blind design was implemented to examine the efficacy of the CMR (versus PL) in the morning and the afternoon. Magnitude-based inferences were used to evaluate treatment effects on performance time. **RESULTS**: CMR did not improve cycling performance in the morning [PL = 343 ± 33 s; CMR = 348 ± 32 s; 'possibly' impaired performance (62% likelihood)] or in the afternoon [PL = 346 ± 42 s; CMR = 349 ± 41 s; 'possibly' impaired performance (43% likelihood)]. Treatment effects were similar between the morning and afternoon trials, with no clear effect of time of day. **CONCLUSIONS**: CMR provided in the fed state did not improve 3-km cycling performance, and responses were similar during trials conducted in the morning and the afternoon. When considered in the context of our prior study, these findings suggest that the efficacy of CMR on cycling performance may be influenced by feeding state, but not time of day.

2407   Board #243   June 1 11:00 AM - 12:30 PM

Acute Caffeine Ingestion Enhances Upper and Lower Body Torque During Isometric and Isokinetic Muscle Actions

Daniel T. Flahie, Donovan S. Conley, FACSM, Tammy K. Evetovich, FACSM. *Wayne State College, Wayne, NE.* (Sponsor: Donovan Conley, FACSM)

(No relevant relationships reported)

A comprehensive meta-analysis reported caffeine ingestion (CI) produces greater maximal voluntary contraction (MVC) force in lower body (LB) versus upper body (UB) musculature (Warren et al., Med. Sci. Sports Exerc. 42:1375-1387, 2010). However, research is lacking on direct comparisons between UB versus LB force production, particularly comparing these muscular strength measures across the same subjects. **PURPOSE**: To compare the effects of caffeine supplementation in subjects who self-report low (LOWCS) vs. moderate/high (MHCS) sensitivity to caffeine during isokinetic and isometric muscle actions for the forearm flexor (FORE) and knee extensor (KNEE) muscle groups. **METHODS:** Sixteen recreationally trained males volunteered to participate in the study (M±SD, age=20.6±1.73 y, height=180.1±6.87 cm, mass=83.5±11.48 kg, body fat=10.6±3.04 %). Subjects were randomly assigned to either CAF (5 mg·kg⁻¹) or placebo (NOCAF) treatments using a double-blind design with at least 48 h between testing sessions. Testing was conducted using a HUMAC NORM for both KNEE and FORE at 60°·sec⁻¹ and two-6 sec isometric muscle actions. Testing began immediately after 45 min of either CAF or NOCAF treatments. **RESULTS:** Statistical analysis indicated for isokinetic strength, there was a greater response for KNEE (CAF=213.84 ± 25.38 Nm; NOCAF 201.47 ± 28.56 Nm) versus FORE (CAF= 62.29 ± 6.41 Nm; NOCAF= 58.46 ± 8.27 Nm). For isometric peak torque, the results revealed significantly (p<0.05) greater torque for CAF (M±SD=150.44 ± 22.9Nm) compared to NOCAF (140.39 ± 29.7 Nm) collapsed across upper/lower body and group. **CONCLUSION:** Our data indicates caffeine (5 mg·kg⁻¹), consumed approximately 45 min before performance improves isokinetic and isometric peak torque in both lower and upper body muscle groups and, has a significantly greater effect on dynamic LB vs UB force production in recreationally resistance trained men, regardless of self-reported habitual caffeine consumption. This suggests that ingestion of moderate doses of caffeine 45 min prior to sports and physical activity performance may enhance muscular strength independent of habitual caffeine use.

The Effects of Caffeine Gum Administered in a Divided Dose on Cycling Performance

Edward J. Ryan[1], Mohammed Alshedokhi[1], Shaima Alhabib[1], Samaher Shikh[1], Emily J. Ryan[2], Jason R. Edsall[1], Andres E. Carrillo[1]. *[1]Chatham University, Pittsburgh, PA. [2]West Virginia University, Morgantown, WV.*

(No relevant relationships reported)

PURPOSE: Previous work in our lab has demonstrated that a single bolus of caffeine gum (300mg) enhanced cycling performance.The purpose of the present study was to determine the effects of caffeine gum administered in a divided dose on cycling performance. **METHODS**: Seven apparently healthy, younger (27 ± 10 years) adults of modest fitness (42 ± 10 ml·kg⁻¹·min⁻¹) participated in three separate laboratory sessions. During the first visit, subjects underwent a graded exercise test on a Lode cycle ergometer to determine maximal oxygen consumption (VO$_{2max}$). For the next two visits (experimental testing) subjects arrived at the Exercise Science Laboratory in the fasted state between 0600 and 1200 hours. Subjects consumed a light breakfast consisting of a plain bagel and a sports drink then rested for 10 min. Thereafter two pieces of Military Energy Gum [caffeine (CAFF) or placebo (PLA)] were administered in a double blind manner. Subjects were instructed to chew the gum for 5 min then expectorate. Following a standard warm-up, subjects cycled at 70% VO$_{2max}$ (constant Wattage) for 15 min. Subjects rested for 20 min and were then instructed to chew two additional pieces of Military Energy Gum for 5 min. Following the second

administration, the ergometer was set to linear mode and subjects were instructed to complete as much work as possible in a 15-min performance ride. Total work (kJ) completed was used as the primary outcome variable. Each piece of caffeinated Military Energy Gum has 100mg of CAFF and the order in which the subjects completed the experimental trials was counterbalanced.
RESULTS: Performance data were analyzed using a two-way paired samples t-test. Total work completed did not differ between trials (CAFF = 157.8 ± 45 kJ, PLA = 157.6 ± 40 kJ) and no main effect of treatment was evident (t = 0.035, p = 0.97). **CONCLUSIONS**: These data demonstrated that caffeine gum administered in a divided dose does not improve total work completed during a 15-min performance ride in physically active adults.

Neither Coffee Nor A Stimulant Containing "Pre-workout" Drink Alter Cardiovascular Drift During Walking In Young Men

Stephanie M. Paulsen, Gregory A. Brown, FACSM. *the University of Nebraska at Kearney, Kearney, NE.* (Sponsor: Gregory A. Brown, FACSM)

(No relevant relationships reported)

Caffeine is a widely used stimulant that is often consumed in coffee. Caffeine is also the main ingredient in many "pre-workout" drinks, which are purported to enhance exercise performance. Due to the stimulatory effects of caffeine on the heart and the potential diuretic effects of caffeine, drinking coffee or a pre-workout drink before exercise may exacerbate cardiovascular drift**. PURPOSE**: The purpose of this study was to compare the effects of coffee and a commercially available pre-workout drink on cardiovascular drift during prolonged moderate intensity walking. **METHODS**: Eight healthy, recreationally active males consumed coffee (containing 120 mg caffeine), decaffeinated coffee, a pre-workout drink (containing 120 mg caffeine), or a placebo in a randomly assigned cross over design one hour before walking for 40 minutes on a treadmill at a workload that corresponded to 50% of their VO$_2$ max. **RESULTS**: Heart rate gradually increased (P<0.05) from 123.2 ± 5.5 beats/min at 10 minutes to 132.8 ± 8.6 beats/min for all treatments, but there was no main effect of treatment or interaction effect of treatment X time on heart rate. Respiratory exchange ratio (RER) gradually decreased (P<0.05) from 0.76 ± 0.02 at 10 minutes to 0.73 ± 0.04 for all treatments, but there was no main effect of treatment or interaction effect of treatment X time on RER. Similarly, there was no main effect of treatment or interaction effect of treatment X time on oxygen consumption. **CONCLUSIONS**: The gradual increase in heart rate in the present study demonstrates cardiovascular drift during 40 minutes of walking at 50% VO$_{2max}$, with no changes due to consuming coffee or a pre-workout drink 1 hour prior to exercise. Furthermore, the ingestion of coffee or a pre-workout drink 1 hour prior to exercise did not alter the RER indicating no effects on fat or carbohydrate use. The lack of difference in oxygen consumption indicates that ingesting coffee or a pre-workout drink 1 hour prior to exercise does not alter energy expenditure. Overall, the lack of effects of coffee or a pre-workout drink in the present investigation suggest that while the caffeine dose does not present additional challenges to cardiovascular function, the caffeine dose does not influence exercise performance during 40 minutes of walking at 50% VO$_2$max.

Effects of Varying Caffeine Dosage on Free Throw Accuracy Before and After Exhaustive Intermittent Exercise

Bulent Sokmen, Molly Kommer, Carly Gill, Katrina Buhagiar. *Sonoma State University, Rohnert Park, CA.*

(No relevant relationships reported)

PURPOSE: This study evaluated the effects of varying caffeine dosage on free throw accuracy before and after exhaustive intermittent exercise.
METHODS: Fourteen NCAA Div 2 collegiate female basketball players participated (mean ± SD; age = 19.9 ± 1.04 yrs; body mass = 67.25 ± 8.17 kg; height = 171.45 ± 8.41 m; BMI = 22.85 ± 1.72; percent body fat = 22.45 ± 4.16%). Participants each completed baseline tests with a familiarizing session and three randomized double-blind experimental trial sessions in the course of this study. The experimental trials included ingestion of placebo (0 mg•kg•BW⁻¹), of caffeine at 1.5 mg•kg•BW⁻¹, and of caffeine at 3 mg•kg•BW⁻¹. Each trial was administered following 12h overnight fasting, separated by at least one week, and with no moderate to heavy exercise 48h prior to the trial. At the lab, subjects consumed a standard breakfast and 500ml of fluid, with a varying caffeine dose or placebo. Subjects performed 20 free throws, rested 1 min, then ran ten 20m sprints at full speed, with 20 sec recovery. They rested 1 min, and performed 20 free throws again. All free throws were performed with a soundtrack playing music and recorded crowd noise at high volume in the background.
RESULTS: Our results found that only the 3 mg•kg•BW⁻¹ caffeine dosage showed significant improvement (Δ=7.17%) in free throw performance following exhaustive intermittent exercise (P<0.05). No change was observed in free throw performance with 1.5 mg•kg•BW⁻¹ caffeine dosage and placebo (P>0.05).

CONCLUSIONS: This study demonstrated that a moderate dose of caffeine can improve free throw ability following exhaustive intermittent exercise compared to low dose and placebo conditions in NCAA Division 2 female basketball players.

Caffeine and Citrate Aurantium Supplementation Alter Resting Cardiac Autonomic Function but Not During Recovery

Emily Bechke, Cassie Williamson, Paul Bailey, Wade Hoffstetter, Cherilyn McLester, Brian Kliszczewicz. *Kennesaw State University, Kennesaw, GA.* (Sponsor: Mark Tillman, FACSM)

(No relevant relationships reported)

Purpose: To examine the combined effects of the pre exercise complex Citrate Aurantium and Caffeine (CA+C) on cardiac autonomic activity following ingestion and immediately after high-intensity anaerobic exercise in habitual caffeine users. **Methods:** Ten physically active males (25.1± 3.9 years; mass 78.7± 9.5kg) who habitually consume caffeine ($\geq$ 1 serving a day [95mg] 4 days a week) participated. This was a double-blind crossover design, where either a CA+C or a placebo capsule was consumed followed by a 45-min ingestion period, a repeated Wingate protocol, and a 45-min recovery period. Cardiac autonomic activity was assessed through Heart Rate (HR), plasma epinephrine (E) and norepinephrine (NE), and markers of Heart Rate Variability (HRV): root mean squared of successive R-R differences (RMSSD); Standard Deviation of R-R intervals (SDNN); High-Frequency (HF); Low-Frequency (LF); and its ratio (LF:HF). Markers were taken at four time points: pre-Ingestion (PRE-ig), 40-45-min post (Post-ig); Wingate recovery (PRE-rcv), 40-45-min post recovery (Post-rcv). **Results:** Markers that violated normality were naturally log transformed prior to further analysis (ln). Pre-planned comparisons were performed to assess differences between pre and post time points as well as the corresponding time point of the other trial within their respected phase. During the CA+C trial, an increase in HR, lnSDNN, lnLF, EPI, and NE were observed at Post-ig when compared to Pre-ig (p≤0.05). Significant differences were observed in all markers, except LF:HF, during the CA+C and PLA trials from the Pre-rcv to Post-rcv (p≤0.05). **Conclusion:** The consumption of CA+C stimulates sympathetic activity during rest (e.g. ingestion phase) without influencing parasympathetic activity. CA+C provides no influence over cardiac autonomic recovery.

2412　　　Board #248　　　　June 1 11:00 AM - 12:30 PM

Effects of Energy Drinks on Resting Cardiovascular Measures

Will Peveler[1], Andy Bosak[1], Gabe Sanders[2]. *[1]Liberty University, Lynchburg, VA. [2]Northern Kentucky University, Highland Heights, KY.* (Sponsor: James Schoffstall, FACSM)

(No relevant relationships reported)

The use of energy drinks among athletes has risen greatly. Reviews of energy drink related health complications have highlighted adverse cardiovascular events. **PURPOSE:** To examine the effects of three commercially available energy drinks on resting cardiovascular measures prior to exercise. **METHODS:** Twenty-five healthy subjects participated in this study. Subjects reported to the laboratory on four separate occasions where they ingested a placebo or one of three commercially available energy drinks (energy drink 1, energy drink 2 and energy drink 3). Trials were conducted subject blinded and counterbalanced. During each trial blood pressure and heart rate were measured at three key points: prior to beverage ingestion, at 30 minutes post ingestion and at 60 minutes post ingestion. Subjects remained seated and in a relaxed state for the duration of the 60 minute trials. Means for dependent measures were analyzed using repeated measures ANOVA with an alpha of 0.05 to determine significance. **RESULTS:** Heart rate was found to be significantly increased from pre-ingestion measures to 60 minute measures for both energy drink 2 (Pre = 65.12 ± 9.81 bpm and 60 min = 73.08 ± 10.82 bpm at p=0.010) and energy drink 3 (Pre = 65.76 ± 8.44 bpm and 60 min = 73.52 ± 11.25 bpm at p=0.005). Systolic blood pressure was found to be significantly increased from pre-ingestion to 60 minutes for energy drink 1 (Pre = 114.84 ± 9.33 mmHg and 60 min = 120.80 ± 9.43 mmHg at p=0.003), energy drink 2 (Pre = 113.56 ± 8.55 mmHg and 60 min = 121.44 ± 8.86 mmHg at p=0.004), and energy drink 3 (Pre = 113.24 ± 7.09 mmHg and 60 min = 119.40 ± 10.58 mmHg at p=0.037). **CONCLUSION:** These findings demonstrate that energy drinks impact cardiovascular measures by increasing both heart rate and blood pressure during a resting state. While the demonstrated increases may not be dangerously high, users should be aware of the impact of these drinks on cardiovascular measures.

Menstrual Phase Influence and Oral Contraceptive Use on the Ergogenic Effects of Caffeine during Cycling

David L. Wenos, Annette M. Lemanski, Nicholas D. Luden, Christopher J. Womack, FACSM, Michael J. Saunders, FACSM. *James Madison University, Harrisonburg, VA.* (Sponsor: Michael J. Saunders, FACSM)

(No relevant relationships reported)

It is suggested that inter-individual differences in the ergogenic effects of caffeine may be attributed to individual variability in caffeine absorption and metabolism. It is known that menstrual status and oral contraceptive (OCS) use affects caffeine metabolism, but it is not clear whether these factors mediate the ergogenic effects of caffeine consumption. **Purpose:** To determine whether menstrual phase or OCS use influence the effects of caffeine ingestion on 3-km cycling performance. **Methods:** Sixteen recreational cyclists completed two 3-km time trials (TT) during both the follicular (early) and luteal (late) phases. Riders ingested either a placebo or 6mg/ kg caffeine capsule one hour prior to each trial. Subjects were divided into a non-OCS users group (n = 8; age, 20.9 ± 2.1 yr; VO2max = 50.9 ± 7.8 ml/kg/min) and an OCS users group (n=8; age = 21.4 ±1.4 yr; VO2max = 48.0 ± 4.0 ml/kg/min). Magnitude-based inferences were used to evaluate the effects of treatment (placebo versus caffeine), menstrual phase (follicular versus luteal) and group (OCS users versus non-users) on power output during the cycling TT. **Results:** Overall, caffeine improved power output during the TT, regardless of menstrual phases or OCS use. Among non-OCS users, caffeine 'likely' improved power output in the follicular phase (6.7 ± 6.1%), and 'very likely' improved power output in the luteal phase (6.7 ± 4.8%). In the OCS users, caffeine 'likely' increased power output in the follicular phase (4.7 ± 5.6%), and 'very likely' improved power output during the luteal phase (7.2 ± 3.7%). Differences in the ergogenic effects of caffeine between the two groups (OCS users versus non-users) and between menstrual phases were 'unclear'. **Conclusion:** Caffeine ingestion improved power output during a 3-km cycling TT. However, the magnitude of the ergogenic effects of caffeine were not affected by OCS use, or menstrual phase.

The Influence Of Caffeine And A CYP1A2 Polymorphism On The Ventilatory Threshold - A Pilot Study

Paul R. Nagelkirk[1], Liam F. Fitzgerald[1], James Sackett[1], Ahmed El-Sohemy[2], Christopher J. Womack, FACSM[3]. *[1]Ball State University, Muncie, IN. [2]University of Toronto, Toronto, ON, Canada. [3]James Madison University, Harrisonburg, VA.* (Sponsor: Christopher J. Womack, FACSM)

(No relevant relationships reported)

Previous research suggests acute caffeine supplementation may alter substrate utilization and/or ventilatory responses that influence the ventilatory threshold (VT). Caffeine metabolism is influenced by a single nucleotide polymorphism at intron 1 of the cytochrome P450 (CYP1A2) gene, which may influence the ergogenic effects associated with caffeine use. **PURPOSE:** The purpose of this study was to examine the influence of caffeine on exercise responses at the VT, and determine the effect of the CYP1A2 polymorphism on those responses. **METHODS:** 17 healthy men (age 24.8 ± 2.7 yrs; weight 79.5 ± 9.2 kg) participated in this study. Subjects performed graded maximal exercise tests on a cycle ergometer after consuming either 6 mg/kg of caffeine or placebo. Subjects were categorized as possessing the C allele (C allele carriers) (n = 8) or being homozygous for the A allele (AA homozygotes) (n = 9). VT was determined using the V-slope method. The effects of caffeine (CAF) vs placebo (PL), genotype, and treatment x genotype were assessed using a two-factor ANOVA. **RESULTS:** At the VT, caffeine significantly augmented workload (CAF= 220 ± 43 Watts, PL= 211 ± 46 Watts), VO_2 (CAF= 33.5 ± 8.2, PL= 32.2 ± 7.7 ml/kg/min), VO_2 as a % of VO2max (CAF= 69.0 ± 8.2%, PL= 64.8 ± 9.6%), RER (CAF= 0.98 ± 0.06, PL= 0.95 ± 0.07), and HR (CAF= 155 ± 16, PL= 151 ± 16 bpm), compared to placebo (all p<0.05). A significant treatment x genotype interaction was observed for RER (AA group: CAF= 0.99 ± 0.07, PL= 0.91 ± 0.08; C allele: CAF= 0.97 ± 0.07, PL= 0.97 ± 0.09). A non-significant between group trend was observed for VO_2 as a % of VO2max (AA group 62.5 ± 6.6%, C allele = 67.2 ± 9.6% p=0.10, eta^2=0.17) and workload (AA group 196.4 ± 37.7, C allele = 214.1 ± 40.0 Watts, p=0.10, eta^2=0.17). **CONCLUSION:** Caffeine enhances exercise performance at the VT. The CYP1A2 polymorphism likely modulates substrate utilization and exercise intensity at the VT. Additional research is needed to verify these preliminary findings.

Abstracts were prepared by the authors and printed as submitted.

Caffeine Does Not Increase Heat Stress during Endurance Exercise in a Hot, Humid Environment

Christopher W. Bach, Jack W. Ransone, FACSM. *University of Nebraska - Lincoln, Lincoln, NE.*

(No relevant relationships reported)

The diuretic effects of caffeine and its subsequent role on fluid balance have been highly debated for years. Given the lack of mechanistic understanding behind many of its effects, it is important to determine if caffeine presents a risk to normal thermoregulatory patterns during exercise in hot, humid conditions. **PURPOSE**: To determine if caffeine (CAFF) ingestion increases core body temperature in physically active subjects exercising in a hot, humid environment during repeated endurance exercise tests (EET). **METHODS**: This study used a placebo-controlled, double-blind, cross-over experimental design to investigate the effects of caffeine ingestion on heart rate (HR) and core body temperature in physically active males when exercising in a hot and humid environment. Twenty-one healthy male subjects (age 27.70±2.90yrs; height 1.76±0.10m; weight 74.19±7.10kg) performed a maximal graded exercise test (GXT) and two endurance exercise tests (EET) separated by at least 48hrs. Subjects were randomly assigned to consume either 6mg/kg of body weight of a placebo (PLAC) or CAFF supplement for one EET and the opposite substance (PLAC or CAFF) for the second test. In addition, the subjects consumed a CorTemp® core body temperature sensor to measure core body temperature throughout each test. Each EET consisted of cycling on a cycle ergometer at 65% of their VO_{2max} for 40min in a controlled hot, humid environment (36.37±0.58°C; 59.46±5.14%RH). **RESULTS**: Results indicated no significant difference between groups for core body temperature or heart rate at any time point, with the exception of an elevated HR 5min post-exercise in the CAFF group when compared to PLAC (136.82±7.51 vs. 127.65±3.17, respectively; p=0.011). A significant increase in HR from pre-exercise to 40min was observed in both groups (CAFF: 84.27±4.19 to 164.50±5.13, PLAC: 79.23±3.47 to 162.71±3.26; p<0.01), but CAFF consumption elicited no synergistic effects on HR or core body temperature before, during, or after exercise. Interestingly, CAFF consumption did elicit a diminished HR recovery within the first 5min of recovery, potentially indicating a greater degree of heat stress in the CAFF group. **CONCLUSION**: Based upon this evidence, caffeine consumption does not impair normal thermoregulatory patterns during exercise in a hot, humid environment.

Caffeine Intake Maintains 3-km Cycling Time Trial Performance the Morning Following Sleep Restriction

Jeremy Via, Erin Horil, Michael Saunders, FACSM, Trent Hargens, FACSM, Christopher Womack, FACSM, Nicholas Luden. *James Madison University, Harrisonburg, VA.* (Sponsor: Michael Saunders, FACSM)

(No relevant relationships reported)

Athletes are at an increased risk for acute sleep loss due to the physiological and psychological tolls of heavy training and competition. We recently reported that a single night of sleep restriction (SR) following heavy exercise impaired 3-km cycling performance the next morning. Because caffeine can mitigate fatigue and enhance physical and cognitive function, caffeine is a logical candidate to offset the negative impact of sleep restriction on next-day performance. **PURPOSE:** The primary aim of this project was to determine the effects benefit of caffeine supplementation for exercise performance following one night of SR in trained cyclists. **METHODS:** Ten (8 male; 2 female) cyclists (age, 21 ± 3 yrs; VO2max, 61 ± 8 ml/kg/min) completed four experimental phases. Each phase consisted of an evening of heavy exercise (EX1; 3-km cycling time trial followed by 60 min of high intensity cycling intervals) followed by a morning session (EX2) to evaluate perceived fatigue and 3-km TT performance. EX1 and EX2 were separated by an assigned sleep condition [FULL, ~6.4 hrs vs. Sleep Restriction (SR), ~3 hrs]. Each sleep condition was implemented twice with cyclists receiving 6 mg/kg of caffeine (CAF) and placebo (PLA) 60 min prior to EX2 after FULL and SR. Magnitude-based inferences were used to compare perceived fatigue and subsequent 3-km TT performance (mean power output) between each of the following conditions: FULL/PLA, FULL/CAF, SR/PLA, and SR/CAF. **RESULTS:** Surprisingly, 3-km TT power output was 'possibly' [44% Likelihood (LH)] greater following SR/PLA vs. FULL/PLA (+0.9%). Power output was 'likely' higher (94% LH) following SR/CAF vs. SR/PLA (+6%), with no systematic differences between SR/CAF and FULL/CAF. Perceived fatigue was rank ordered as SR/PLA>SR/CAF>FULL/PLA>FULL/CAF. **CONCLUSION:** The current data suggests that caffeine has the ability to offset performance impairments that may result from a single night of SR compared to a full night of sleep. However, in contrast to our previous report, this interpretation is weakened by the fact that EX2 performances were similar between SR and FULL. Regardless, athletes may want to consider caffeine supplementation as a viable strategy to offset the negative impact of occasional sleep restriction.

Acute Effect of Different Doses of Caffeine on Strength and Calcium Release

Luis H. Boiko Ferreira[1], Andre C. Smolarek[1], Luis P. G. Mascarenhas[2], Cleyton S. Oliveira[1], Bruna A. Zandoná[1], Brad J. Schoenfeld[3], Alan C. Utter, FACSM[4], Steven R. McAnulty[5], Tácito P. Souza-Junior[1]. *[1]Universidade Federal do Paraná, Curitiba, Brazil. [2]Universidade Estadual do Centro-Oeste, Irati, Brazil. [3]CUNY Lehman College, Bronx, NY. [4]Texas Woman's University, Dentron, TX. [5]Appalachian State University, Boone, NC.* (Sponsor: Alan C. Utter, FACSM)

(No relevant relationships reported)

Although the benefits of caffeine on aerobic performance have been well-established, knowledge about the effect of different doses of caffeine on strength and mechanisms related to calcium release, such as inhibition of specific phosphodiesterases and antagonistic actions at the level of adenosine receptors are lacking. We aimed to analyze these effects on resistance exercises. PURPOSE: Analyze the acute effect of different doses of caffeine on strength and calcium release in recreationally trained men. METHODS: The effect of different doses of caffeine on strength, calcium release, RPE, and TG were assessed in 13 recreationally active young adults (age 19 ± 2 yrs), who performed three tasks on three different occasions with a washout of 14 days between sessions. Day one involved collecting baseline data and acclimating participants to the protocol to determine the weight loads at each subject's 10 RM. Participants were instructed to avoid food or beverages that may contain caffeine two days before the tests. The effect of different doses of caffeine on strength was evaluated in three different resistance exercises: bench press (BP); deadlift (DL); and squats (SQ). Blood samples were collected immediately upon arrival to the laboratory, followed by consumption of a standardized isocaloric shake along with capsules containing different doses of caffeine: 6mg • kg $^{-1}$ (CF1); 8mg • kg $^{-1}$ (CF2); or placebo (CG). A additional blood samples were collected 45 minutes after caffeine/placebo consumption and immediately after the execution of each exercise. The supplementation followed a double-blind, randomized model. RESULTS: The strength on BP, DL and SQ statistically improved between CG and CF2 (BP 94.3 ± 5.2 to 101.4 ± 3.4; DL 120.7 ± 7.7 to 136.3 ± 7.09; SQ 119.4 ± 7.4 to 132.1 ± 5.2 p<0.05). Although a strength increase was found at CF2 compared to CF1, no other statistical differences were found (BP 98.1 ± 3.8 to 101.4 ± 3.4; DL 130.2 ± 8.3 to 136.3 ± 7.09; SQ 129.5 ± 8.01 to 132.1 ± 5.2 p=0.001). Calcium release statistically improved in CF2 in comparison to CF1 and CG (10.9 ± 0.2 to 8.9 ± 0.4 and 10.9 to 8.3 ± 0.2 p=0.001). CONCLUSION: An 8 mg • kg $^{-1}$ dose of caffeine seems to be more effective than 6 mg • kg $^{-1}$ for improving strength levels in the BP, DL and SQ; these enhancements were directly related to improvements in calcium release during CF2.

The Associations Between metabolic Syndrome and Thyroid Function In U.S. Adolescents: Nhanes Iii

Jonathan Austin, Kelly Laurson. *Illinois State University, Normal, IL.*

(No relevant relationships reported)

The global prevalence of metabolic syndrome (MetS) and its associated components (high fasting glucose, waist circumference, blood pressure, triglycerides, and low HDL) have increased over the past few decades. In addition, abnormal thyroid hormone levels have been found to manifest in a cascade of metabolic dysfunction, which may be linked to MetS in youth. **PURPOSE:** The purpose of the study is to investigate the association between MetS, its components, and markers of thyroid function in a nationally-representative sample of adolescents. **METHODS:** The National Health and Nutrition Examination Survey III (1988-1994) collected data on the components of metabolic syndrome and thyroid function in 1,322 adolescents aged 12-18.9 years (613 males and 709 females). Participants were grouped based on MetS status, number of MetS components, and markers of thyroid function using age- and sex-specific reference values (including thyroid stimulating hormone [TSH], thyroxine [T4], antimicrosomal antibody [AMA], and anti-thyroglobulin antibody [TgAb]. Logistic models were used to predict the status of the thyroid markers (as high/low) from MetS status, controlling for age, sex, and race/ethnicity. **RESULTS:** The prevalence of metabolic syndrome was 5.4% in the full sample. The logistic models indicated the MetS positive group had a significantly lower odds of having a low TSH (OR = 0.06, 95%CI [0.01, 0.5], p = 0.005) compared to the MetS negative group. However, follow-up analyses revealed adolescents with ≥ 2 MetS components were more likely to have high TSH (OR = 5.0, 95%CI [1.4, 18.2], p = 0.013) and be

positive for AMA (OR = 2.6, 95%CI [1.1, 6.7], p = 0.042), while being less likely to have low TSH (OR = 0.07, 95%CI [0.01, 0.31], p < 0.001) compared to those with 1 or 0 components. No associations were found between high/low T4 or TgAb and MetS or MetS components (all p > 0.05). **CONCLUSION:** In this nationally-representative sample of adolescents, those with multiple MetS components were more likely to have elevated TSH and be positive for AMA, while being less likely to have low TSH. T4 and TgAb values were similar, regardless of MetS status. Even in adolescence metabolic dysfunction appears to be associated with some markers of thyroid function.

Evidence of Hypothalamic Regulation by AVP and CRH on Running-Induced Stress Response

Kanako Takahashi, Takeru Shima, Jangsoo Yook, Mariko Soya, Hikaru Koizumi, Masahiro Okamoto, Subrina Jesmin, Hideaki Soya. *University of Tsukuba, Tsukuba, Japan.*

(No relevant relationships reported)

Moderate exercise with an intensity near the lactate threshold (LT) is beneficial to human health and one of the possible underlying mechanisms of this may be exercise-induced activation of the hypothalamus with enhanced stress and metabolic responsiveness. In general, adrenocorticotropic hormone (ACTH) secretion, a potential systemic stress marker, is regulated by the hypothalamic corticotropin-releasing hormone (CRH) through the CRH type 1 receptor (CRH1R), which is enhanced by hypothalamic arginine vasopressin (AVP) via the AVP V_{1b} receptor (V_{1b}R). Conversely, it has been suggested that ACTH secretion during exercise above the LT is mainly regulated by AVP, not CRH. However, to date there is no clear evidence for how exercise-induced ACTH secretion is enhanced *via* these factors. **PURPOSE**: To elucidate whether AVP and/or CRH regulates exercise-induced ACTH secretion using specific receptor antagonists.
METHODS: Rats acclimatized to treadmill running were randomly divided into four groups: Vehicle, SSR (V_{1b}R antagonist), CP (CRH1R antagonist), and SSR+CP injection groups, based on i.p. injection of these drugs before running on a treadmill at just above LT (21.5 m/min) for 30 min. Blood was collected from a catheter inserted into the right external jugular vein before the injection and pre- and post-running to measure blood lactate and plasma ACTH levels.
RESULTS: Baseline lactate and ACTH levels in all groups were unaffected irrespective of drug treatment. Post-running blood lactate levels were significantly higher than pre-running (p<0.0001, all groups) with no inter-group difference. Plasma ACTH levels did not increase after running in the SSR+CP group (p>0.05 for SSR+CP group, cp. p<0.0001 for Vehicle, SSR and CP groups). Post-running ACTH levels were lower in all antagonist groups compared to the Vehicle group (p<0.0001 for SSR, CP, and SSR+CP vs. Vehicle group). ACTH levels for the SSR+CP group decreased compared to those for the SSR and CP groups (p<0.05 for SSR+CP vs. SSR and CP, respectively).
CONCLUSIONS: We revealed for the first time that exercise-induced ACTH secretion is regulated by both AVP and CRH with concomitant blood lactate increase. Further, our results suggest that AVP and CRH cooperatively enhance exercise-induced ACTH response independent of metabolic response.

Changes in Muscle Strength Following Cross-sex Hormone Treatment in Transgender Individuals

Anna Wiik, Tommy R. Lundberg, Mats Lilja, Daniel P. Andersson, Stefan Arver, Thomas Gustafsson. *Karolinska Institutet, Stockholm, Sweden.*

(No relevant relationships reported)

Many biological differences seen in men and women are driven by relative differences in estrogen and testosterone levels. In transgender individuals, gender-affirming treatment includes inhibition of endogenous sex hormones and subsequent replacement with the cross-sex hormones. Yet, the effect of this treatment on functional muscle strength remains poorly described. **PURPOSE**: The aim of the current study was to assess the effects of an altered sex hormone pattern on muscle strength.
METHODS: Twelve transgender individuals, 6 male to female (tranwomen) and 6 female to male (transmen) who had been accepted to start gender-affirming medical intervention, were recruited. Knee extensor and flexor muscle strength was assessed using isokinetic dynamometry at three different angular velocities (0, 60 and 90 °/s). The assessments were made at four time points: (T1) before treatment initiation, (T2) four weeks after initiated gonadal hormonal down regulation but before hormone replacement, (T3) three months after hormone replacement therapy and (T4) eleven months after hormone replacement therapy.
RESULTS: There were significant (P<0.05) group x time interactions at each angular velocity. Thus, while the transmen increased their strength over the four time points, strength levels were generally maintained in the transwomen. When averaging the three strength tests, knee extension (16%) and knee flexion (34%) strength increased from T1 to T4 in transmen. The corresponding changes in the transwomen group were -6% and 0%, respectively.

CONCLUSIONS: These results show that ~1 year of cross-sex hormone treatment results in increased muscle strength in transmen. However, transwomen maintain their strength levels throughout the treatment period. We conclude that the altered sex hormone pattern induced by gender-affirming treatment differentially affect muscle strength in transmen vs. transwomen.

Soy Protein Supplementation Is Not Adipogenic Or Estrogenic In Young Men When Combined With Resistance Training

Cody Haun, C. Brooks Mobley, Christopher Vann, Matthew Romero, Paul Roberson, Petey Mumford, Wesley Kephart, James Healy, Romil Patel, Shelby Osburn, Darren Beck, Michael Roberts. *Auburn University, Auburn, AL.*

(No relevant relationships reported)

PURPOSE: : Sex hormone physiology (e.g., estradiol, testosterone) may be affected by soy and/or whey protein consumption. Alterations in sex hormones due to resistance training (RT) and/or protein supplementation may explain meaningful variation in adipocyte and skeletal myocyte size alterations. Consequential molecular signaling in these cell types remain unclear. Therefore, we examined effects of RT and soy (SPC), whey (WPC), or placebo (PLA) supplementation in young men.
METHODS: 47 healthy, young men were partitioned into PLA, SPC, or WPC groups and completed 12 weeks of RT. Body composition, serum hormones, androgen signaling markers in myocytes, and estrogen signaling markers in adipocytes were examined using DXA, ELISA, western blotting, PCR, and immunohistochemistry.
RESULTS: Testosterone increased over time, but more so in subjects consuming WPC (p<0.05). Adipocyte mRNA expression of the estrogen receptor alpha increased (p<0.05), as did hormone sensitive lipase over time (p<0.05). Skeletal muscle androgen receptor mRNA expression increased while ornithine decarboxylase mRNA decreased over time (p<0.05). Alterations in body composition, adipocyte, and myocyte morphology were not significantly different between groups (p>0.05). Changes in 17β-estradiol and testosterone explained <3% of alterations in adipocyte and myocyte size.
CONCLUSIONS: These data suggest primarily RT-mediated effects with little influence of protein type and hormonal changes.

Relationship Between Wnt Signaling Inhibitors And Muscle Function In Young And Middle-aged Premenopausal Women

Pragya Sharma Ghimire[1], Samuel Buchanan[2], Michael G. Bemben, FACSM[2], Debra A. Bemben, FACSM[2]. *[1]Lander University, Greenwood, SC. [2]The University of Oklahoma, Norman, OK.* (Sponsor: Dr. Debra A Bemben, FACSM)

(No relevant relationships reported)

The Wnt signaling pathway, an important regulator of skeletal development, is inhibited by several glycoproteins including sclerostin and Dickkopf -1 (DKK-1). Animal studies have reported Wnt 7a plays an important role in skeletal muscle growth and improving strength. However, to date, no studies have examined relationships between circulating levels of sclerostin and DKK-1 and muscle function in humans. **PURPOSE:** This study investigated the relationship between sclerostin and DKK-1 with jump and strength variables in young (20-30 yrs, n=25) and middle-aged (35-45 yrs, n=25) women. Further, the effects of age group and physical activity level on muscle function variables were evaluated. Physical activity levels were based on the International Physical Activity Questionnaire. **METHODS:** Serum sclerostin and DKK-1 levels were measured in fasting morning blood samples by ELISA. Lower body strength and power were assessed by a two-leg press maximal strength test (1RM) and a vertical jump test (Just Jump Mat, Tendo Sports Machine), respectively. **RESULTS**: Two-way ANOVA showed a significant age group effect for JH, relative jump power (RJP), and 1RM (p<0.05), which were higher in young women (Table 1). There were no significant differences in muscle performance variables based on physical activity levels. Jump height (JH) was negatively correlated (r= -0.27, p< 0.05) with sclerostin levels. **CONCLUSION:** Lower muscle strength and jump height in middle-age women supports an age-related decrease in muscle function. Generally, sclerostin and DKK-1 were not related to muscle performance variables.
Table 1. Muscle Function Variables based on Age Group and Physical Activity Levels (Mean ± SD)

Variables	Young (n=25)		Middle-aged (n=25)	
	Low-Moderate (n=13)	HEPA-Active (n=12)	Low-Moderate (n=12)	HEPA-Active (n=13)
JH (inches) **	13.43 ± 3.10	14.13 ± 2.69	11.12 ± 2.52	11.20 ± 3.33
Velocity (m/s)	0.99 ± 0.13	1.04 ± 0.09	0.94 ± 0.13	0.94 ± 0.09
Jump Power (watts)	647.40 ± 107.99	698.13 ± 141.61	622.91 ±142.39	593.20 ± 127.62
RJP (watts/ kg)*	9.85 ± 1.30	11.44 ± 3.69	9.22 ± 1.49	9.17 ± 1.02
1RM (kg)*	125.17 ± 25.07	144.29 ± 36.90	113.24 ± 20.18	121.67 ± 29.23

** $p<0.01$, * $p<0.05$ Significant age group effect; HEPA-Health enhancing physical activity

Acute Resistance Exercise on Bioactive and Immunoreactive Growth Hormone in Women.

Emily M. Post[1], Matthew K. Beeler[1], William H. Dupont[1], Lydia K. Caldwell[1], John P. Anders[1], Vincent H. Hardesty[1], Emily C. Barnhart[1], Emily C. Borden[1], Jeff S. Volek[1], Wesley C. Hymer[2], William J. Kraemer, FACSM[1]. [1]*The Ohio State University, columbus, OH.* [2]*The Pennsylvania State University, University Park, PA.* (Sponsor: Dr. Wiliiam J. Kraemer, FACSM)
(No relevant relationships reported)

PURPOSE: The purpose was to determine the differences between trained and untrained women for concentrations of BGH and IGH in response to acute resistance exercise.
METHODS: Untrained recreationally active women (UT) (N= 12), mean ± SD: 24 ± 2.4 yr, 167 ± 6.3 cm, 68.8 ± 7.3 kg, 27.3 ± 4.0% body fat, and trained women (TW) (N= 12), 25 ± 3.4 yr, 168 ± 7.3 cm, 69.8 ± 6.3 kg, 19.3 ± 2.7% body fat gave informed consent. Trained status was determined by participation in aerobic/resistance training programs for at least 1 year. The women were tested for 1 repetition maximum strength (1 RM) in the squat and were familiarized with the squat test protocol that consisted of 6 sets of 10 repetitions at 75% of their 1 RM with 2 minutes rest between sets. Testing was performed during the early follicular phase between 0630 and 1100 after an 8- to 12-h fast. Pre-exercise blood samples were obtained via standard venipuncture 15 min before the test and post-exercise samples were obtained immediately after the resistance training test protocol. Plasma was collected and assayed for IGH using polyclonal and monoclonal assays. Total BGH was assayed using the rat tibial line *in vivo* bioassay. A two-way analysis of variance (2 X 2) for group and time were used to analyze the data, with $p \leq 0.05$ defined as significance.
RESULTS: The TW were significantly stronger than the UT in the squat. Both groups significantly increased their IGH concentrations post-exercise, with the monoclonal assay showing significantly higher values than polyclonal assays and TW showing greater post-exercise values than UT [Monoclonal: (TW: 5 ± 2 to 19 ± 3 µg/L-1, UT: 4.9 ± 2 to 10.2 ± 3.0 µg/L-1)]. BGH did not increase pre to post exercise in either group, yet TW had significantly higher pre-exercise and post-exercise BGH (3900 ± 233 to 4100 ± 323 µg/L-1) than UT women (2500 ± 333 to 2100 ± 223 µg/L-1). BGH was significantly higher than IGH assays at all time points.
CONCLUSIONS: Resistance training impacts both the BGH and IGH secretion patterns from the anterior pituitary gland. IGH is acutely increased in response to resistance training in women, with an even higher response in trained women. BGH is chronically higher in trained women than untrained, but shows no response with acute resistance training. These findings may be more responsible for GH's role in chronic resistance training adaptations.

The Reliability And Criterion Validity Of A Novel Dorsiflexion Range Of Motion Screen

Kyle B. Kiesel[1], Kate Schwartzkopf-Phifer[1], Bethany Huebner[1], Garrett S. Bullock[2], Mary Beth Garner[1], Joshua Hayden[1], Kyle Matsel[1], Risa Ricard[1], Phillip J. Plisky[1]. [1]*University of Evansville, Evansville, IN.* [2]*Mountain River PT, Chatham, VA.*
(No relevant relationships reported)

Purpose: Limited ankle dorsiflexion (DF) is associated with abnormal biomechanics as well as lower extremity injuries. Identifying and correcting restricted ankle DF may be a viable preventative strategy to normalize motor control and reduce injury. A reliable ankle screen may help clinicians to identify decreased ankle range of motion (ROM). The purpose of this study was to determine the reliability and criterion validity of a novel standing ankle dorsiflexion screen (SADS). It is proposed that the SADS will demonstrate strong inter-rater reliability and criterion validity. **Methods:** 37 healthy subjects (74 ankles) participated in the study. Ankle DF ROM was measured using an electronic inclinometer by 2 raters. Four raters measured ankle DF using the criteria of the SADS. The SADS is performed in a heel-to-toe position. Subjects performed DF by dropping their back knee forward as far as possible without lifting their back heel. The back-ankle DF is scored by identifying the position of the anterior knee in relation to the medial malleolus of the front limb. It scored as either beyond the front of the malleolus (pass), or behind the front of the malleolus (fail). Measurements were obtained by four raters, two times per ankle, with 5 minutes of rest between measurements to prevent a treatment effect. Reliability was calculated using an ICC between the 2 raters using the electronic inclinometer and using a Kappa coefficient between the 4 pairs of raters for the SADS. **Results:** The ICC values from the electronic inclinometer were reported as mean values for the 3 trials at 0.95 (0.92-0.97). The Kappa values were calculated for a single trial for SADS and ranged from 0.61-0.81 with percent agreement ranging from 86%-94%. There was a statistically significant difference ($p<0.001$) in ankle DF ROM between the behind category (mean DF = 41.3° SD 4.7°) and the beyond category (mean value was 51.8° SD 6.1°). **Conclusions:** This novel ankle screen can be considered reliable for screening ankle DF ROM. Criterion validity, as compared to a standard goniometric measure, can also be considered meaningful. The screen may provide clinicians an effective tool to screen for ankle DF ROM deficits.

Validation of a Modified Functional Movement Screen Test for Division III Female Soccer Players

Tiffany R. Widseth, Ana B. Freire Ribeiro. *Augsburg University, Minneapolis, MN.* (Sponsor: Dr. Mark Blegen, FACSM)
(No relevant relationships reported)

Abstract
Background: The Functional Movement Screen (FMS) is comprised of seven tests to identify compensatory movement patterns that may increase injury risk and reduce performance. A modified FMS (MFMS) was created by Augsburg Athletic Trainers to improve screening efficiency and includes three original FMS tests: shoulder mobility, active straight leg raise, trunk stability pushup, and a newly added test; the vertical drop jump (VDJ), all scored on a simplified 0-2 scale.
Objective: This study aimed to validate the MFMS for DIII female soccer players.
Methods: Sixteen NCAA DIII soccer players and twenty non-athlete controls were recruited and completed two trials of FMS and MFMS. Reliability was calculated as Pearson Product Moment. Concurrent validity was calculated between FMS and MFMS scores, using R Statistical Software.
Results: Mean age of soccer group was 21 (SD=1.37) and control 21.05 (SD=1.61). Mean FMS score for soccer group was 14.38 (SD=1.54) and control 13.35 (SD=2.39). Mean MFMS score for soccer was 5.62 (SD=0.96) and control 4.95 (SD=0.69). Soccer scores for the first MFMS trial were significantly larger than controls' (p=0.02). FMS reliability coefficient was 0.99 and MFMS' was 0.88.
Discussion: There were moderate positive correlations between FMS and MFMS for the
soccer group (r=0.51) and for controls (r=0.46), but they were not large enough to validate the MFMS. When the MFMS was rescored on the original 0-3 scale (excluding VDJ) it was valid for both groups (soccer r = 0.79, controls r= 0.83).
Conclusion: The MFMS is not valid, suggesting potential issues with the new scoring system.

Keywords: Functional Movement Screen (FMS), validity, reliability, DIII Female soccer players

Effect of Instability in Legpress Testing on Strength & Muscle Activity in Functional Ankle Instability

Mina Khajooei, Chiao-I Lin, Müller Steffan, Frank Mayer. *Potsdam University, Potsdam, Germany.*

(No relevant relationships reported)

Compensating instable situations is an important functional capability to maintain joint stability, to compensate perturbations and to prevent (re-)injury. Therefore, a reduced maximum strength and altered neuromuscular activity is expected by inducing instability to high loading test situations. Possible effects are not clear for induced instability during maximum legpress tests in healthy and furthermore in subjects with functional ankle instability (FAI).

PURPOSE: First, to compare maximum strength and lower leg muscle activity between stable (S) and unstable (UN) maximum legpress tests. Second, to evaluate the association between FAI and effect of instability during testing. 18 male subjects (12 healthy/6 subjective FAI, age: 28±4yrs, height: 180±8cm, weight: 80±9kg, physical activity: 6±5h/wk) were included and their ankle function was quantified by the Foot and Ankle measure (FAAM) questionnaire. Five maximum strength test with leg press isokinetic device in concentric (CON) and eccentric (ECC) mode were measured. Muscle activity were recorded by EMG of m. tibialis anterior (TA), m. peroneus longus (PL) and m. soleus (SOL). Peak force (F_{Peak}, Nm) for maximum strength and root mean square (RMS, Hz) for EMG amplitude of TA, PL and SOL were calculated. Comparisons of conditions (S vs UN) were analyzed descriptively and with paired T-tests. For association, Pearson correlation was applied using FAAM score and RMS differences (condition UN − S). **Results:** UN lead to a significant peak force reduction of 10.1% (CON) and 13.7% (ECC) significantly (p<0.001). RMS of PL in CON and TA in CON and ECC mode were 26.2%, 59.7% and 35.8% respectively significant higher in UN footplate in comparison with S (p<0.01). In addition, no correlations between FAI and loss of strength or changes in muscle activity have been found. **Conclusion:** Reduction in peak force and increased muscle activity confirmed the expected increased effort to compensate instability. The missing association between FAI and amount of altered strength or muscle activity might be attributed to a low level of FAI in the included subjects.

Comparing The Possible Ankle Dorsiflexion Effects Of The Mulligan Ankle Dorsiflexion Mwm In Weight-bearing To The Mulligan Fibula Mwm For Dorsiflexion In Non-weight-bearing

Smokey Fermin[1], Lucas Bianco[2], Robert Oates[3]. [1]*University of Idaho, Moscow, ID.* [2]*Georgia Southwestern State University, Americus, GA.* [3]*Wilmington College, Wilmington, OH.*

(No relevant relationships reported)

Decreased ankle dorsiflexion can be a factor that limits participation in activities and predisposes individuals to chronic issues. Traditionally, stretching protocols, strengthening of muscles, balance training, and traditional joint mobilizations have been used to increase ankle dorsiflexion. Although current methods have been successful at mitigating ankle dorsiflexion restrictions, alternative treatments should be researched. **Purpose:** Determine the possible effect of two Mulligan Mobilization with Movement (MWM) Techniques on ankle dorsiflexion **Methods:** Individuals were recruited at three college athletic training clinics around the United States. Participants were randomly allocated into two groups, the Mulligan Ankle Dorsiflexion MWM in weight bearing and the Mulligan Fibula MWM for Dorsiflexion in non-weight-bearing. Once allocated, clinicians applied a single treatment of three sets of ten. Distance from wall and Tibial angle for the weight-bearing dorsiflexion lunge test was collected pretreatment, post treatment, at a 48-hour follow up, and at a one week follow up. **Results:** Significant effect was found for WBLT Distance ($F(2,11) = 54.8$, $p < .001$), WBLT Angle ($F(2,11) = 77.5$, $p < .001$) Y-Balance Composite ($F 2,11) = 6.1$, $p < .004$), and WBLT PSFS ($F(2,11) = 12.9$, $p < .004$). **Conclusions:** The results support the use of both the Mulligan Concept techniques to increase ankle dorsiflexion ROM. The immediate increases in ankle dorsiflexion ROM were maintained at one week follow-up.

Early Sport Specialization and Bilateral Tissue Differences in Overhead Athletes

Aaron Struminger[1], Alfred Atanda, Jr.[2], James Richards[3], Thomas Buckley[3], Charles B. Swanik[3]. [1]*Eastern Michigan University, Ypsilanti, MI.* [2]*Nemours/Alred I. DuPont Hospital for Children, Wilmington, DE.* [3]*University of Delaware, Newark, DE.*

(No relevant relationships reported)

Early sport specialization is a growing concern because it may lead to repetitive stress and excessive joint loading. Current data indicate that early specialization leads to injury, but its role in producing underlying tissue changes has not been examined. **PURPOSE:** To determine effects of sport specialization on upper extremity tissue characteristics. **METHODS:** Seventy-five collegiate baseball, softball, and tennis players (36 male, 39 female; age = 19.8 ± 1.4 years, height = 175.3 ± 10.4 cm; weight = 76.0 ± 13.9 kg) participated. Subjects completed surveys and were grouped based on age when they chose a primary sport and started competing for more than 8 months/year. Shoulder range of motion was measured with an inclinometer. Posterior capsule thickness, humeral retrotorsion, and ulnar collateral ligament (UCL) thickness were collected via ultrasound. For each measurement, non-dominant arm values were subtracted from dominant arm. Data were analyzed with hierarchical multiple regression, which determined group differences while controlling for sport played. **RESULTS:** Sport specialization criteria were met by 21 athletes before age 11 (Early), 28 athletes between the ages of 11-14 (Middle), and 25 athletes age 15 or older (Late). Shoulder internal (Early = -9.7 ± 5.6°; Middle = -8.8 ± 7.0°; Late = -8.2 ± 6.2°) and external (Early = 9.6 ± 11.1; Middle = 10.4 ± 11.8; Late = 9.9 ± 8.1) rotation produced clinically significant variations bilaterally but no statistically significant group differences (Internal: $R^2 = .08$, p = .23; External: $R^2 = .07$, p = .26). No group differences were noted for posterior capsule thickness ($R^2 = .07$, p = .28), humeral retrotorsion ($R^2 = .16$, p = .07), or UCL thickness ($R^2 = .11$, p = .09). Mean humeral retrotorsion (10.2 ± 6.1°) and UCL thickness (0.42 ± 0.61 mm) were greater on the dominant arm. **CONCLUSIONS:** Early sport specialization does not appear to exacerbate the bilateral tissue differences naturally present in collegiate overhead athletes. Therefore, sport specialization may be less concerning at the tissue level than the stress of overhead sport for the average athlete. Since the magnitude of tissue maladaptation associated with injury remains unknown, more data should be collected to determine connections among specialization, tissue characteristics, and injury rates in this population.

Preseason Physicals, Are Important Factors Missing?

Garth Babcock. *Eastern Washington University, Cheney, WA.* (Sponsor: Wendy Repovich, FACSM)

(No relevant relationships reported)

Research shows NFL football players are at increased risk for Metabolic Syndrome (MetS) but it is unclear when MetS develops or whether additional tests in a sports pre-particpation (PPE) exam might identify risk factors (RF). **PURPOSE:** To identify MetS RF and their associations using the National Cholesterol Education Program Adult Treatment Panel (NCEP ATP) III standards and measures of abdominal fat in college players. **METHODS:** Forty-seven freshmen from a Division 1 FCS (n = 15), and a Division 3 (n = 32) football team volunteered to be tested during their PPE. Tests included fasting Triglycerides (TG), High Density Lipoprotein (HDL), blood glucose (BG), blood pressure (BP), supra-iliac (SIWC) and umbilical (UWC) waist circumference, percent body fat (%BF), and subcutaneous (SCAT) and visceral (VAT) fat depth. All NCEP ATP guidelines were followed and %BF, SCAT, and VAT were measured using a BodyMetrix™ Ultrasound. Statistical analysis using SPSS (v24) included descriptive statistics, a Pearson Correlation, and a Stepwise Multiple Regression to determine RF present, and the relationship between all clinical measures. **RESULTS:** Ten players (21%) met the criteria for MetS (n = 2 with 3, n = 6 with 4, and n = 2 with 5 RF). Division 1 had a higher percent of players (n = 5, 33%, 3 were offensive linemen) meeting the criteria compared to Division 3 (n = 5, 16%, 1 was an offensive lineman). All NCEP ATP III risk factors except BG were correlated (all positive except HDL) with meeting the criteria for MetS, with the SWC being the highest (r = .77, p = .001). Using non NCEP ATP III RF, significant positive correlations were found between %BF (r = .65, p = .0001, SCAT (r = .35, p = .013),and VAT (r = .49, p = .001). Lineman meeting the criteria for MetS had a %BF >21. Five variables (SIWC, TG, HDL, BG & VAT) were statistically significant in predicting MetS (p = .001, $R^2 = .83$). The stepwise multiple regression reported that SIWC accounted for the greatest variance on the MetS prediction (p < .000, ß = .65, $R^2 = .65$), and when combined with TG accounted for 73% of variance. **CONCLUSIONS:** The data suggests that freshmen football players have a high incidence of MetS RF. Waist circumference, specifically at the supraliac location, TG, and %BF should be included in PPE evaluation with follow up for early intervention as necessary.

Ultrasound Imaging to Evaluate Acute Adaptations of the Medial Elbow Joint Complex

Kevin P. Lynch, Arie J. van Duijn, Shawn D. Felton, Mitchell L. Cordova, FACSM. *Florida Gulf Coast University, Fort Myers, FL.* (Sponsor: Mitchell L. Cordova, FACSM)

(No relevant relationships reported)

Musculoskeletal ultrasound imaging (MSKUI) has become an increasing studied assessment tool in orthopedic sports medicine. Several studies have investigated ulnar collateral ligament (UCL) integrity and morphology in the throwing arm of baseball players with MSKUI. Research data has indicated that UCL thickening and medial joint space (MJS) widening occurs in athletes during sustained competition. **PURPOSE**: To examine acute UCL thickness and MJS adaptations in the throwing arm of Division I collegiate baseball pitchers with MSKUI following one in-game performance. **METHODS**: Ten NCAA Division I collegiate baseball pitchers (mean age 20.4 ± 1.4 yrs) with no history of significant upper extremity injuries participated. Musculoskeletal ultrasound images were obtained with a GE LOGIQ e ultrasound unit before and immediately after (< 15 minutes) pitching performance during each subject's first game of the season. A 3 kg valgus force was applied with a handheld dynamometer (Hoggan Scientific microFET 2) 20 cm distal to the medial epicondyle of the throwing arm during imaging. Post-imaging ligament thickness measurements were performed at the mid-substance of UCL and at the apex of the trochlea. Moreover, post-imaging measurements were performed from the apex of the trochlea to the apex of the ulna to evaluate MJS. Changes to UCL thickness (mid-substance and apex of the trochlea) and MJS were analyzed using paired samples t-tests. **RESULTS**: There was no significant difference in mid-substance UCL thickness width before (5.72 ± 0.7mm) and after performance (5.70 ± 0.7mm; t (9)= .36, p = .73). With respect to apex of trochlea UCL width, no significant differences were found before (2.67 ± 0.7mm) and after (2.61 ± 0.6mm; t (9)= 1.30, p = .23) performance. When assessing MJS, a significant change of ~4% was observed before (6.30 ± 1.5 mm) and after [6.60 ± 1.5; p= .005). Controlling for the innings pitched [F (1,7) = .11, p = .75] and pitch count [F (1,7) = .21, p = .66] did not affect the change in MJS. **CONCLUSIONS**: A significant MJS widening did occur after one pitching outing at the start of the season; whereas, no changes were observed in UCL thickness measured at two different locations. Further research is needed to understand the etiology of increased medial elbow joint widening in pitchers at the start of the collegiate baseball season.

Does Shoulder Joint ROM Predict Medial Elbow Joint Space and UCL Thickness?

Shawn D. Felton, Arie J. van Duijn, Mitchell L. Cordova, FACSM. *Florida Gulf Coast University, Fort Myers, FL.* (Sponsor: Mitchell L. Cordova, FACSM)

(No relevant relationships reported)

Baseball athletes, especially pitchers, are prone to ulnar collateral ligament (UCL) injuries of the elbow. It is well documented that baseball athletes typically exhibit an increase in shoulder external rotation range of motion (ERRM) and a decrease in internal rotation range of motion (IRRM) while maintaining total rotational range of motion (TROM) in the throwing extremity. Furthermore, loss of TROM and ERRM may be associated with increased risk for UCL injury. Ultrasound imaging allows clinicians to evaluate UCL thickness and medial joint space (MJS) opening non-invasively. **PURPOSE**: To examine if shoulder joint motion (ERRM, IRRM, TROM), predicts medial elbow joint space (MJS) opening and UCL thickness in asymptomatic collegiate baseball pitchers at the start of the pre-season. **METHODS**: Nineteen asymptomatic NCAA Division I collegiate baseball pitchers (age 20.4 ± 1.45 yrs) participated in this study. Ultrasound images were obtained of the medial joint space and UCL on the participant's throwing arm using a GE LOGIQ e ultrasound unit. Participants were placed supine with a wedge placed underneath their pitching hand to maintain elbow position at 30 degrees. A 3 kg valgus force, as measured by a hand held dynamometer, was applied 20 cm distal to the medial epicondyle. Ligament thickness measurements were performed at the mid-substance of UCL and at the apex of the trochlea. Imaging measurements to evaluate MJS opening were performed from the apex of the trochlea to the apex of the ulna. Standard goniometric procedures were performed with the athlete supine to obtain ERRM, IRRM, and TROM values. Three stepwise linear multiple regression analyses were performed to determine if shoulder joint motion could predict UCL thickness and MJS. **RESULTS**: Shoulder joint range of motion did not significantly predict MJS [R² = .05, F (2,16) = 0.44, p=0.65,], UCL thickness at the mid-substance [R² = .01, F (2,16) = 0.12, p=0.89], or UCL thickness at the apex of the trochlea [R² = .04, F (2, 16) = 0.36, p=0.70].

CONCLUSIONS: Measures of shoulder joint ROM do not predict MJS or UCL thickness in asymptomatic baseball pitchers at the start of the season. Further research is recommended to perform multiple imagining sessions throughout the competitive season to further evaluate relationships between shoulder ROM and medial elbow structures.

Do Biomarkers Play A Role On Tendinopathy?

Leonardo P. Oliveira, Anoop Mayampurath, Nzuekoh Nchinda, Jennifer M. Wolf. *University of Chicago, Chicago, IL.* (Sponsor: Holly Benjamin, MD, FACSM)

(No relevant relationships reported)

PURPOSE: It is estimated that lower extremity tendinopathy (LE) affects 1.4% of the population and that prevalence increases with the type of sport, level of performance, and body part involved. Achilles and patellar tendon are two sites commonly associated with tendinopathy in the LE. In the upper extremity (UE), the shoulder and elbow are the most frequent locations. The pathophysiology of tendinopathy is thought to be secondary to repetitive use leading to injury. However, medical risk factors such as diabetes have been associated with higher prevalence of the disease. Our goal in this study was to understand the impact of biomarkers and medical risk factors on the prevalence of tendinopathy. **METHODS**: Retrospective chart review of the medical charts of patients evaluated in the ambulatory clinics at the University of Chicago Medical Center from 2006 to 2016 were reviewed for the ICD9/10 codes for tendinitis. Biomarkers (HbA1c, TSH, 25-Hydroxy-VitaminD[VITD], Hemoglobin[Hbg], ANA, ESR, CRP, and Creatinine) were considered valid if obtained within 3 months prior to the diagnosis. Chi-Square Analysis and Independent T-Tests were completed using R, with p<0.05 indicating significance. **RESULTS**: Among 19,682 patients that were found to have biomarkers fulfilling the study criteria, 1648 had the diagnosis of tendinopathy. VITD as a continuous variable (shown on table) as well as categorical (<30 or ≥ 30 ng/dl) was not significantly different between groups. However, quartile-based analysis revealed a higher prevalence of tendinopathy in patients with VITD 18-26 ng/dl (p=0.025). Lower ESR, CRP, and HbA1c were also associated with higher prevalence of tendinopathy. **CONCLUSIONS**: VITD between 18-26 ng/ml was associated with higher prevalence of tendonitis. Tendinopathy was more prevalent in individuals with lower inflammatory markers and fewer comorbidities. VITD deficiency appears to play a role in tendon disease.

Association of Biomarkers and Tendinopathy			
Biomarkers	With The Diagnosis of Tendinopathy	WithoutThe Diagnosis of Tendinopathy	P-Value
25-hydroxy-Vitamin D(ng/ml), mean±SD	26.2 ±9.2 ng/ml	26.5±12.4 ng/ml	0.7966
Hemoglobin A1c, mean±SD	6.5±1.21 %	7.5±1.75 %	<0.01
ESR ≥30 mm/hr (n/%)	63(40%)	684 (53%)	0.0021
CRP ≥ 6 mg/L (n/%)	61 (36%)	747 (47%)	0.006
Hbg(Abnormal) men: <13.5 mg/dl or > 17.5 mg/dl / women:<11.5mg/dl or > 15.5 mg/dl (n/%)	138 (32%)	3854 (48%)	<0.01

Acceptability of Personal Sensing to Develop a Digital Biomarker of Stress-Related Injury Risk in Athletes

Giampietro L. Vairo, David E. Conroy, Vasant G. Honavar. *The Pennsylvania State University, University Park, PA.* (Sponsor: W. Larry Kenney, FACSM)

(No relevant relationships reported)

Stress is a dynamic internal risk factor for musculoskeletal injury but existing monitoring tools are not well-suited for triggering just-in-time adaptive interventions to reduce risk during times of vulnerability. People carry smartphones with a rich array of sensors as they go about their daily lives. Data collected from these sensors offer unprecedented opportunities for developing digital biomarkers to improve health and wellbeing. Realizing the full potential of such data for reducing musculoskeletal injury risk is contingent upon the willingness of individuals to permit the collection and analyses of such data. This may depend on a variety of factors, e.g., those having to do with the target population, intended use of the data, specific types of information being collected, the individuals with whom the information is to be shared and the conditions under which it will be shared, etc. **PURPOSE:** This study examined the willingness of athletes to permit the collection and analyses of their smartphone sensor data to develop digital biomarkers that reliably predict the risk of stress-related musculoskeletal injuries. **METHODS:** College student-athletes (n=75)

completed a 46-item online questionnaire about their interest in a digital biomarker for monitoring stress-related injury risk, and their willingness to share data from specific smartphone sensors to develop that digital biomarker. **RESULTS:** Most athletes (82%) expressed an interest in a digital biomarker for monitoring their stress-related injury risk; however interest was significantly lower if medical staff (73%), coaches (64%), or administrators (60%) would have access to the biomarker (all $p < .01$). Most were willing to share data from sensors capturing motion (88%), environment (93%), location (73%), connections (77%), and usage (65%). Keyboard input was the least accepted source of data with almost 40% reporting they would never share that data to create a digital biomarker. **CONCLUSION:** Athletes generally find it acceptable to share their smartphone sensor data if the data will be used to identify digital biomarkers of stress-related injury risk and to recommend just-in-time stress management interventions for injury prevention.

The Development of a Single Leg Hurdle Test to Assess Return to Sport Readiness

Hayley Reed, Chelsey Roe, Samantha Price, Gaelen Athanaze, Jessica Schilling, Brian Noehren, FACSM. *University of Kentucky, Lexington, KY.* (Sponsor: Brian Noehren, FACSM)
(No relevant relationships reported)

Few tests of dynamic quadriceps muscle asymmetry exist for return to sport testing. Such a test would be beneficial, as quadriceps asymmetries are associated with higher injury levels once athletes return to play. Current hop tests emphasize horizontal progression, which previous studies have shown recruits the gluteal muscles much more than the quadriceps. Implementing an assessment, such as jumping over a hurdle, into a hop test may require increased demands of the quadriceps. As a first step, we sought to determine the reliability of a new type of hop test using a series of hurdles. **PURPOSE:** The objective of this study was to assess the between and within session reliability of a new single leg hurdle test. **METHODS:** 20 healthy subjects (11 M, ages 22.4 ± 3.1, BMI 22.9 ± 3.0) with no prior lower extremity injuries completed a single leg hop over a series of four consecutive 30.5 cm high hurdles. The distance between the hurdles was equal to the subject's leg length with 2 trials preformed on each leg. Performance was measured as the time it took to complete the hurdle series and how many attempts it took them to complete successfully. An error occurred if the subject knocked over a hurdle, hopped to the side of the hurdle or did not stick the landing on the final hop. Reliability between raters as well as within and between days was assessed using an Intraclass Correlation Coefficient (ICC). **RESULTS:** The average time to complete the hurdle test was (3.63 ± 1.59 seconds), and the average difference between days was (0.66 ± 0.95 seconds). Between rater reliability (ICC>0.99), between day reliability (ICC=0.90), and within rater same day reliability (ICC=0.98) were all excellent. **CONCLUSION:** The single leg hurdle test shows excellent within and between day reliability to complete the task. These results indicate that the test is a reliable assessment and establishes its face validity. The greater vertical component associated with this test may bias the hop towards greater quadriceps activation and help screen individuals for asymmetries. Having established the tests reliability, subsequent studies should assess its use for determining return to sport for patients following an injury.

Development of a Lateral Hop Endurance Test

Jessica Schilling, Chelsey Roe, Samantha Price, Gaelen Athanaze, Hayley Reed, Brian Noehren, FACSM. *University of Kentucky, Lexington, KY.* (Sponsor: Brian Noehren, FACSM)
(No relevant relationships reported)

Functional tests for patients attempting to return to sports, typically focus on sagittal plane movement such as a hop test. Additionally, most functional tests do not have an endurance component to them. Many injuries involve aberrant frontal plane control and occur later in a game situation. The development of a lateral endurance hop may prove useful to identify at risk athletes. As a first step, we sought to determine the reliability of a newly developed lateral hop test. **PURPOSE:** The purpose of this study was to evaluate the reliability of a new lateral hop endurance test. **METHOD:** 19 healthy subjects (11 M, ages 22.4 ± 3.1, BMI 22.9 ± 3.0) with no prior lower extremity injuries completed 30 second intervals of single legged lateral hopping with the targets separated by 15.24 centimeters. Performance was measured by counting the number of times the subject was able to hop completely over and back. An error was classified as putting a foot down or landing on the target and not counted. Reliability between raters as well as within and between days was assessed using an Intraclass Correlation Coefficient (ICC) and Pearson Product Moment Correlation. **RESULTS:** The average number of successful hops was (29.20 ± 6.35 hops). Between rater reliability (ICC>0.99), between day reliability (ICC=0.94), and correlation between days (r=0.89, p=<0.001) were all excellent.

CONCLUSION: The 30 second lateral hop endurance test had excellent reliability between raters and between days as well as a strong correlation between days. Having established the reliability of this test between days and rater, subsequent studies will evaluate differences within injured athletes.

Jump Training Improves Psychological Impairments and Facilitates Greater Sports Participation in Athletes with ACL Reconstruction

Ryan L. Mizner, Audrey R. Elias. *University of Montana, Missoula, MT.*
(No relevant relationships reported)

PURPOSE: About 35% of athletes with anterior cruciate ligament (ACL) reconstruction fail to return to their preinjury level of sports participation. Psychological factors, such as fear of reinjury, often prevent athletes who wish to return to their sport from achieving their goal. Limited evidence is available to direct patient care to target these psychological impairments. Most ACL injuries are non-contact in nature and typically occur during a deceleration task such as jump landing. We propose that training focused on improving jump landing performance will improve psychological factors and facilitate increased sports participation. **METHODS:** Forty-eight athletes completed screening tests an average of 2 years after unilateral ACLR (Wk0). Testing included the ACL-Return to Sport after Injury (ACL-RSI) scale as measure of psychological readiness for sports participation. Athletes (n = 25, 9 men, age = 23 ± 5 yr) who scored below normative ACL-RSI recovery standards (<65%) completed 8 weeks of twice-weekly jump landing training. Retesting occurred at midtraining (Wk4), posttraining (Wk8), and 2 months after training (Wk16). Athletes answered a survey measuring perceived changes in sports participation at the end of training. Changes observed during training were determined via repeated measures ANOVA. **RESULTS:** ACL-RSI scores improved substantially throughout treatment (mean ± SD; Wk0: $53 \pm 18\%$, Wk4: $67 \pm 15\%$, Wk8: $76 \pm 16\%$; p<0.001). Treatment benefits were maintained over the retention period (Wk16: $81 \pm 15\%$; p=0.052). Four out of 5 athletes trained report that they were more likely to participate in their sports activities after training and two thirds of the cohort described at least a moderate increase in their sports participation. **CONCLUSIONS:** Progressively dosed jump training that focuses on correcting aberrant landing movements is effective at addressing psychological factors in athletes who self-identified as having limited readiness for sport. The training was also effective at facilitating increased sports participation. Clinicians should consider implementing similar jump training interventions to help athletes who are struggling to return to their desired sports participation because of limited confidence or high fear of reinjury. Funded in part by the Foundation for Physical Therapy.

An Evaluation of Star Excursion Balance Test In Identifying Athletes At Risk For Injury

Mackenzie Pierson[1], Karlee Burns[2], Mimi Nakajima[2]. *[1]The University of North Carolina at Greensboro, Greensboro, NC. [2]California State University Long Beach, Long Beach, CA.*
(No relevant relationships reported)

PURPOSE: The use of the Star Excursion Balance Test (SEBT) is to screen deficits in dynamic postural control due to musculoskeletal injuries and to identify athletes at greater risk for lower extremity injury. However, the use of the SEBT has not proved reliably in female soccer populations in identifying potential lower extremity injury when assessed during pre-participation physical examinations. **METHODS:** 23 healthy NCAA Division I female soccer athletes; 20.3 (1.2) years, 165.1 (7.62) cm, 59.8 (8.6) kg, participated in this study. Prior to the start of the season, the anterior, posteromedial, and posterolateral SEBT reach distances were measured bilaterally. Each reach distances were normalized for lower limb length. Throughout the season, injury record was maintained by the certified athletic trainer. The athletes were grouped into injured (INJ) and non-injured (N-INJ) athletes. Composite scores for all three reach distances were also calculated. **RESULTS:** Independent t-test was conducted to compare reach distances for the SEBT between INJ and N-INJ athletes. There were no significant differences between the INJ and N-INJ group for normalized reach distances, nor composite scores of the SEBT. However, there was a significant difference in anterior reach asymmetries for those that sustained an injury (M= 6.06, SD=4.5); t(21)=2.78, p= 0.011) and those that did not sustain a lower extremity injury (M=2.5, SD=1.3). **CONCLUSIONS:** In this study, the SEBT showed differences for lower extremity injury in the female soccer population when assessing the anterior asymmetries. Our results suggest that portions of the SEBT can be incorporated into pre-participation physical examinations to identify soccer athletes who may have a significant difference between limbs and potentially be at an increased risk for lower extremity injury.

Limb Asymmetries in Post-ACL Reconstruction Patients

Mark Vorensky[1], Nicole Veltri[2], Jamie Kronenberg[2], Joshua M. Tome[2], Rumit Singh Kakar[2]. [1]NYU Langone Health Orthopedic Center, New York, NY. [2]Ithaca College, Ithaca, NY.
(No relevant relationships reported)

The reinjury rate of young athletes post anterior cruciate ligament reconstruction (ACLR) is 23%. Return to sport (RTS) testing, assessing limb asymmetries between the affected limb (AL) and unaffected limb (UAL), is utilized with hopes of preventing injury. **PURPOSE** To compare performances of the AL and UAL ≥ 12 months post ACLR to the dominant limb (DL) and non dominant limb (NDL) of healthy controls during common RTS tests. **METHODS** 11 ACLR (9 females, 2 males, 22.4±3.7 years old, 5.4±4.2 years post op) and 11 healthy BMI matched controls (9 females, 2 males, 21.7 ±2.1 years old) were recruited. Tests included: Y excursion (anterior, posteriolateral, posteriomedial), hop tests (single hop, triple hop, and triple cross over hop, timed 6m hop), weight bearing lunge and isokinetic concentric peak flexion and extension torque at 60, 120 and 300deg/sec (Biodex System 4 Dynamometer MVP). 3 Acceptable trials for each test and limb were recorded. The limb symmetry index (LSI) equaled 100(AL/UAL) and 100(DL/NDL) for ACLR and control groups respectively and was compared between groups using MANOVA (p<.05). LSI ≤ 85% and LSI ≥ 115% were deemed clinically important differences. Pearson correlation coefficients were calculated between peak isokinetic torques and functional tests. **RESULTS** No statistically significant differences between ACLR and control LSIs were observed (F=1.691, p=0.293, η^2=0.844, Power=0.289). A clinically significant difference was observed in peak flexion torque at 120deg/s (118.7±55.3%) for controls. There were no clinically significant differences for the ACLR group (93.4±8.8% - 113.4±35.9%). Primarily small correlations were shown between isokinetic and RTS tests. One strong correlation presented between NDL triple hop and 60deg/s peak extension torque for controls (r=0.74). **CONCLUSION** For athletes ≥ 12months post ACLR, no statistically or clinically important asymmetries were found for RTS tests compared to controls. These findings question the sensitivity and validity of the current RTS assessment. 3D motion analysis has shown kinematic asymmetries that affect function 2 years post ACLR. Future studies should investigate the role of 3D biomechanical analyses in RTS testing, with hopes to improve injury prevention.

The Relationship Between The Half Kneeling Ankle Dorsiflexion And A Novel Weight Bearing Lunge Tests

Garrett S. Bullock[1], Phillip J. Plisky[2], Kyle Matsel[2], Allison Weaver[3], Jenna Gourlay[3], Kyle Kiesel[2]. [1]Mountain River PT, Chatham, VA. [2]University of Evansville, Evansville, IN. [3]ProRehab-PC, Evansville, IN.
(No relevant relationships reported)

Purpose: Decreased ankle dorsiflexion has a relationship to lower extremity injury. Utilizing screens to effectively identify decreased dorsiflexion can help improve clinicians' efficiency. The purpose of this study was to compare ankle dorsiflexion range of motion (ROM) using an ordinal scored modified weight bearing lunge test (MWLT) and the established half kneeling ankle dorsiflexion test (HDT). It is proposed that there will be a relationship between MWLT dorsiflexion ordinal scoring and the HDT ROM measurements. **Methods:** 30 healthy subjects (60 ankles) participated in this study. Ankle dorsiflexion ROM was measured using the MWLT and HDT. The MWLT was completed in a standing heel to toe position. The dorsiflexion of the back ankle was scored in relation to how anterior the back knee aligns relative to the medial malleolus of the front ankle. The MWLT is scored on an ordinal scale: behind, within, or beyond the malleolus. The HDT was performed with the patient in a half kneeling position, placing a digital inclinometer just inferior to the tibial tuberosity on the forward leg. Subjects were instructed in both the HDT and MWLT to bring their knee as forward far as possible without lifting their heel off of the ground. All measurements were obtained two times per side, with 5 minutes of rest between measurements to prevent a treatment effect. Statistical analysis was completed using a series of ANOVAs. Tukey post-hoc were used to identify specific group-to-group differences (*p*<0.05). **Results:** Significance was found between HDT and MWLT (*p*<0.001). The mean HDT measurement for the MWLT score of behind was 33.5±2.0 degrees, within was 38.6±1.2 degrees, and beyond was 43.0±0.78 degrees. Tukey post hoc analysis showed that there was a significant difference comparing MWLT score of beyond and behind (*p*<0.001) and beyond and within (*p*=0.0097). No differences were found comparing MWLT score of within and behind to HDT (p=0.0760). **Conclusions:** There was a distinct difference in ankle dorsiflexion ROM between the MWLT scores of beyond and behind and beyond and within, when comparing to HDT. There was no difference in the MWLT scores of behind and within when compared to HDT. Future studies should compare goniometric measure of the MWLT to the ordinal scale and further elucidate the differences and underlying causes in the MWLT ordinal scores.

Assessing Psychological Readiness After ACL Reconstruction: Is It Possible With One Questionnaire?

Adam Meierbachtol, Michael Obermeier, Terese Chmielewski. *TRIA Orthopedic Center, Bloomington, MN.*
(No relevant relationships reported)

Purpose: The return to sport following anterior cruciate ligament reconstruction (ACLR) may be impeded by psychological factors such as high fear of re-injury (kinesiophobia) or low confidence (self-efficacy). Screening psychological readiness for sport can identify individuals in need of additional intervention. The Anterior Cruciate Ligament Return to Sport after Injury (ACL-RSI) is a 12-item questionnaire to assess psychological readiness for sport in domains of Emotions, Confidence, and Risk Appraisal. The ACL-RSI contains 2 fear of re-injury items (Emotions domain) and 5 confidence items (Confidence domain). Fear of re-injury has lower representation in the ACL-RSI total score and may not be identified to the same extent as confidence level. The purpose of this study was to examine during return to sport after ACLR 1) the relative ranking of ACL-RSI fear of re-injury item scores compared to other item scores and association with ACL-RSI total score, and 2) the association of ACL-RSI domain and total scores with kinesiophobia and self-efficacy questionnaire scores. **Methods:** Participants were 21 patients with ACLR (mean 17.4 years, 11 males) enrolled in a 5 week (10 visit) group-based return to sport training program. ACL-RSI, Tampa Scale for Kinesiophobia-11 (TSK-11) and Knee Activity Self Efficacy (KASE) questionnaires were administered before and after training. **Results:** All questionnaire scores improved from pre- to post-training (ACL-RSI: 63.2 to 73.8, TSK-11: 21.4 to 17.3, KASE: 78.5 to 92.5; p < .01). Both ACL-RSI fear of re-injury items ranked in the lowest 3 item scores at pre- and post-training, but had moderate to high correlation with ACL-RSI total score (range: r=.56 to .83, p<.01). ACL-RSI Confidence domain score and total score were positively correlated with KASE score at pre-training, post-training, and in the pre- to post-training change (range: r=.50 to .73, p <.05). ACL-RSI Emotions domain score and total score were not significantly correlated with TSK-11 score at any time point (p>.05). **Conclusions:** Athletes with high fear of re-injury should be appropriately identified by their ACL-RSI score. It appears necessary to administer the TSK-11 separately to identify high kinesiophobia, whereas a separate questionnaire for knee self-efficacy does not appear warranted.

Closed Kinetic Chain Upper Extremity Stability Test (CKCUEST) in DIII Collegiate Baseball and Softball Players

Aaron Mallace, David Schilling, Ashraf Elazzazi. *Utica College, Utica, NY.*
(No relevant relationships reported)

PURPOSE:
The Closed Kinetic Chain Upper Extremity Stability Test (CKCUEST) has been used as an alternative to the push up test to examine upper extremity stability and function. However, no studies have investigated its use in division III collegiate baseball (BB) and softball (SB) players. The purpose of this study was to describe the normative values, power and normalized scores for the CKCUEST for this population.
METHODS:
Seventy four division III collegiate athletes (SB n=24; BB n=50) between 18-21 years old signed an approved informed consent. Participants assumed a push-up (male) or a modified push-up (female) position and were instructed to alternately touch two pieces of tape placed on the ground 36 inches apart as many times as possible for 15 seconds. After one submaximal warm-up, the average number of lines touched (CKCUEST value) from three trials was calculated. Power and a normalized score were calculated based on the CKCUEST value and the participant's weight or height, respectively. Additionally, shoulder strength was measured bilaterally for internal and external rotation using a handheld dynamometer in the standard testing position.
RESULTS:
There was a significant difference (p<.001) between the power of BB (71.35±14.4) and SB (55.37±11.6) players. However, there was no significant difference between the two groups in in the CKCUEST value or the normalized score. There were small and nonsignificant correlations between the CKCUEST and shoulder internal (IR) or external rotation (ER) strength.
CONCLUSIONS:
This study reported the normative values for the CKCUEST for division III SB and BB players with representation from all positions. The significant differences in power between BB and SB players may be linked to sex, training regimens and/or the physical requirements of each sport. The small correlation of shoulder IR and ER strength and the CKCUEST value may be related to the rotator cuffs primary stabilization function; which may not influence the CKCUEST value as much as the strength of the prime movers of the shoulder during the motion prescribed by the test. Strength of the pectoralis major and deltoid may better correlate with the values of the CKCUEST for this population and should be considered in future research.

2442   Board #278   June 1 9:30 AM - 11:00 AM

Asymmetry Of Knee Extension Strength And Single-leg Landing Impact In ACL reconstructed Athletes

Junya Aizawa, Kenji Hirohata, Shunsuke Ohji, Takehiro Ohmi, Kazuyoshi Yagishita. *Tokyo Medical and Dental University, Tokyo, Japan.*

(No relevant relationships reported)

PURPOSE: Excessive magnitude, speed, and asymmetry of single-leg landing impacts contribute to re-injury risk in athletes after ACL reconstruction (ACLR). The limb symmetry index (LSI) of knee strength tends to decrease after ACLR even after return to sport. We analyzed relationships between the asymmetry of vertical ground reaction force (VGRF) parameters during single-leg jump landings and the knee isokinetic extension strength in athletes after ACLR. **METHODS:** Twenty-six participants were recruited based on the inclusion criteria: age 16-40 years at time of measurement; primary or one-sided ACL injury; >150 and <240 days since anatomical double-bundle ACLR using a hamstring tendon autograft; completed athletic rehabilitation within the same protocol; and agreement to participate in single-leg hop exercise and basic noncontact practice of jump-landings and cutting sports. The isokinetic strength of the quadriceps was tested at an angle of 60°/sec. Participants were subdivided into groups according to LSI for quadriceps strength (low quadriceps [LQ], <85% LSI, N10; high quadriceps [HQ], >90% LSI, N12). A 20-cm step was placed 60 cm from the center of a force plate. The participants stood on one leg on the step with their arms crossed, then jumped forward without any intended upward action and landed as naturally as possible on the same leg in the center of the force plate. The VGRF was collected at a sampling rate of 1000 Hz, filtered using a low-pass Butterworth filter with a cut-off frequency of 50 Hz, and normalized by body weight. Loading rate was calculated as peak VGRF (pVGRF) divided by the time from initial contact to pVGRF. The LSI of pVGRF and loading rate were compared between groups using non-paired t-tests. **RESULTS:** The quadriceps strength LSI of the LQ and HQ groups were 76±6.7% and 96.5±7.2%, respectively. The pVGRF LSI were 104.0±1.3% and 98.0±8.7%, respectively. Loading rate LSI were 115.9±23.6% and 98.8±21.7%, respectively. Loading rate LSI of LQ was significant larger than HQ ($p=0.041$). The pVGRF LSI of LQ tended to be larger than HQ ($p=0.074$). **CONCLUSIONS:** Smaller asymmetry in knee extension isokinetic strength is important for symmetrical landing impact during single-leg anterior jump-landings performed by athletes after ACLR. Supported by JSPS KAKENHI Grant number 26350606.

2443   Board #279   June 1 9:30 AM - 11:00 AM

Relations Between Return to Play Unilateral Knee Extension Strength and Triple-Hop Tests

Lauren E. McIntosh[1], Alexander J. Hron[2], Benjamin C. Noonan[2], Colin W. Bond[2]. [1]*North Dakota State University, Fargo, ND.* [2]*Sanford Health, Fargo, ND.*

(No relevant relationships reported)

Unilateral assessments are used to monitor the restoration of strength and strength symmetry following unilateral injury, such as an anterior cruciate ligament (ACL) tear. **PURPOSE:** To assess the relation between unilateral isokinetic knee extension (KE) strength and triple hop distance in post-operative ACL reconstruction patients at the time of return to sport (RTS). **METHODS:** Thirty patients (15 male; 18 ± 6 y; 1.75 ± 0.13 m; 76 ± 19 kg) were assessed for unilateral isokinetic KE strength at 180° s[-1] and triple hop distance. Peak KE strength on the involved leg (IL) and uninvolved leg (UIL) were averaged to obtain an overall strength value and strength asymmetry was calculated between legs as a percentage. Participants were stratified into four groups based on the cohort's overall median strength and strength asymmetry values (low strength low asymmetry, low strength high asymmetry, high strength low asymmetry, and high strength high asymmetry). Pearson correlations were used to determine the relation between KE strength and triple hop distance. One-way analysis of variance was used to assess the effect of group on triple hop distance on IL and UIL. T-tests were used to determine the source of identified effects and to compare IL to UIL in each group. **RESULTS:** For all patients, the mean IL and UIL KE strength was 1.52 ± 0.59 Nm kg[-1] and 1.68 ± 0.61 Nm kg[-1], respectively, and the median KE strength asymmetry was 13.2%. The mean IL and UIL triple hop distance was 4.27 ± 1.09 m and 4.26 ± 1.27 m, respectively. No significant correlations were identified between UIL KE strength and triple hop distance ($r = 0.34$; $p > 0.05$), but were identified for IL KE strength and triple hop distance ($r = 0.40$; $p = 0.03$). No significant effect of group for IL was identified ($p > 0.05$) but was identified for UIL ($p = 0.03$), though individual comparisons were not significant ($p > 0.05$). Among all groups, triple hop distance was not significantly different between IL and UIL ($p > 0.05$). **CONCLUSION:** The low explained variance between KE strength and triple hop distance suggests these test shouldn't be used in isolation during RTS testing. Groups may have demonstrated similar triple hop distance because demand may be shifted to proximal or distal joints during unilateral hopping, which masks unilateral KE strength deficits and results in symmetrical unilateral function.

Knee Extensor Strength In The Uninjured Leg Following Anterior Cruciate Ligament Reconstruction: A Meta-analysis

Christopher M. Jeanfreau, Katherine A. Hamblin, Gordon L. Warren, FACSM, Sharon L. Leslie, Liang-Ching Tsai. *Georgia State University, Atlanta, GA.* (Sponsor: Gordon L. Warren, FACSM)

(No relevant relationships reported)

PURPOSE: After anterior cruciate ligament reconstruction (ACLR), the uninjured leg is often used for comparison to determine knee extensor (KE) strength deficit in the ACLR leg. This meta-analysis examined the KE strength of the uninjured leg when compared to healthy controls.
METHODS: 1702 studies conducted between 2010 and 2016 were collected from 10 databases and screened for the following inclusion criteria: 1) unilateral ACLR and 2) KE strength reported for ACLR patients' uninjured legs and healthy controls. Studies were excluded if they were non-English or if the strength was measured only at ≥10 years post-ACLR. A total of 20 studies with 636 ACLR subjects and 504 healthy controls met the selection criteria and resulted in 73 Cohen's d effect sizes (ESs) for analysis. A positive ES equates to the KE of the patients' uninjured legs being stronger than those of healthy controls.
RESULTS: While the overall ES revealed no difference between the uninjured legs and healthy controls (ES = 0.089, $P = 0.305$), high between-study variance was observed ($P < 0.001$). Meta regressions indicated a significant association of the time post-ACLR with the study ES ($P = 0.037$). Based on the regressions, the uninjured legs would be predicted to be stronger than healthy controls (i.e. ES > 0) after 9 months post-ACLR. For the first 44 months post ACLR, the ES in studies using patella tendon autografts was greater than that in studies using hamstring tendon autografts ($P < 0.001$). The ES from studies involving patients with concomitant injuries (e.g., meniscus tears) was smaller than that from those without concomitant injuries ($P = 0.012$). Regressions also indicated a greater study ES as the isokinetic testing speed increased ($P = 0.040$).
CONCLUSIONS: Time post-ACLR, graft type, concomitant injuries, and isokinetic testing speed may explain some of the between-study variability in the KE strength of ACLR patients' uninjured legs when compared to healthy controls. Future studies are needed to examine the causal effects of these identified variables on the uninjured leg's KE strength post-ACLR. Current practice using the uninjured leg as the reference for recovery post-ACLR may need to be implemented with caution, particularly in patients in the early stages of rehabilitation, with hamstring tendon autografts, and/or with concomitant injuries.

Comparison of Handheld and Human Norm Dynamometry for Lower Extremity Muscle Strength Measurements

Karlee Burns[1], Mackenzie Pierson[2], Will Wu[1], Mimi Nakajima[1]. [1]*California State University, Long Beach, Long Beach, CA.* [2]*UNC, Greensboro, Greensboro, NC.*

(No relevant relationships reported)

Purpose: The use of hand held dynamometry is commonplace in research and clinical practice when an isokinetic unit is not available for muscle strength testing. However, the use of a hand-held dynamometer alone or in conjunction with a patient stabilization strap has not been thoroughly examined and compared to the isokinetic machine. **Methods:** Nine healthy convenience sample volunteers (2 males, 7 females; age: 24.40(5.78) years; height: 67.0(4.0) inches; mass: 72.30(17.25) kg) participated in the study. The participants randomly completed isometric strength tests of knee flexion and extension with the handheld dynamometer (HD), handheld dynamometer with patient stabilization strap (SHD), and HUMAC NORM Dynamometer (HN; CSMi, Stoughton, MA). The average of three trials was normalized by body weight and the ratio between knee flexion and extension strength was recorded for analysis. **Results:** A repeated measures ANOVA was performed to determine significant differences (P < .05 a priori) between variables; F(2) = 19.352 p < .01. Post hoc comparison showed SHD (mean = 2.7070.245) was significantly greater than HD (1.3960.065) and HDS was significantly greater than HN (mean=1.649 0.164). HD and HN produced similar results. **Conclusion:** Results indicated that using a hand-held dynamometer without the use of a patient stabilization strap produced similar measurements to the HUMAC NORM dynamometer. Using the patient stabilization strap overestimated the patients' strength. Using a handheld dynamometer for these measurements may be used to produce similar results without the time obligation and expense of using a Humac Norm dynamometer unit.

Quantification of Three Clinical Tests for the Assessment of the Femoroacetabular Impingement : Preliminary Results

Marc-Olivier St-Pierre, Stephane Sobczak, Naomi Fontaine, Nour Saade, Karine Boivin. *University of Quebec in Trois-Rivières, Trois-Rivières, QC, Canada.*

(No relevant relationships reported)

Femoroacetabular impingement (FAI) is a growing orthopedic condition among athletes and general population. It has been reported as being a precursor of hip pain and osteo-arthritis development. Many orthopedic manual (OM) tests are currently used to assess FAI. The cause of their low reliability is related to the variability between practitioners in their approach. **Purpose:** To quantify three tests commonly used to diagnose FAI (FABER, FADIR and the impingement sign). **Methods:** A sample of twenty healthy participants (10 men, 10 women) without hip, knee, or back pain will be recruited. Presently, measurements were performed on the thirteen first participants during two sessions (one day apart) by three raters. We quantified the FABER height (Distance of the tibial tuberosity to the table) and ROM (in millimeter and degree), FADIR ROM and impingement sign ROM (magnitude in internal rotation in degree) using four conditions for each test: (C1) classic, (C2) using an algometer to document pressure variability between tests and raters, (C3) under a hip positioning personalized according to a specific functional task and (C4) including the two last one. Reliabilities of measurements were determined using mean intraclass correlation coefficient (min-max) and the confidence intervals. **Results:** Regarding intra-rater reliability (Table 1), impingement sign and FADIR tests had higher ICC values thru all the conditions when compared to FABER. Concerning the use of an algometer, intra-rater reliability increased for the three tests in comparison to C1 and C2 (mean values). Concerning inter-rater reliability, the analysis showed best mean value for C1. The use of an algometer did not increase ICC between C1 and C2. **Conclusion:** Impingement sign, with a simpler hip positioning, had the highest intra and inter reliability values. Using an algometer while performing OM tests seems to be helpful to improve reliability of test measurements. However, FABER test still needs improvement.

E-42   Free Communication/Poster - **Obesity and Exercise**

Friday, June 1, 2018, 7:30 AM - 12:30 PM
Room: CC-Hall B

2447   Board #283   June 1 9:30 AM - 11:00 AM

Interindividual Variability For Change In Waist Circumference And Body Weight In Response To Standardized Exercise

Matthew W. Nelms[1], Brittany P. Hammond[1], Andrea M. Brennan[1], Andrew Day[1], Paula J. Stotz[1], Benoit Lamarche[2], Robert Ross, FACSM[1]. *[1]Queen's University, Kingston, ON, Canada. [2]Laval University, Quebec City, QC, Canada.*

(No relevant relationships reported)

Substantial interindividual variability in response to a standard dose of exercise exists independent of the trait under investigation. Whether interindividual variability attributed to exercise exists after accounting for random variability is unknown. **PURPOSE**: To determine the magnitude of the interindividual variability in response to exercise for waist circumference (WC) and body weight (BW) after accounting for random variability and, the extent to which the variability is explained by lifestyle behaviors. **METHODS**: Participants were 181 (61% female) sedentary, abdominally obese adults (mean, (SD)) 53, (7.5) years) who completed a 24-week

intervention. Participants were randomly assigned to: control (n=44) or 5 weekly sessions of low amount, low intensity (LALI) (180 and 300kcal/session for women and men respectively at 50% V02peak, n=46); high amount, low intensity (HALI) (360 and 600kcal/session for women and men respectively at 50% V02peak, n=53); or high amount, high intensity (HAHI) (360 and 600kcal/session for women and men respectively at 75% V02peak, n=38). Adherence was ≥ 80% in all exercise groups. Physical activity (PA) performed outside of the prescribed exercise was measured by accelerometer. Daily self-report diet records were used to derive energy intake (kcal) and diet quality (Canadian-Healthy Eating Index-2010, Mediterranean Score). The variability in response to exercise (SDR) was determined by separating the random variability from the intervention variability using the standard deviations (SD) from both the control and intervention groups. **RESULTS**: WC and BW were substantially reduced at 24 weeks in all exercise groups compared to control (P<0.01). The variability due to exercise (SDR) for change in WC was 3.1, -0.3 and 3.1 cm for LALI, HALI and HAHI groups respectively. Corresponding values for BW were 3.8, 2.0 and 3.5 kg for LALI, HALI and HAHI respectively. No dietary or PA variable was identified as a determinant of the individual variability in response to exercise for WC or BW (p>0.05). **CONCLUSIONS**: A substantial individual variability in response to exercise was observed for change in WC and BW after accounting for the random variability. The determinants of the heterogeneity in response to exercise remain to be determined. Supported by CIHR Grant OHN-63277.

Effects Of Exercise Training On Strength And Functionality In Obese Subjects Undergoing Bariatric Surgery: Preliminary Findings

Hamilton Roschel, Saulo Gil, Wagner S. Dantas, Igor H. Murai, Carlos Merege, Filho, Marco A. Santo, Roberto Cleva, Bruno Gualano. *University of Sao Paulo, Sao Paulo, Brazil.*

(No relevant relationships reported)

PURPOSE: To examine the effects of exercise training on strength, functionality and physical activity level in women undergoing bariatric surgery. **METHODS**: Twenty-nine obese women were randomly allocated into one of two groups: bariatric surgery (BAR: BMI = 46.5±6.2 kg/m²) and bariatric surgery plus exercise training (BAR+EX: BMI = 48.3±5.2 kg/m²). Patients were assessed at baseline, three (3mo), and nine months (9mo) after surgery. The 6-month exercise intervention started 3 months after surgery for BAR+EX while BAR follow standard care. Lower- and upper-limb 1RM, functionality [timed-up-and-go (TUG) and timed-stands (TST) test], and physical activity level [light activity (LA) and moderate to vigorous activity (MVPA)] were assessed. A mixed-model for repeated measures with Tukey adjustment was used. Significance level was set at p<0.05. **RESULTS**: Both groups presented with reduced lower- (BAR = 31% and BAR+EX = 25%, p<0.01) and upper-limb 1RM (BAR = 27% and BAR+EX = 31%, p<0.01) at 3mo. Importantly, BAR+EX increased lower- and upper-limb 1RM at 9mo in comparison to 3mo (45 and 13%, respectively; both p<0.01). In contrast, no significant differences were observed in BAR group at the same points (3 and 5% for lower- and upper-limb 1RM, respectively; both p>0.05). Additionally, lower-limb 1RM was significantly greater in BAR+EX when compared with BAR at 9mo (p<0.01). No significant changes on TUG and TST were observed in any of the groups at 3mo (all p>0.05). BAR+EX showed improved TUG and TST scores in comparison to 3mo (8 and 22%, respectively; p<0.01) while no significant differences were observed in BAR (3 and 7%, respectively, both p>0.05). Finally, TUG and TST scores were significantly greater in BAR+EX when compared with BAR at 9mo (all p<0.01). No significant changes in physical activity level were noted at any time point (all p>0.05). **CONCLUSIONS**: Our data suggest that a 6-month exercise training program is effective in counteracting strength and functionality impairments observed after bariatric surgery without any changes in physical activity-related behaviors.

Modifications Taken in a Yoga Practice in Overweight versus Normal Weight Individuals

Sally A. Sherman, Renee J. Rogers, Kelliann K. Davis, John M. Jakicic, FACSM. *University of Pittsburgh, Pittsburgh, PA.* (Sponsor: John M. Jakicic, PhD., FACSM)

(No relevant relationships reported)

Vinyasa yoga has demonstrated to elicit energy expenditure that is comparable to brisk walking. Whether overweight adults need to modify their yoga practice compare to normal weight adults, and whether this elicits a difference in energy expenditure is unclear. **PURPOSE:** To compared the number of modifications taken by participants, and the energy expenditure, during a yoga session between overweight and normal weight individuals. **METHODS:** Forty adults (men=20; women=20) participated in this study, with 21 classified as normal weight (BMI=22.0±1.6 kg/m²; age=30.8±8.8 years) and 19 classified as overweight (BMI=27.2±2.3 kg/m²; age=30.8±8.8 years). Participants engaged in a 60-minute Vinyasa yoga session that included a yoga sequence on a video that contained the instructor's cues along with a

person demonstrating the sequence. Participants were instructed to follow the verbal cues, but were permitted to take modifications of the poses to match their skill level. A trained instructor of Vinyasa yoga monitored whether each pose was performed in a manner consistent with the video or whether the individual modified the pose. Heart rate was assessed with a chest-worn monitor and energy expenditure was assessed with a portable metabolic indirect calorimetry device. **RESULTS:** The number of modifications to the asanas did not differ between overweight (4.5±3.7) vs. normal weight (4.6±3.3) across the yoga session (p=0.93). Total energy expenditure during the yoga session was greater in overweight (315.3±68.1) vs. normal weight (190.1+51.3) (p=0.80). However, energy expenditure relative to body weight (kcal per kg) did not differ between overweight (3.8±0.5) vs. normal weight (3.7+0.7) (p=0.80), and mean METs per minute did not differ between overweight (3.6±0.6) vs. normal weight (3.6±0.5) (p=0.85). **CONCLUSIONS:** In a 60-minute yoga session, the number of modifications to the asanas and the relative energy expenditure did not differ between overweight and normal weight participants. These findings may suggest that yoga is a viable form of exercise for both normal weight and overweight adults, which may have implications for enhancing energy expenditure and for body weight regulation.

Cardiac Autonomic Modulation Following Acute Aerobic Exercise in Young Obese Adults

Kanokwan Bunsawat[1], Georgios Grigoriadis[2], Sang Ouk Wee[3], Garett Griffith[2], Bo Fernhall, FACSM[2], Tracy Baynard, FACSM[2]. [1]University of Utah, Salt Lake City, UT. [2]University of Illinois at Chicago, Chicago, IL. [3]California State University San Bernardino, San Bernardino, CA. (Sponsor: Tracy Baynard, Ph.D., FACSM)

(No relevant relationships reported)

INTRODUCTION: Obesity is associated with cardiac autonomic dysfunction at rest and may also influence the ability to recover from acute aerobic exercise (AE), but this still remains unclear. This is important, because acute AE induces a shift in autonomic balance towards sympathetic dominance, especially at moderate to vigorous intensities, which places greater stress on the cardiovascular system. The inability to return this balance to homeostatic levels quickly and efficiently after AE is an important indicator of risk. **PURPOSE:** To evaluate cardiac autonomic function at rest and during exercise recovery using heart rate variability (HRV) analyses in young, otherwise healthy obese vs. lean adults. **METHODS:** Seventeen lean (female=6; 26±5 yrs; 22.7±1.7 kg/m²) and 17 obese adults (female=7; 27±4 yrs; 32.3±2.2 kg/m²) performed moderate-intensity cycling exercise for 60 min. HRV was assessed at baseline, and at 30, 60, and 90-min post-exercise in both the frequency (total power (TP), low frequency (LF), high frequency (HF), and LF/HF ratio) and time domains (Root mean square of successive differences (RMSSD)). Frequency data were log-transformed (Ln) to create normally distributed data. **RESULTS:** No baseline differences were observed for any variable (p>0.05). During recovery, heart rate and LnLF/LnHF ratio increased from baseline, whereas all other HRV parameters decreased from baseline similarly in both groups (p<0.05). In both groups, LnHF, LnLF, and RMSSD returned to baseline at 90-min post-exercise, whereas heart rate and LnLF/LnHF remained above and LnTP remained below baseline at 90-min post-exercise (p<0.05). **CONCLUSION:** Our findings suggest that compared with lean counterparts, young otherwise healthy obese adults did not exhibit altered cardiac autonomic modulation following acute AE. Furthermore, our findings highlight that it may take longer than 90 min for both groups to recover from the autonomic shift induced by acute moderate-intensity AE.

The Effects of HIIT on Maximal Oxygen Uptake and Peak Power in Sedentary, Obese Women

Amy S. Clark, Annie B. De La Rosa, Jamie L. DeRevere, Todd A. Astorino. *California State University San Marcos, San Marcos, CA.*

(No relevant relationships reported)

Globally, 1.9 billion adults are overweight, with 600 million classified as obese which creates a serious public health problem (World Health Organization 2015). In 2008, only 20 % of adults in the United States met the CDC physical activity guidelines. Low levels of physical activity contribute to obesity, and a sedentary lifestyle along with obesity is related to higher risk of cardiovascular disease, type 2 diabetes, hypertension, and dyslipidemia (Abate 2000). High intensity interval training (HIIT) induces rapid increases in maximal oxygen uptake (VO₂max) in the initial weeks of exercise training, which is essential in obese populations, and is a more time efficient and enjoyable form of exercise than endurance training (Bartlett et al. 2011). Yet, few studies have investigated the effects of different HIIT regimes on change in VO₂max in obese, sedentary individuals.
PURPOSE: To investigate effects of two HIIT regimes on VO₂max and peak power output (PPO) in obese, sedentary women.
METHODS: 17 obese sedentary women (age and BMI=37.5±10.5 yr and 39.0±4.7 kg/m²) participated in a six-week exercise intervention with three training sessions per week. Participants were randomized to low volume HIIT (LOW) (n=9, VO₂max=21.5±3.2 mL/kg/min) or periodized HIIT (PER) (n=8, VO₂max=17.3±2.4mL/kg/min). VO₂max was measured on a cycle ergometer at baseline and at 3 and 6 weeks using a ramp exercise test. Women in LOW completed repeated 60 s bouts of HIIT at 70-85% PPO; whereas, women in PER performed a different number of bouts and intensities each week.
RESULTS: There was a significant difference in relative (p=0.001; LOW: 21.5±3.2 vs. 22.5±3.2 mL/kg/min; PER: 17.3±2.41 vs. 18.0±2.2 mL/kg/min) and absolute (p=0.002; LOW: 2.1±0.3 vs. 2.2±0.3 L/min; PER: 1.9±0.4 vs. 2.0±0.3 L/min) VO₂max across time, but no interaction (p>0.05). PPO also increased in response to training (p=0.01; LOW: 178.4±21.1 vs. 193.7±30.7 W; PER: 169.0±21.2 vs. 174.8±24.1 W) but there was no interaction (p>0.05).
CONCLUSION: Although there were no significant differences between regimes, HIIT elicits significant changes in PPO and VO₂max in sedentary obese women, which are beneficial to
health. The magnitude of change in VO₂max is lower than previously-reported values which raises the question if morbid obesity diminishes VO₂max response to training.

Apelin Secretion In Overweight/obese Adults Following A Single Bout Of Exhaustive Exercise

Jun Seok Son[1], Song Ah Chae[2], Min Du[1], Wook Song[3]. [1]Washington State University, Pullman, WA. [2]University of Idaho, Moscow, ID. [3]Seoul National University, Seoul, Korea, Republic of.

(No relevant relationships reported)

Obesity and associated metabolic dysfunction has reaching epidemic levels. Physical activity is beneficial for preventing metabolic symptoms, of which myocytes secreted during exercise play a major role. In this study, the circulatory level of apelin, one of the myokines, was assessed in patients with obesity and metabolic diseases.
PURPOSE: To examine the effects of body composition, metabolic parameters, and physical fitness on apelin secretion following a single bout of exhaustive exercise.
METHODS: A total 60 subjects [34 women (21 lean and 13 overweight/obese) and 26 men (8 lean and 18 overweight/obese)], age 30-59 years, with body max index (BMI) of 18-30 kg/m² were recruited based on the guidelines for overweight (BMI of 23-24.9 kg/m²) and obesity (BMI of over 25 kg/m²) in Korean. Body composition, clinical parameters, and physical fitness test were conducted. During an acute treadmill exercise following Bruce protocol, the blood before and 0, 15, 30 min after exercise were collected for analyses of apelin, lactate, lactate dehydrogenase (LDH), and creatine kinase (CK). Relationships among exercise-induced apelin, metabolic factors, and physical capacity were then analyzed. All measurements were conducted using independent, paired *t*-test between groups/time points, and *Pearson* correlations.
RESULTS: There are significant positive correlations in post-exercise apelin level and skeletal muscle mass (r = 0.350, P = 0.006), homeostatic model assessment of insulin resistance (HOMA-IR; r = 0.366, P = 0.004), HOMA insulin secretion (HOMA-%B; r = 0.360, P = 0.005), and isokinetic flexion and extension tests in 60° and 240°/sec (all variables, P < 0.05), but these parameters were not correlated with pre-exercise apelin levels. In men, the area under the curve of plasma apelin level was significantly higher in obese than lean individuals (P < 0.05), but this difference was not observed in women.
CONCLUSIONS: A single bout of exhaustive exercise induced apelin secretion, which not only correlated with muscle mass, and insulin resistance and secretion,

FRIDAY, JUNE 1, 2018

Abstracts were prepared by the authors and printed as submitted.

but also associated with upper and lower limbs' physical capacity. Our data suggest that apelin may be a therapeutic target to overcome metabolic dysfunction in obese patients.

High Intensity Interval Training is Feasible Outside of a Laboratory Setting in Sedentary, Obese Women

Annie B. De La Rosa, Amy S. Clark, Jamie L. DeRevere, Todd A. Astorino. *California State University, San Marcos, San Marcos, CA.*

(No relevant relationships reported)

High intensity interval training (HIIT) is a suitable alternative to endurance exercise (Burgomaster et al. 2008) as it elicits similar adaptations yet is more time efficient and enjoyable (Kong et al., 2016). Results from Sawyer et al. (2016) and Higgins et al. (2016) reported that HIIT is effective in persons with obesity. However, the majority of existing data supporting efficacy of HIIT were acquired in a laboratory in which trained personnel supervise all sessions. This setting may not translate to HIIT performed in a "real world" environment. **PURPOSE:** The purpose of this study was to determine the feasibility of HIIT outside of a laboratory setting in sedentary, obese women. **METHODS:** 17 sedentary, obese women (age=37.51 ± 10.53 yr.; BMI=39.11+4.34 kg/m²) participated in a 6-week exercise intervention with 3 training sessions per week, 2 in the laboratory (LAB) and 1 at home (HOME). Sessions were held at the same time of day within subjects and were performed a minimum of 24 hr apart. Heart rate (HR) was recorded via telemetry during LAB sessions, which were performed on a cycle ergometer. However, subjects were allowed to select the exercise modality for the HOME sessions, including running, cycling, or elliptical. The instructions for the HOME exercise mimicked the structure of the LAB sessions. Subjects were given downloadable HR monitors (Polar Inc., Lake Success, NY) to record HR during each HOME session. Subjects were asked to complete a HOME session 1 day/week at Rating of Perceived Exertion equal those attained during LAB on the Borg CR-10 scale. There were no consequences if the sessions were not completed. **RESULTS:** The average compliance rate for HOME in all 17 subjects was 73.53 ± 30.65%. Peak HR was higher during HOME for Week 1 (174.09 ± 18.63 vs 163.50 ± 14.98 b/min; p=0.01), Week 2 (175.56 ± 16.76 vs 157.50 ± 18.54 b/min; p=0.007), Week 3 (167.92 ± 20.45 vs 158.83 ± 13.89 b/min; p=0.014), and Week 4 (167.22 ± 21.38 vs 155.11 ± 15.77 b/min; p=0.026) versus LAB. There were no differences in peak HR between HOME and LAB peak HR for Week 5 (158.67 ± 26.08 vs 157.00 ± 16.30 b/min; p =0.99) or Week 6 (154.00 ± 28.82 vs 129.67 ± 31.66 b/min; p=0.31). **CONCLUSION:** In obese women, compliance to home-based HIIT is relatively high, and selected intensities are higher than those attained during lab sessions.

Comparison of Measured and Predicted Resting Energy Expenditure Equations in Obese Pre-bariatric Surgery Patients

Chelsea L. Wenrich[1], Scott T. Jamieson[2], G. Craig Wood[2], Adam M. Cook[2], Christopher D. Still[2], Luke Haile[1], Curt B. Dixon, FACSM[3], Joseph L. Andreacci, FACSM[1]. [1]*Bloomsburg University, Bloomsburg, PA.* [2]*Geisinger, Danville, PA.* [3]*Lock Haven University, Lock Haven, PA.* (Sponsor: Joseph Andreacci, FACSM)

(No relevant relationships reported)

PURPOSE: To compare measured resting energy expenditure (MREE) to predicted resting energy expenditure (PREE) determined by three pre-programmed multi-frequency bioelectrical impedance analysis prediction equations in obese pre-bariatric surgery patients.
METHODS: Ninety women and twenty-six men (age: 42.6 ± 11.0 years, BMI: 48.1 ± 9.1 kg/m²) were included in this sample. After 3 hours of seated rest, MREE was measured prior to bioelectrical impedance analysis (SECA-mBCA 514) body composition assessment. MREE was obtained over a 10-minute period using a hand-held indirect calorimetry device (Korr REE-VUE). Three preprogrammed equations in the bioelectrical impedance analyzer (i.e. Mueller 2004, Liu 1995, and FAO/WHO/UHU) were used to calculate PREE.
RESULTS: The mean MREE determined by indirect calorimetry was 2164.1 ± 460.2 kcal. The PREE values (mean ± SD) for the Mueller, FAO/WHO/UHU, and Liu equations were 2182.5 ± 427.8 kcal, 2129.2 ± 521.2 kcal, and 2352.2 ± 473.4 kcal, respectively. Following statistical comparison, no significant differences were observed between MREE and PREE determined by the Mueller (14.6 ± 313.6 kcal, p = 0.896) and FAO/WHO/UHU (-38.8 ± 371.8 kcal, p = 0.102) equations. However, a significant difference was observed between MREE and PREE by Liu (184.2 ± 333.3 kcal, p = 0.003).

CONCLUSIONS: Our findings indicate that the Mueller and FAO/WHO/UHU programmed bioelectrical impedance analysis equations produce similar resting energy expenditure values as indirect calorimetry. These findings are important to weight management clinics without access to indirect calorimetry that currently use or are considering the use of this bioelectrical impedance analysis technology for their patients. Resting energy expenditure can be predicted in obese patients prior to individualized diet and exercise programming.

Obesity in the Trauma Patient Delays Hospital Discharge and Increases Treatment Cost

Bushra Irshad[1], Lariel J. Mateo[1], Michelle M. Amaral[1], Lewis E. Jacobson[2], Jonathan M. Saxe[2], Courtney D. Jensen[1]. [1]*University of the Pacific, Stockton, CA.* [2]*St. Vincent Hospital, Indianapolis, IN.*

(No relevant relationships reported)

In the United States, more than one third of all adults are obese, classified by a BMI ≥ 30 kg/m². Direct medical costs for these individuals account for approximately 6% of national health expenditure. Several mechanisms have been proposed, but most consistently, obesity has been shown to complicate treatment and inflate resource utilization. Another possible explanation is obesity's role in prolonging recovery. Currently, information regarding the relationship between obesity and the duration of care is limited.
PURPOSE: To examine the effect of obesity on hospital discharge and consequent treatment cost.
METHODS: Our study involved 1,201 patients admitted to a Midwestern hospital who had complete demographic, anthropometric, and treatment data. Independent variables were age, sex, anthropometric indices, and five measurements of injury severity. Dependent variables were hospital length of stay (number of days) and total patient billing (dollars). Independent-samples t tests assessed differences between obese and non-obese patients, a negative binomial regression evaluated hospital length of stay, and a multiple linear regression tested logged cost data.
RESULTS: Across the sample, average age was 55.1 ± 20.3 and 67.5% of patients were male. Average BMI was 28.4 ± 6.6 and 14.4% of patients were obese. Mean injury severity score was 16.3 ± 10.6 and average length of stay was 7.7 ± 9.0 days. Independent-samples t tests found obese patients to have 19.4% longer hospital stays (1.5 days; p=0.061) and 31.4% greater hospital bills (p=0.015) than non-obese patients. With confounding variables held constant, the negative binomial regression found obesity to predict a 17.1% longer hospital stay (1.3 days; p=0.007). While the multiple linear regression showed a non-significant increase for the effect of BMI on logged patient charges (p=0.111), classification of obesity on logged patient charges supported a trend for increase in patient cost (p=0.078).
CONCLUSIONS: Obesity in the hospitalized patient associated with a significantly longer duration of care and a trend for increased total expenditure. Exercise may function as a preventive strategy to avert the temporal and financial ramifications of obesity.

2456   Board #292   June 1 9:30 AM - 11:00 AM

Reducing Attrition and Improving Program Adherence in a Physician-Referred Weight Loss Program for Adults.

Jennifer J. Zwetsloot[1], Rebecca A. Battista, FACSM[1], Kristopher Hartley[2], Chris Demczar[2], Alanna Young[2], Erica Larson[1]. [1]*Appalachian State University, Boone, NC.* [2]*Appalachian Regional Healthcare Systems, Paul H. Broyhill Wellness Center, Boone, NC.* (Sponsor: Rebecca A. Battista, FACSM)

(No relevant relationships reported)

It has been shown that physician-referred hospital-based team-approach programs can be effective interventions for weight loss for adults. Programs that include strategies in behavior change may assist in successfully completing a weight loss program. **PURPOSE:** The purpose of this project was to evaluate the effectiveness of behavioral contracting to improve program adherence and reduce attrition in a physician-referred weight loss program for adults. **METHODS:** Participants included obese (BMI≥30) adults (Age 53.4±1.3yrs) enrolled in a physician-referred program. Participants were enrolled without signing an accountability contract (CONTROL, N=48) or enrolled after signing an accountability contract (CONTRACT, N=48). Starting and final weights were recorded before and after a 16-24 week intervention period that included supervised exercise sessions (EX), and scheduled consultations with a registered dietitian (RD, N=4) and a behavioral health specialist (BHS, N=4). The CONTRACT group signed an accountability statement that listed program goals, standards/expectations, and an acknowledgment of commitment statement. Attendance for EX, RD, and BHS sessions was recorded. Program completion was determined if a final weight was recorded for a participant at the end of the program. Independent sample t-tests (p<0.05) were used to determine differences in participant characteristics. **RESULTS:** There were no significant differences in participant characteristics for

CONTRACT as compared to CONTROL (Age 53.0±13.6 vs. 53.8±12.0; Sex 81.3% vs. 81.3% female; Starting Weight (lbs) 238.1±44.7 vs. 228.1±38.9; % Weight Loss -6.7±3.3% vs. -4.8±4.5%). Program completion was higher for CONTRACT as compared to CONTROL (87.5% vs. 58.3%). The proportion of participants who attended 75-100% of required consultation visits was higher for CONTRACT as compared to CONTROL (RD 85% vs. 29%; BHS 77% vs. 25%). However, EX attendance was slightly lower for CONTRACT as compared to CONTROL (44% vs. 52%). **CONCLUSION:** Behavioral contracting may be an effective tool for increasing specialized consultation adherence and reducing attrition in a physician-referred weight loss program. Additional research is required to determine how to increase exercise session adherence.

F-05   Thematic Poster - **Fitness Assessment**

Friday, June 1, 2018, 1:00 PM - 3:00 PM

Cardiometabolic Risk Factors, Muscular Fitness, and Cardiorespiratory Fitness in Apparently Healthy Young Adult Females

Ryan Tyler, Timothy A. Rengers, Samantha C. Orr, Mary A. Elsesser, Evan Eschker, Tamara Hew-Butler, FACSM, Charles R.C. Marks, Myung D. Choi, Kristin R. Landis-Piwowar, Elise C. Brown. *Oakland University, Rochester, MI.*

(No relevant relationships reported)

Although most of the data linking physical fitness to cardiometabolic (CMB) health explores assessments related to body composition and cardiorespiratory fitness, emerging evidence suggests muscular fitness also plays a key role in the pathogenesis and prevention of CMB diseases. However, the majority of this research has focused on men and have used a handgrip test to assess muscular strength which tests small muscle groups. **PURPOSE:** Therefore, the purpose of this study was to examine the associations between individual CMB risk factors and physical fitness in apparently healthy non-obese young adult females using barbell exercises involving large and small muscle groups to measure muscular strength. **METHODS:** A total of 19 non-obese [body mass index (BMI) < 30 kg/m2] females aged 22.9± 4.8 years participated in this cross-sectional study. After obtaining informed consent, each participant was assessed for: resting heart rate and blood pressure; fasting blood biomarkers [triglycerides, glucose, total cholesterol, high-density lipoprotein cholesterol (HDL-C), and low-density lipoprotein cholesterol (LDL-C)]; muscular strength [1 repetition max (1 RM) back squat, press, and deadlift], muscular endurance, muscular power, and VO$_2$max. A composite muscular strength index was calculated by dividing individual 1 RM scores by bodyweight and then transformed into z-scores. The average of these three z-scores was computed to form a muscular strength index. Spearman's rho (ρ) was used to examine bivariate correlation coefficients between physical fitness and CMB risk variables. Statistical significance was set a priori at P ≤ 0.05. **RESULTS:** Significant correlations were observed between muscular strength and HDL-C (ρ = 0.542, P = 0.02), muscular power and LDL-C (ρ = -0.523, P = 0.02), and VO$_2$max and resting heart rate (ρ = -0.664, P = 0.001). No significant associations were found between muscular endurance and CMB risk variables. **CONCLUSION:** Muscular strength was positively associated with HDL-C, while muscular power and VO$_2$max were negatively associated with LDL-C and resting heart rate, respectively. These findings support the inclusion of muscular strength and muscular power training in addition to cardiovascular fitness training in healthy women in the prevention of CMB disease.

2478   Board #2   June 1 1:00 PM - 3:00 PM

Exercise Thresholds on Trial: Are They Really Equivalent?

Kevin Caen. *Ghent University, Ghent, Belgium.*

(No relevant relationships reported)

Purpose: The interchangeable use of whole-body exercise thresholds and breakpoints (BPs) in local oxygenation responses, as measured via near-infrared spectroscopy (NIRS), has recently been questioned in scientific literature. Therefore, the present study aimed to longitudinally investigate the interrelationship of four commonly used exercise thresholds: critical power (CP), the respiratory compensation point (RCP) and BPs in muscle (m[HHb]$_{BP}$) and brain (c[O$_2$Hb]$_{BP}$) oxygenation.
Methods: Nine male participants (21.8±1.2 years) completed six weeks of cycling interval training. Prior to and following the intervention period, subjects performed a ramp incremental (RI) exercise protocol to determine RCP, m[HHb]$_{BP}$ and c[O$_2$Hb]$_{BP}$ and four constant work rate (WR) tests to calculate CP.
Results: WRs associated with CP, RCP, m[HHB]$_{BP}$ and c[O$_2$Hb]$_{BP}$ increased with 7.7 ± 4.2%, 13.6±9.0%, 9.8±5.7% and 11.3±11.1%, respectively. CP was lower (pre: 260±32W, post: 280±41W) (*P* < 0.05) than the WRs associated with RCP (pre: 281±28W, post: 318±36W) and c[O$_2$Hb]$_{BP}$ (pre: 283±36W, post: 313±32W) which occurred concomitantly (*P* = 0.683). M[HHb]$_{BP}$ occurred at the highest WR and differed from all others (pre: 313±23W, post: 344±32W) (*P* < 0.05). Training-induced WR differences (ΔWR) did not contrast between thresholds and initial parameter differences were not affected by the intervention (*P* = 0.253). Thresholds were partly correlated before (R = 0.67-0.85, *P* < 0.05) and after (R = 0.83-0.96, *P* < 0.05) training, but ΔWR were not interrelated (*P* > 0.05).

Conclusion: Results of the present study strongly question true equivalence and interchangeability of whole-body thresholds and BPs in the local oxygenation response during RI exercise, thereby suggesting that BPs in muscle and brain oxygenation should not be used as a replacement for classical threshold concepts.

2479   Board #3   June 1 1:00 PM - 3:00 PM

Altered Kinematics Over a 2-minute Continuous Push-up Assessment

Jennifer Hewit. *United States Military Academy, West Point, NY.*

(No relevant relationships reported)

Push-ups are a common and fundamental muscular endurance exercise performed by individuals of all ages and abilities. Ensuring that the body maintains proper positioning throughout such an activity is crucial for both optimizing performance as well as minimizing the risk of injury. **PURPOSE:** To investigate the changes in body positioning (i.e. hand positioning and torso angle) throughout a standardized 2-minute continuous push-up test. **METHODS:** Video of the entire 2-minute push-up bout was collected for a total of 26 males (23.3 ± 6.9 years old). Of interest to the researchers was 1) Hand Height (HH) – distance the hand was in relation to the shoulder, 2) Hand Width (HW) – distance between the 3rd metacarpophalangeal joint of each hand, and 3) Torso Angle (TOR) - angle of the torso to the horizontal axis. Three consecutive repetitions at the start and end of the bout were averaged and used for comparative analysis. Paired t-tests were used to compare the means of the beginning and ending repetitions. An alpha level of 0.05 was used throughout. **RESULTS:** Both HH and TOR significantly decreased by the end of the bout (HH: 10.8 ± 5.4cm vs. 6.8 ± 5.6cm, p = 0.00; TOR: 24.7 ± 6.5° vs. 17.8 ± 8.8°, p = 0.00), while HW significantly increased (0.54 ± 0.06cm vs. 0.56 ± 0.05cm, p = 0.01). **CONCLUSION:** As participants became tired, they assumed a body position that likely allowed for a greater percentage of their body weight to be supported by their lower body (i.e. hands wider and closer to the shoulder with greater hip flexion). While this adjustment allowed them to continue the exercise, compensational patterns like this should be identified and addressed in training in order to strengthen the primary muscles targeted by the exercise (e.g. pectorals, triceps brachii and abdominals).

Free Weight Bench Press Muscular Fitness Normative Data for Adults Aged 20-29 Years

Young Sub Kwon[1], Robert A. Robergs[2], Hosung So[3], Christine M. Mermier[4]. [1]*Humboldt State University, Arcata, CA.* [2]*Queensland University of Technology, Brisbane, Australia.* [3]*California State University, San Bernardino, CA.* [4]*University of New Mexico, Albuquerque, NM.* (Sponsor: Ann Gibson, FACSM)

(No relevant relationships reported)

The only available norms for the bench press muscular fitness tests for the general population are the norms developed by the Cooper Institute. These norms were developed using the Universal Gym DVR bench press equipment, which makes these values not directly applicable to free weight bench press. **PURPOSE**: The free weight bench press test is one of the most convenient tests used to evaluate muscular fitness and the effectiveness of resistance training programs for a variety of sports. However, its use and interpretation as an evaluative measurement for health-related physical fitness tests are limited because there are few published reference values derived for the general population. Therefore, the aims of the present study were to generate normative values for free weight bench press 1 repetition maximal (RM) and 4 sets of 65% of 1RM training volume (total repetitions × resistance) for 20- to 29-year-olds for men and women. **METHODS**: We recruited healthy 606 subjects for this study. 351 males (mean±SD, age=23 ± 2 yr, height= 177±7cm, body mass=83±16kg) and 255 females (age=23±3 yr, height=167±6cm, body mass=67±11.3kg) aged 20 to 29 years from different universities comprised the subject pool. Data collected from the bench press test included absolute (1RM) and relative (the ratio of 1RM to body weight) strength, and the total repetitions and absolute and relative total volumes of the 1st set and 4 sets of 65% of 1 RM bench press test with 30 second rest periods between sets. Percentile norms and descriptive statistics were generated. **RESULTS**: Table 1 reports the %tile rank values for the bench press exercise for men and women. **CONCLUSIONS**: Our results provide, for the first time, reference standards for the general population aged 20 to 29 years sex-and age-specific free weight bench press 1RM and training volumes of the 4 sets of 65% of bench press test with 30 second rest periods between sets.

Table 1. %tile rank for bench press muscular fitness for men and women				
	1RM (kg)		Total Training Volume (kg)	
%tile rank	Men	Women	Men	Women
75	119	54	2480	1115
50	98	49	1795	925
25	81	41	1500	684

Lower Limb Peak Power As A Predictor Of Radial Trabecular Bone Strength

Priscilla Franson, Kimberly D. Espartero, Andrew Denys, Maria G. Alvarez, Arianna M. Mazzarini, Rebekkah J. Reichert, Vanessa R. Yingling, FACSM. *California State University, East Bay, Hayward, CA.* (Sponsor: Vanessa R Yingling, FACSM)
(No relevant relationships reported)

A field measure of muscle function that can be used in recreational and educational settings to detect bone strength can be an important component in bone health programs and decrease the incidence of fracture as people age. Recent studies reporting significant correlations between muscle power and bone strength (Janz, 2015, Yingling, 2017) have focused on cortical bone sites, however trabecular bone is a common site of fracture. As well, bone's response to mechanical loading is site specific and thus a loading stimulus to the lower limbs should not have an effect on the bones of the upper limbs. **PURPOSE:** To determine if relative grip strength or lower limb peak power is more predictive of radial trabecular bone strength. **METHODS:** Eighty-six Division II athletes, 56 females and 30 males (age (yrs) 20.2 ± 1.7, height (m) 1.7 ± 0.1, body fat % 17.0 ± 7.4) performed a grip strength (RGS) test using a hand dynamometer and a maximum vertical jump test using a Vertec. Peak Power (PP) was calculated from vertical jump height and combined relative grip strength was calculated. Trabecular Bone Mineral Content (vBMC.tb), Trabecular Bone Mineral Density (vBMD. tb), Total Area (T.Ar.tb), and Bone Strength in compression (BSIc) were measured using peripheral Quantitative Computed Tomography (pQCT) at the 4% radial site. Linear regressions were run to relate muscle function and trabecular bone strength. **RESULTS**: PP and RGS were significantly related to each of the four bone strength variables. Yet, PP explained more of the variability in bone strength than RGS. PP had larger R^2 values for all measurements: vBMC.tb (RGS [R^2=0.1233] PP [R^2=0.5085]), vBMD.tb (RGS [R^2=0.1051] PP [R^2=0.3012]), T.Ar.tb (RGS [R^2=0.1227] PP [R^2=0.4162]), BSIc (RGS [R^2=0.1713] PP [R^2=0.5240]). **CONCLUSION:** PP using vertical jump and RGS using a hand dynamometer can be used to assess trabecular bone mass, geometry and architecture. Interestingly PP, a lower limb measurement explained more variance in bone strength of the distal radius. PP is a measure of power which may be a more predictive measure of trabecular bone strength than a muscle strength measure, even one specifically for the upper limb. Lower limb muscle power calculated by vertical jump assessment could provide a means to monitor trabecular bone strength parameters in the upper limb.

Hemodynamic and Metabolic Responses to Self-Paced and Ramp Graded Exercise Protocols

Nicholas Beltz[1], Fabiano T. Amorim[2], Ann L. Gibson, FACSM[2], Jeffrey M. Janot[1], Len Kravitz[2], Christine M. Mermier[2], Nathan Cole[2], Terence A. Moriarty[2], Tony P. Nunez[3], Sam Trigg[2], Lance C. Dalleck[4]. *[1]University of Wisconsin-Eau Claire, Eau Claire, WI. [2]University of New Mexico, Albuquerque, NM. [3]Metropolitan State University of Denver, Denver, CO. [4]Western State Colorado University, Gunnison, CO.*
(No relevant relationships reported)

PURPOSE: Compare metabolic and hemodynamic responses between self-paced (SP) and ramp (RAMP) graded exercise testing (GXT) protocols. Given that SP is controlled for time while RAMP is not, similarities in physiological responses between protocols may support SP as a viable testing option from a time-management standpoint.
METHODS: Sixteen recreationally trained men (23.7±3.0 yrs) completed two separate treadmill GXT protocols. SP consisted of five 2-min stages (10 min total) of increasing speed clamped by the Borg RPE$_{6-20}$ scale. RAMP increased speed by 0.16 km/hr every 15 s until volitional exhaustion. All testing was performed at 3% incline. Oxygen consumption (VO_2) was measured via indirect calorimetry; hemodynamic function was measured via thoracic impedance, and blood lactate (BLa$^-$) was measured via portable lactate analyzer. Differences between SP and RAMP protocols were analyzed as group means by using paired samples t-tests (R Core Team (2017))**.**
RESULTS: Maximal values for SP and RAMP were similar ($p > 0.05$) for VO_2 (47.1±3.4 vs. 47.4±3.4 mL•kg^{-1}•min^{-1}), heart rate (198±5 vs. 200±6 beats•min^{-1}), ventilation (158.8±20.7 vs. 159.3±19.0 L•min^{-1}), cardiac output (26.9±5.5 vs. 27.9±4.2 L•min^{-1}), stroke volume (145.9±29.2 vs. 149.8±25.3 mL•beat^{-1}), arteriovenous oxygen difference (18.5±3.1 vs. 19.7±3.1 mL•dL^{-1}), and peak BLa$^-$ (11.7±2.3 vs. 11.5±2.4 mM•L^{-1}), respectively.
CONCLUSIONS:SP elicits similar maximal metabolic and hemodynamic responses in comparison to RAMP for our sample. These results support SP as a feasible GXT protocol. Electing to utilize SP may benefit clinicians and researchers from a time-management perspective.

2483   Board #7   June 1 1:00 PM - 3:00 PM

Revisiting The ACSM Metabolic Equation For Walking: Development Of A Cadence (steps/min) Metabolic Equation

Christopher C. Moore[1], Scott W. Ducharme[1], Elroy J. Aguair[1], John Staudenmayer[1], Stuart R. Chipkin[1], John M. Schuna Jr.[2], Tiago V. Barreira[3], Catrine Tudor-Locke, FACSM[1]. *[1]University of Massachusetts Amherst, Amherst, MA. [2]Oregon State University, Corvalis, OR. [3]Syracuse University, Syracuse, NY.* (Sponsor: Catrine Tudor-Locke, FACSM)
(No relevant relationships reported)

The ACSM has long published a metabolic equation using walking speed and grade to predict oxygen consumption. The small homogeneous sample (n=3, trained men) used to derive the speed component of this equation calls into question its generalizability. Further, the equation's free-living application is limited by the difficulty of measuring speed. Conversely, walking cadence (steps/min) is a practical and measurable metric that has been shown to be a reasonable proxy for walking intensity. **PURPOSE:** To develop a metabolic equation using cadence to predict oxygen consumption (VO_2; mL/kg/min) during level walking (and compare its predictive accuracy to that of the ACSM metabolic equation) in a large sample of men and women aged 21-40 years. **METHODS:** Sixty-nine adults (52% women, mean±SD age=30.0±5.6 years, BMI=24.6±3.3 kg/m^2) completed 5-min treadmill bouts separated by 2-min rest at four speeds: 53.6, 67.1, 80.5, and 93.9 m/min (2.0, 2.5, 3.0, 3.5 mph). The cadence-VO_2 relationship was quantified with a quadratic model of best fit, producing the cadence metabolic equation. For an unbiased evaluation of this equation, leave one out cross-validation (LOOCV) was then performed and the root mean square error (RMSE) was calculated. The ACSM metabolic equation for walking was then applied to these data for comparison, and its predictive accuracy was evaluated by determining its RMSE. The bias of both metabolic equations was also calculated. **RESULTS:** The cadence metabolic equation was [VO_2 (mL/kg/min) = $0.0021*C^2 - 0.24*C + 15.4$, where C = cadence]. The RMSE [±95% CI] from the LOOCV of the cadence metabolic equation was 2.5 [±1.0] mL/kg/min and its bias [±95% CI] was 0.6 [±0.3] mL/kg/min. The RMSE from applying the ACSM walking metabolic equation to this data was 3.1 [±1.2] mL/kg/min, with a bias of -2.5 [±0.2] mL/kg/min. **CONCLUSION:** In the same way that speed is used in the ACSM metabolic equation, cadence may also be used in a walking metabolic equation with similar error and reduced bias. The greater sample size and sex distribution used herein to develop this cadence-based metabolic equation suggests greater potential to produce accurate and generalizable estimations. Future research should test this equation during overground walking and incorporate grade as an additional variable.

Validity of My Jump App to Measure Vertical Jump Height of the Elderly

Iransé Oliveira-Silva[1], Rejane M. Cruvinel-Cabral[2], André R. Medeiros[2], Daniel A. Boullosa[2]. *[1]UniEVANGÉLICA, Anápolis, Brazil. [2]UCB, Brasília, Brazil.* (Sponsor: Carl Foster, FACSM)
(No relevant relationships reported)

Vertical jump has been widely used as a method to evaluate the neuromuscular performance of the lower limbs in several populations. Vertical jump is highly recommended for this purpose because its simplicity and rapid application in different settings. More specifically, vertical jump is a predictor of functional capacity, fall risk, and loss of anaerobic capacity in the elderly. Recently, the iPhone App "My Jump" has emerged as an interesting alternative to measure vertical jump height. This App has showed a similar precision as the contact mat, which is considered a reference method for jumping height evaluation. However, My Jump App has been validated only with a sample of young individuals therefore its validity for evaluation of the elderly is unknown. PURPOSE: To verify the validity of the iPhone App "My Jump" for evaluation of countermovement jump (CMJ) height of the elderly. METHODS: Forty-one elderly (29 women), 71±7 years old, 66.5±12.4 kg of body mass, volunteered to participate in this study. After evaluation of body mass, all participants performed 3 CMJs between 8:00 and 10:00 h. Every participant performed the jumps on a contact mat connected to a computer with a specific software (Chronojump, v. 1.6.2, Boscosystem, Spain). At the same time, the jump was recorded with a mobile (iPhone 7, Apple, USA) at a sampling rate of 240 Hz, using the My Jump App. The best jump was used for further analyses. The intraclass correlation coefficient (ICC), and the coefficient of variation (CV%) were used to verify the relative and absolute reliability. Pearson's correlation coefficient was used to verify the strength of the relationship between both evaluations. RESULTS: CMJ height was 10.78±5.23 cm when recorded with contact mat, and 10.87±5.32 when recorded with My jump App. The ICC was 0.997, and the CV% was 1.77. There was a nearly perfect correlation between methods (r=0.999; p=0.000). CONCLUSION: Our results suggest that My Jump App is a valid method to evaluate vertical jump performance in the elderly when using a contact mat as the reference method.

The Effects Of Intensive Weight Loss On Metabolome In Female Fitness Competitors

Heikki Sarin[1], Anni Joensuu[1], Matti Jauhiainen[1], Katja Borodulin[1], Satu Männistö[1], Joseph Lee[2], VIlle Isola[3], Juha Ahtiainen[3], Keijo Häkkinen[3], Kati Kristiansson[1], Juha Hulmi[3], Markus Perola[1]. [1]*National Institute for Health and Welfare, Helsinki, Finland.* [2]*University of Columbia, New York City, NY.* [3]*University of Jyväskylä, Jyväskylä, Finland.*
(No relevant relationships reported)

Intensive weight reduction has become popular in many performance and aesthetic sports. However, health effects of prolonged semi-starvation are scarcely studied in a longitudinal, systems biology setting.
PURPOSE: The aim of our study was to examine how intensive weight loss with large amount of exercise affects system biological pathways and health related biomarkers in female fitness/physique athletes aiming for low body fat while maintaining their lean mass.
METHODS: The study population consisted of healthy fitness/physique athletes divided in Diet (n=25) and Control (n=17) group. The study included three time point measurements: before the weight loss period (PRE), after the 19.8±3.6 weeks of weight loss period (MID) and after the 17.5±2.6 weeks of recovery period (POST). Control-group was instructed to maintain their usual fitness lifestyle, exercise levels and energy intake constant during the study. NMR-platform was used for the determination of metabolome. Data analysis was performed using R and significance threshold was set to 2.1×10^{-3}.
RESULTS: Intensive weight loss in the Diet-group was composed of mainly large (~51 %) decreases in total body fat mass (p <0.001) waist circumference (~8 %) and the android region (~70 %) reflecting visceral fat mass (p < 0.001). This was accomplished by decreased energy intake (~18 %) and increased total amount (METh) of exercise (~15 %). Weight loss affected significantly on several inflammation related biomarkers such as α_1–acid glycoprotein (p=2.47×10^{-9}) and various HDL-metabolites (p=8.22×10^{-12}). The reduction of visceral fat mass was significantly associated with the observed changes in lipid and inflammation biomarker concentration after adjusting for confounding factors. All detected changes in metabolome were reversed back to baseline levels during the recovery period. No changes were observed in the controls.
CONCLUSIONS: Intensive weight reduction has positive, but temporary effects on serum metabolome in fitness/physique athletes. Decrease in visceral fat mass seem to explain majority of these effects of weight reduction on lipid profile and inflammation related biomarkers.
Supported by Academy of Finland (grant No. 275922 to JH and No. 269517 to MP), Finnish Fitness Sports Association and Department of Biology of Physical Activity.

Evaluation of Dietary Intake &lt Training Volume During Army Initial Entry Training

Jeremy McAdam, Kaitlin McGinnis, JoEllen Sefton. *Auburn University, Auburn, AL.*
(No relevant relationships reported)

PURPOSE: : Evaluate training volume and dietary intake, and estimate energy balance in Army Initial Entry Training (IET) soldiers.
METHODS: Dietary intake was assessed by collecting diet logs for 3 meals on each of 3, non-consecutive days during the first week of IET. Training volume was measured across 12 weeks using Actigraph wGT3X accelerometers. A total of 96 (Age = 18.7 yrs. Sd. ± 1.9, Wt. = 71.6 sd. ± 12.4 kg) male trainees were monitored and completed diet logs; monitoring occurred at all time, with 12 soldiers assessed each week. Energy expenditure estimates were calculated using metabolic equivalents and actigraph reported intensities and duration.
RESULTS: On average IET soldiers daily accumulated 183 (sd. ± 16) min low, 89 (sd. ± 16) min moderate, 17 (sd. ± 6) min vigorous, and 4 (sd. ± 1) min of very vigorous intensity physical activity across 12 weeks. Estimated overall energy expenditure was 3,154 (± 187) calories per week with a negative net energy balance of -482 (± 187) calories. Regression analysis revealed body weight was a significant predictor (adj. R^2 = 0.5512, p < 0.001) for negative energy balance. For every 1-kilogram increase in body mass, energy balance became more negative by 52.4 calories.

CONCLUSIONS: IET is a physically demanding environment with large volumes of training and high energy expenditures. IET soldiers are likely exposed to chronic net negative energy balance, those weighing more are at an elevated risk. Nutritional strategies including supplementation may be needed to meet the calorie demands of training.

Leptin and Ghrelin Predict Resting Metabolic Rate and Energy Expenditure in Female Collegiate Runners

Mindy Patterson, Dina Acosta, Jenna Lin, Rita DelloStritto, Alexis Ortiz, FACSM. *Texas Woman's University, Houston, TX.* (Sponsor: Alexis Ortiz, FACSM)
(No relevant relationships reported)

Leptin and ghrelin are counterregulatory hormones that maintain energy balance through food intake and energy expenditure through hypothalamic signaling. Leptin circulates in the blood proportional to fat mass (FM) and decreases food intake and promotes energy expenditure through hypothalamic signaling. Ghrelin is released from the stomach to stimulate food intake also via hypothalamic actions.
PURPOSE: To examine the relationship of leptin and ghrelin with resting metabolic rate (RMR) and total energy expenditure (TEE) in female collegiate runners and inactive females.
METHODS: Outcomes were compared between female collegiate runners (n=12; age 22.2±3.3 years) logging a minimum of 30 miles per week and inactive females (n=14; age 25.3±1.9 years) using a cross-sectional study design. RMR and TEE were measured by air displacement plethysmography (BOD POD®). Fasting leptin and fasting ghrelin were quantified using enzyme-linked immunosorbent assay. Fat mass (FM) and lean mass (LM) were determined by dual-energy X-ray absorptiometry. Stepwise regression predicted the association of fasting concentrations of leptin and ghrelin on RMR and TEE in each group.
RESULTS: BMI (runners: 19.8±1.4 kg/m²; inactive: 22.6±2.8 kg/m²; p = .004), FM (runners: 10.76 kg; inactive: 18.32 kg, p ≤ .001) and TEE (runners: 2,420 kcal/d; inactive: 1,469 kcal/d; p ≤ .001) differed between groups, but not LM and RMR. In runners only, higher leptin predicted higher RMR (*Beta* = .338; p = .004), but to a lesser extent than LM (*Beta* = .685; p ≤ .001). Together leptin and LM strongly, positively contributed to the variance of RMR (adj. R^2 = .99). Leptin (*Beta* = .337; p = .004) and LM (*Beta* = .686; p ≤ .001) predicted TEE in the same manner as RMR in runners only. Ghrelin negatively predicted RMR and TEE (*Beta* = -.72; p = .019) similarly. In inactive females, neither leptin nor ghrelin predicted RMR or TEE.
CONCLUSION: LM was the strongest predictor of RMR and TEE in collegiate female runners. Higher leptin and lower ghrelin also predicted higher RMR and TEE indicating both biomarkers impact hypothalamic signaling to influence energy expenditure to maintain energy homeostasis in endurance trained females.

Energy Balance, Body Composition, and Bone Health in Female Lacrosse Players

Hannah Zabriskie, Brad Currier, Patrick Harty, Richard Stecker, Andrew Jagim, Chad Kerksick, FACSM. *Lindenwood University, St. Charles, MO.*
(No relevant relationships reported)

In female athletes, prolonged energy deficits increase the risk of a syndrome known as the female athlete triad; characterized by dysmenorrhea, disordered eating, and reduced bone mineral density (BMD). This syndrome is more common in endurance or aesthetic sports, and has yet to be explored in some team sports. **PURPOSE:** The purpose of this study was to evaluate the relationship between energy status, body composition, and bone health in Division II female lacrosse players. **METHODS:** Twenty-two female lacrosse players (20.4 ± 1.8 years, 69.1 ± 8.7 kg, 168 ± 6.3 cm, 28.1 ± 2.99% fat, 1.03 ± 0.06 g/cm² BMD) wore a physical activity monitor and recorded diet over a four-day period approximately four months prior to starting NCAA season play. The physical activity monitor measured total daily energy expenditure, activity energy expenditure, and physical activity level (PAL). Each player completed a DEXA scan and a resting metabolic rate (RMR) test. Correlations and linear regression with backward selection were utilized for analysis. **RESULTS:** Players presented with an average RMR of 1542.20 kcal/day (SD = 145.97), a PAL of 2.24 (SD =0.42), and an energy deficit of 1,186.85 kcal (SD = 813.09). Those with greater fat free mass (FFM) (r = 0.602, p=0.003) and greater fat mass (FM) (r = 0.656, p = 0.0009) had a higher RMR. Total body mass was found to have stronger influence on RMR than FFM or FM (p = 0.007). Players with greater energy deficit had more absolute (r = -0.447, p = 0.037) and relative (r = -0.445, p = 0.038) FM. Bone mineral content tended to worsen with increased energy deficit (p=0.0693) though energy balance had no relationship with BMD (p= 0.8742). **CONCLUSIONS:** Our results imply that total body size is the strongest predictor of RMR. Furthermore, players with greater absolute and relative FM tended to display greater energy deficits, possibly reflecting attempts to lose weight by cutting calories and increasing activity, thereby inducing an energy deficit. This behavior may be a symptom of disordered

eating, a component of the female athlete triad. Overall, female lacrosse players had a significant energy deficit of enough magnitude to suggest that performance may be impaired. Though bone health was not negatively affected in this study, prolonged energy deficit in a similar population could lead to reduced bone mineral density.

Higher Activity Energy Expenditure And Lower Resting Energy Expenditure Among Healthy Female Athletes

Kazuko Ishikawa-Takata[1], Motoko Taguchi[2], Suguru Torii[2]. [1]*National Institutes of Biomedical Innovation, Health and Nutrition, Tokyo, Japan.* [2]*Waseda University, Saitama, Japan.*
(No relevant relationships reported)

Among non-athletes, total energy expenditure (TEE) and physical activity energy expenditure (PAEE) increases over the low and middle range of physical activity, but resting energy expenditure (REE) does not (Pontzer, 2016). However, compensatory metabolic adaptation is found among highly trained athletes (Silva, 2017).**PURPOSE**: To clarify the relationship between TEE and its components over a wide range of physical activity levels (PAL) among healthy female athletes.**METHODS**:Eighty-five healthy female college athletes (short, middle and long distance runners, jumpers, throwers, walkers, swimmers, rhythmic sportive gymnasts, judo players, and lacrosse players) were evaluated during the training season. TEE and REE were assessed by the doubly labelled water method and respirometry, respectively. Total energy intake (TEI) was assessed using 7-day dietary record. PAEE was determined as TEE-0.1(TEE)-REE, and PAL was determines as TEE/REE. Among them, 41 athletes were measured for training induced energy expenditure (TIEE) using heart-rate monitoring. Adjusted TEE, REE, TIEE, and TEI were calculated using the residuals of regression analysis to eliminate the effects of fat free mass, fat mass, age and height. Estimated REE (eREE) was calculated using an equation used in Taguchi's study (2011). **RESULTS**: Adjusted TEE, PAEE and TIEE were significantly positively correlated with PAL (r=0.636, 0.848, and 0.425, p<0.001, p<0.001, and p=0.001). Adjusted REE and the difference between REE and eREE were significantly negatively correlated with PAL (r=-0.531 and -0.468, p<0.001 for both). However, adjusted TEI did not correlate significantly with PAL (r=0.198, p=0.069). **CONCLUSIONS**: Both higher energy expenditure related to physical activity and/or training and lower REE lead to higher PAL among female athletes. Lowered REE may be caused by insufficient energy intake in relation to high energy expenditure.

Examination of Male Athlete Triad Symptoms in Endurance Trained Athletes

Erin M. Moore[1], Toni M. Torres-McGehee[1], Clemens Drenowatz[2], Dave F. Stoddan[1], Justin M. Goins[1], Thaddeus C. Broderick[1], Brittany T. Williams[1]. [1]*University of South Carolina, Columbia, SC.* [2]*Pädagogische Hochschule Oberösterreich, Linz, Austria.*
(No relevant relationships reported)

Male Athlete Triad (MT), composed of 1) low energy availability (LEA), 2) low bone mineral density (BMD) and 3) decreased reproductive hormones is novel and not established. The impact of LEA in males needs further examination. **PURPOSE:** Examine 2 components of MT: 1) energy availability (EA) and 2) BMD in endurance-trained male athletes. Secondarily examine: energy intake (EI), exercise energy expenditure (EEE), and macronutrients (carbohydrates [CHO], protein [PRO], and fats). **METHODS:** A cross-sectional design of 14 endurance-trained male athletes (age: 25.9 ± 4.2 years; weight: 71.1 ± 5.6kg; height: 179.3 ± 4.6cm; VO_{2max} of 63 ± 6.7ml·kg^{-1}·min) was used. Inclusion criterion included participants training for competition, have $\leq$12% body fat and a VO_2max $\geq$41ml·kg^{-1}·min. Data was collected across 2 training weeks (high volume [HV] and low volume [LV]) and included: dietary logs, exercise logs, and BMD via Dual-Energy X-Ray Absorptiometry. Sense-Wear Armbands calculated EEE and EA was calculated as EA= ([EI-EEE]/FFM). Macronutrients were assessed using ACSM recommendations. LEA was defined as $\leq$ 20kcal^{-1}kg^{-1}FFM. **RESULTS:** Overall, EI = 2929.4 $\pm$ 244.4 kcals; EEE = 1263.4 $\pm$ 107.3 kcals; and EA =25.6 $\pm$ 3.2 kcal^{-1}kg^{-1}FFM. A 2 (week) X 7 (days) ANOVA revealed a main effect between the weeks for EA F(1,13)=62.81 (p<0.01, ηp^2=0.83), EI F(1,13) 143.6 (p<0.01, ηp^2=0.92) and EEE F(1,10) 138.5 (p<0.001, ηp^2=0.93). A significant interaction was found between days and EA (p<0.01; ηp^2= 0.35), and EEE (p<0.01; ηp^2= 0.50), as well as the 2 weeks and EEE (p=0.002, ηp^2=0.41). The average Z-score showed no decrease in BMD (2.3 $\pm$ 3.5). Overall, during both HV and LV weeks, participants did not meet the ACSM recommendations for macronutrients. Intakes of CHO were under-consumed (HV: 71.4%; LV: 85.7%), PRO and fats were over-consumed (PRO-HV: 35.7%; LV: 42.9% and fats-HV&LV: 42.9%). **CONCLUSION:** Overall, males presented with an average EA = 25 kcal^{-1}kg^{-1}FFM and normal BMD. There is evidence (EEE and EI) similar to female research specifically, decreased intake of CHO and overconsumption of PRO and fats. Currently, there is

---

limited knowledge on the physiological outcomes of males participating in high EEE activities with decreased EI intake and the corresponding physiological outcomes. Cut points for LEA need to be established in the future.

2492   Board #7   June 1 1:00 PM - 3:00 PM

Is Disordered Eating Related To Muscle-enhancing Supplement Use And Exercise Context in Adolescents?

Kethe M. E. Engen[1], Christine Sundgot-Borgen[1], Monica K. Torstveit[2], Jan H. Rosenvinge[3], Oddgeir Friborg[3], Gunn Pettersen[3], Solfrid Bratland-Sanda[4], Elin Kolle[1], Jorunn Sundgot-Borgen, FACSM[1]. [1]*Norwegian School of Sport Sciences, Oslo, Norway.* [2]*University of Agder, Kristiansand, Norway.* [3]*University of Tromsø, Tromsø, Norway.* [4]*Telemark University College, Bø, Norway.* (Sponsor: Jorunn Sundgot-Borgen, FACSM)
(No relevant relationships reported)

Participation in organized sport at a lower competitive level may protect against disordered eating (DE), whereas exercising in a gym context may increase DE risk. Use of supplements advertised as muscle enhancing is common in both contexts due to the expectancy of performance or appearance enhancement. However, how supplement use (SU) relates to DE dependent on these two exercise contexts in adolescents is not known. **Purpose:** To study how participation in sport or/and a gym context and SU relates to DE in adolescents. **Method:** Participants were 599 boys and 1038 girls enrolled in a RCT to promote a positive body image and prevent DE in high schools. The "Eating Disorder Examination Questionnaire" (EDEQ) short form measured DE. Participants provided information about exercise context (1 = gym + sport, 2 = gym only, 3 = neither sport or gym, 4 = sport only) and SU (1 = protein and creatine (PSU+CSU), 2 = protein only (PSU), and 3 = no SU). ANCOVA was used to examine main and interaction effects of SU and sport context. Effects were considered significant when F test was $p = <.05$. The analyses were stratified for gender. **Results:** Among boys, PSU+CSU was associated with higher EDEQ-score ($b = 1.31$, $p < .01$). In addition, reporting either sport, gym, or gym + sport context was associated with lower EDEQ-score ($b = -1.16$, $p = .01$) in boys. In girls, higher EDEQ-score was associated with reporting gym or gym + sport context ($b = .77$, $p < .01$ and $b = .68$, $p = < .01$), while higher score was associated with sport context ($b = -.33$, $p = .02$). Effects were found for the covariates body mass index (boys, $b = 1.05$, $p < .01$, girls, $b = .18$ $p = .01$) and studying sport program (boys, b -1.21 $p < .01$). No effects were found for other covariates (income, physical activity level and immigration status). **Conclusion:** Boys who reported using protein and creatine supplements and girls who exercised in gyms had higher DE. Interestingly, lower DE in boys was related to both sport and/or gym exercise participation compared to boys not reporting participation in either of the two contexts. Attention and preventive actions should be aimed towards girls engaging in gym exercise, and towards boys who consume protein and creatine supplements, and who do not participate in any of the two exercise contexts. Future studies should however examine how other exercise contexts relates to SU and DE.

2493   Board #8   June 1 1:00 PM - 3:00 PM

Examination of Female Athlete Triad Components in Collegiate Equestrian Athletes

Toni M. Torres-McGehee[1], Kyra Dodson[1], Dawn M. Emerson[2], Kelly Pritchett[3], Erin M. Moore[1], Monica Kimmel[1]. [1]*University of South Carolina, Columbia, SC.* [2]*University of Kansas, Lawrence, KS.* [3]*Central Washington University, Ellensburg, WA.*
(No relevant relationships reported)

Due to the aesthetic demands, Equestrian athletes are at high risks for eating disorders (ED) and in turn may be more susceptible to Female Athlete Triad (Triad) characteristics: low energy availability (LEA) with or without an eating disorder (ED), menstrual cycle dysfunction, and low bone mineral density (BMD). **PURPOSE:** To examine Female Athlete Triad component risks in NCAA Division I female equestrian athletes. A secondary purpose examined: resting metabolic rate (RMR) energy intake (EI), exercise energy expenditure (EEE), energy availability (EA) and macronutrient profile of carbohydrates (CHO), proteins (PRO), and fats. **METHODS:** Female NCAA Division I Equestrian athletes (n = 28, age 19.4 ± 1.3 yrs, height 166.2 ± 5.1 cm, weight 61.7 ± 7.1 kg) participated in the study. Participants completed a demographic survey, menstrual cycle questionnaire, Eating Disorder Inventory-3, ED symptoms checklist, a 7 day online dietary and exercise log. Participants were measured for height, weight, DXA scan (BMD), and RMR through indirect calorimetry (MedGem). Exercise energy expenditure was calculated using Ainsworth equation and EA was calculated by EA = ((EI-EEE)/free fat mass). Macronutrients (CHO, PRO, and fats) were assessed using ACSM recommendations. **RESULTS:** Overall, Triad component risk showed 78.6% (n = 22) equestrian athletes had 1 component and 7.1% (n = 2) had 2 components. Overall risk for LEA was 82.1% (n = 23); 64.3% (n = 18) of those with LEA also presented with ED risk, while 17.8% (n = 5) reported LEA without ED risk. Energy assessment included: RMR = 1441.0 ± 227.9 kcal/day; EI = 1401.6 ± 421.8 kcal/day; EEE = 403.2 ± 161.9 kcal/day, and EA = 21.9 ± 9.9 kcals/kg^{-1}FFM/

---

day. Regarding macronutrient profile, 96.2% (n = 26) athletes reported under the recommendations for CHO intake, 74.1% (n = 20) were under the recommended PRO intake, and 81.2% (n = 22) were within the recommendations for fat intake while 18.8% were over the fat recommendations. **CONCLUSION:** Majority of Equestrian athletes were at risk for at least 1 Triad component and LEA with ED risk was prevalent; thus raising concern for the at large population of Equestrian athletes. Recognition and intervention of Triad components can prevent long lasting health issues and protect the longevity of equestrian athlete's careers and level of performance.

F-07   Thematic Poster - **Physical Activity and Healthy Aging**

Gender-Specific Effects in Cognition and Mobility Following Exercise in Older Adults at Risk for Dementia

Narlon C. Boa Sorte Silva, Dawn P. Gill, Ashleigh De Cruz, Robert J. Petrella, FACSM. *Western University, London, ON, Canada.* (Sponsor: Robert J Petrella, FACSM)

(No relevant relationships reported)

Purpose: To investigate gender-specific adaptations following a 24-week multiple-modality exercise intervention with additional mind-motor training on cognition and mobility.
Methods: Older adults (n = 127, age = 67.5 [7.3] yr, 71% women) were randomized to a 45-min multiple-modality exercise intervention with additional 15 minutes of either mind-motor training (M4 group) or an active control intervention (15 minutes of balance, range of motion and breathing exercises, [M2 group]). Assessment occurred at baseline, 24 weeks (intervention endpoint), and 52 weeks (after a 28-week no-contact follow-up). The study outcomes were: cognition (global cognitive functioning [GCF], concentration, reasoning, planning, and memory), and mobility (usual and dual-task gait velocity, step length and variability). Mixed between-within subjects ANOVA was used to examine: i) main effects of time (baseline vs 24 weeks), intervention group (M4 vs M2) and gender (men vs women); ii) interactions of time x intervention group, and time x gender.
Results: At 24 weeks, trends for greater improvements in GCF and memory favouring M4 (both *p<.08*) were observed, with no interaction effects for gender. For usual gait, M2 showed greater velocity (*p=.001*) and step length (*p=.003*), compared to M4. For dual-task gait, M2 showed greater improvements in velocity (*p=.04*), and trends for significant improvements in variability (*p=.05*). Gender-specific effects were observed for dual-task step length favouring women (*p=.02*).
Results at 52 weeks: M4 showed greater improvements in GCF (*p=.02*) and memory (*p=.03*), compared to M2. As well, trends for gender-specific effects were observed in memory favouring women (*p=.06*). For usual gait, M2 retained improvements in velocity (*p=.05*), compared to M4. For dual-task gait, gender-specific effects were observed in dual-task step length favouring women (*p=.03*).
Conclusion: Additional mind-motor training compared to an active control intervention showed trends for greater benefits to cognition; however, it did not affect gait performance. Overall, gender-specific effects were seen for memory and dual-task step length across groups, suggesting that women benefited more from exercise compared to men, and were able to retain these improvements after a no-contact follow-up. Funding: CIHR MOP 130474

Effects of Tai Chi on Beta Endorphin and Inflammatory Markers In Older Adults with Chronic Pain

Tongjian You, FACSM, Elisa F. Ogawa, Yurun Cai, Ling Shi, Suzanne G. Leveille. *University of Massachusetts Boston, Boston, MA.*

(No relevant relationships reported)

Musculoskeletal pain is associated with dysfunction of the opioid analgesic system and elevated inflammation in older adults. **PURPOSE:** To examine the effects of Tai Chi on blood levels of beta endorphin and inflammatory markers in older adults with chronic pain. **METHODS:** Forty community-dwelling older adults (≥65 years) with multisite pain were randomly assigned to light physical exercise or Tai Chi, each offered twice weekly for 12 weeks. Plasma levels of beta endorphin, C-reactive protein (CRP), interleukin 6 (IL-6), and tumor necrosis factor alpha (TNF-α) were assessed at baseline and within 2 weeks after completing the intervention. Paired t-tests were used to assess changes of log-transformed beta endorphin and inflammatory markers within each group, and pairwise t-tests were used to assess differences between groups. **RESULTS:** Twenty-one participants in the light physical exercise group and nineteen participants in the Tai Chi group provided blood samples. Following the 12-week intervention, neither light physical exercise nor Tai Chi changed levels of beta endorphin and inflammatory markers. However, in older adults who completed 70% or more classes, Tai Chi significantly lowered levels of beta endorphin (p<0.05) from baseline to post-intervention, whereas light physical exercise did not change levels of beta endorphin. **CONCLUSION:** Tai Chi tended to reduce levels of beta endorphin but did not affect levels of inflammatory markers in older adults with chronic pain. Future studies need to focus on the role of the opioid analgesic system and immune system in regulating pain with aging and the long-term effects of Tai Chi on pain-related biomarkers. (Supported by National Institutes of Health R21 AG043883)

A Comparison Of Two Community Based Exercise Interventions For Reducing Falls Risk In Older Adults

Jessica Pope[1], Steven Morrison[2], Amanda Estep[1], Shane Caswell[1], Jatin Ambegaonkar[1], Kathryn Helwig[1], Nelson Cortes[1]. [1]*George Mason University, Manassas, VA.* [2]*Old Dominion University, Norfolk, VA.*

(No relevant relationships reported)

Falls are a major health problem for older adults with a reported 1/3 people over the age of 65 likely to suffer a fall in a given year. Exercise interventions have improved muscle strength and reaction time in older adults. Many interventions have occurred in a controlled setting. Further research is needed to evaluate the impact of fall prevention programs conducted in community settings to improve falls risk factors.
PURPOSE: To compare the effects of two interventions (INT); The Lebed Method (TLM) and Staying Active and Independent for Life (SAIL) on right and left leg strength (RLS & LLS), foot and hand reaction time (FRT & HRT), and timed up and go (TUG) in older adults in community venues.
METHODS: 74 and 103 older adults participated in TLM and SAIL (73±8 years, 1.6±.1 m, 82.1±21.7 kg; 71±7 years, 1.6±.1 m, 80±19 kg, respectively). TLM, a dance therapy program, was implemented for 8 weeks, 1h, 2x/week. SAIL included aerobics, balance, strength, and stretching exercises and lasted 10 weeks, 1h, 3x/week. RLS & LLS (kg), FRT & HRT (ms), and TUG (s) were assessed pre & post INT (time). A 2-way factorial MANOVA was conducted to assess differences between time and INT.
RESULTS: A significant interaction was observed for LLS (p<0.05). LLS improved from pre to post for TLM (pre=14.3±7, post=20.2±8.1) and SAIL (pre=20.9±6.2, post=18.2±6.5). Only main effects were attained for remaining variables (p<0.05). All participants were faster (TUG, pre=9.1±4, post=8.2±3.1), improved FRT (pre=336±91, post=327±101) & HRT (pre=282±87, post=277±86). Faster HRT and FRT were seen for SAIL (319±96, 269±87) compared to TLM (356±90, 298±83). RLS & LLS increased from pre (16.4±7, 16.8±6.9) to post (20.7±7.5, 20.6±6.9). Leg strength was greater in SAIL (RLS=19.3±7, LLS=19.4±6.4) than TLM (RLS=16.6±8.2, LLS=16.9±8).
CONCLUSION: While both interventions were effective at improving leg strength and reaction time, SAIL had the greatest improvements. SAIL includes exercise and music like TLM but was developed for general population, yielding an attractive program while addressing specific modifiable risk factors. Future studies should investigate long-term retention of benefits following intervention, tracking changes in balance, activity level, and number of falls. Supported by grant from Potomac Health Foundation.

Square-stepping Exercise For Older Adults With Chronic Disease To Improve Cognition and Mobility

Erin M. Shellington, Dawn P. Gill, Sonja M. Reichert, Matthew Heath, Robert J. Petrella, FACSM. *University of Western Ontario, London, ON, Canada.*

(No relevant relationships reported)

Square-stepping exercise (SSE) is a visuospatial working memory task with a cued stepping response that improves mobility and cognition in older adults.
Purpose: To determine if a SSE intervention improves cognitive and mobility in older adults with chronic disease (i.e., knee osteoarthritis [KOA]; type 2 diabetes mellitus [T2DM] with self-reported cognitive complaints [sCC]; and dementia), compared to control groups.
Methods: We conducted three pilot randomized controlled trials, with 12- and 24-week intervention periods, compared to wait-list control groups. Assessments focused on: mobility (i.e., 30-second chair stand, and walking speed) for adults with KOA;

cognition [i.e., Cambridge Brain Sciences, antisaccade reaction time (RT)] for adults with T2DM with sCC; and mood and behaviours questionnaire (i.e., Neuropsychiatric Inventory Questionnaire; NPIQ) for adults with dementia.
Results: KOA participants showed trends toward improved 30-second chair stand at 12-weeks (F=1.8, p=0.12, η_p^2=0.16) and 24-weeks (F=3.4, p=0.09, η_p^2=0.18), and walking speed at 24-weeks (F=2.4, p=0.14, η_p^2=0.14), compared to controls after adjusting for baseline. T2DM with sCC improved on planning change scores from 12 to 24-weeks (F=5.8, p=0.03, η_p^2=0.28) compared to controls, and a non-significant improvement in antisaccade RT of 38 ms (SD 16). Adults with dementia improved on NPIQ scores (i.e. symptoms) at 12-weeks (total: F=7.3, p=0.01, η_p^2=0.25; frequency: F=9.4, p=0.01, η_p^2=0.30; and severity: F=7.0, p=0.02, η_p^2=0.24), compared to controls. Conclusions: In our pilot trials, SSE showed promise for improving mobility and cognition in adults with chronic disease and demonstrates the potential for its use in adults with diverse mobility and cognitive impairments.
Funding: Supported by the Department of Family Medicine, University of Western Ontario, Mitacs Accelerate, Ontario Graduate Scholarship, and Schlegel - University of Waterloo Research Institute for Aging.

Physical Activity, Physical Fitness Related To Quality Of Life For Older Adults In Beijing China

CAILIANG ZHOU, Hong REN. *BEIJING SPORT UNIVERSITY, BEIJING, China.*
(No relevant relationships reported)

Physical activity, physical fitness related to quality of life for older adults in Beijing China
Cailiang ZHOU, Hong REN
College of Sport Sciences, Beijing Sport University
Purpose: To explore the relationships between physical activity, physical fitness and quality of life for the elderly population. **Methods:** We included in our study 105 older adults (≥60 years old) from three community in Beijing, China. Data of physical activity was collected by physical activity survey for the elderly (PASE). Items of physical fitness included grip strength, flexibility and balance, assessing according to the measurement manual of National Physical Fitness Surveillance in China. T score (ranging from 0-100) was calculated for each physical fitness item and added up to a total score. Quality of life was measured by the Medical Outcome Study 36-item short form health survey (SF-36). Subscales of SF-36 were summarized into two subdomains of physical component summary regarding physical health, and mental component summary for mental health. Multivariable linear regression was used to explore the relationship between physical activity, physical fitness and quality of life. **Results:** Among the study population physical activity and total score of all 3 items of physical fitness were the most important impact factors for physical component summary (standardized regression coefficients were 0.39 and 0.33, respectively). As regarded to mental component summary, total score of all 3 items of physical fitness, but not physical activity, was the major influencing factor (standardized regression coefficient was 0.24). No interactions were found between physical activity and physical fitness in relation to two subdomains of quality of life (P>0.05). **Conclusion:** Both physical activity and physical fitness had independent effects on quality of life for older adults in Beijing,China. Physical activity was the most important factor that associated with physical health, but not with mental health. The summary condition of grip strength, flexibility and balance was positively correlated with both physical and mental health.
Keywords: Physical activities, Physical fitness, Quality of life

Physical Fitness Performance and Normative Score of Elderly Male Rural Dwellers

PEI-SUNG CHIN[1], Meng-Tzu Hou[2], Chih-Hsing Wu[3]. *[1]University of Taipei, Taipei, Taiwan. [2]National Yang-Ming University, Taipei, Taiwan. [3]Department of Family Medicine, National Cheng Kung University Hospital, Taipei, Taiwan.*
(No relevant relationships reported)

PURPOSE: In Taiwan, there is no national consensus on the normative score for assessing physical fitness performance in elderly people living in rural communities. The study thus endeavored to set up the normative score and to understand the current status of physical fitness of elderly male rural dwellers in Taiwan.
METHODS: The study first surveyed the 1,033 men aged 65 and over in Tianliao township of Kaohsiung County. After an entire township sampling, 414 subjects were selected to receive examination, resulting in a response rate of 60.8%. Twelve of the 414 subjects were excluded due to use of assistive devices or severe joint disease, leaving a total of 402 subjects enrolled for formal analysis.Each subject had completed questionnaires and received physical fitness assessment. All of the subjects were divided into five 5-year age subgroups. The normative physical fitness scores were listed by nine-rank percentile distribution(in the order of 5%, 10%, 25%, 30%, 50%, 70%, 75%, 90%, 95% respectively).

RESULTS: The average age of the 402 subjects read 74.5±6.0 years old. The 50 percentile of each physical fitness assessment were listed such as body mass index 24.1 kg/m2, percent body fat 20.6%, grasp test of dominant hand 33.3kg,5-time sit and stand 11.2 sec, 30-s chair stand test 14 time, open-eye stand on right foot 19.6 sec, chair sit-and-reach test -1.2 cm, and 8-feet walking test 8.0 sec. All physical fitness performance was observed to decrease with aging.
CONCLUSIONS: Elderly males in different age groups demonstrate different levels of physical fitness as indicated by the disparities in the normative physical fitness scores, and it seems sensible to adopt different normative physical fitness scores for elderly males living in rural and urban areas.

Efficacy of High-Intensity Resistance and Sprint Interval Training in Older Adults

Scarlett L. Barnes, Kenneth L. Robertson, Boyi Dai, Marci L. Smith, Gretchen M. Sewczak-Claude, Derek T. Smith. *University of Wyoming, Laramie, WY.*
(No relevant relationships reported)

High-intensity interval training has been shown to improve health/fitness factors in adults. Evidence is limited in older adults with chronic disease and increased risk for exercise-related complications and for resistance training modes. **PURPOSE:** Assess the efficacy (aerobic and functional fitness) and safety of high-intensity resistance and sprint-cycle interval training in at-risk older adults. **METHODS:** Forty-eight participants (30 women; 69±6 years; 28.0±5.5 kg/m²; 60% with ≥2 chronic diseases) trained 3 days/week for 6 weeks. Participants were randomized to conditions: 1) high-intensity sprint interval cycle training (SIT; N=17); 2) high-intensity resistance training (HIRT; N=20); or 3) moderate-intensity continuous aerobic exercise (MICE; active control; N=11). Baseline and post-training measures included: maximal aerobic capacity (VO₂max), body composition, functional movement screen (FMS), floor-transfer-time (FTT), timed-up-and-go (TUG), balance, and flexibility. Subjective measures were: satisfaction with physical function, mobility, and physical activity enjoyment (PACES). Data analysis: repeated measure ANOVA and paired-t tests (P<0.05). **RESULTS:** VO₂max improved similarly in all groups (SIT 2.2±0.3; HIRT=3.5±0.7. MICE 2.1±0.5 ml/kg/min, P<0.01 for all). Both high-intensity groups improved in FTT (HIRT=17%, P=<0.01; SIT =12%, P<0.05) and FMS (HIRT=17%, SIT =10%, P<0.01). Only HIRT improved in TUG (10.6%) and balance (9%). Perceived satisfaction with physical function improved in all groups (HIRT=389%; SIT=266%; MICE = 167%; all P<0.01) with similarly high overall enjoyment (5.8-6.3 out of 7; P<0.05). No injuries or adverse events occurred with training. **CONCLUSION:** HIRT and SIT required less time (~28 minutes) than MICE guidelines, elicited equivalent gains in aerobic fitness, and appear to be safe for older adults with chronic disease. Additional functional fitness benefits (mobility and FMS) accompanied high-intensity training (SIT/HIRT). HIRT elicited improvements in mobility, balance, and 4 of 7 FMS measures compared to SIT (2 of 7 FMS measures). These HIRT specific gains are associated with enhanced independence and ability to perform activities of daily living. Future studies should confirm these findings and assess longer training durations.

Heart Rate Increase and Recovery as Predictors of Mobility Decline in Well-Functioning Older Adults

Eleanor M. Simonsick[1], Gerald J. Jerome, FACSM[2], Jennifer A. Schrack[3], Stephanie A. Studenski[1], Luigi Ferrucci[1]. *[1]National Institute on Aging, Baltimore, MD. [2]Towson University, Towson, MD. [3]Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.* (Sponsor: Gerald J. Jerome, FACSM)
(No relevant relationships reported)

PURPOSE: Endurance walk test performance is a powerful predictor of future mobility limitation and decline in older adults; whether other test parameters such as heart rate increase and post-test recovery provide useful metrics of resiliency has received limited attention. METHODS: Using data on 784 well-functioning (able to walk 400m quickly without stopping, not taking beta blockers) men (47%) and women aged 60 to 94 years participating in the Baltimore Longitudinal Study of Aging, we examined heart rate increase (HR-I) from a resting state immediately after completing a fast-pace 400m walk and HR recovery (HR-R; HR decline 2-minutes post-test completion) in relation to 400m time, usual gait speed and reported ability to walk ¼ to 1 mile at baseline and at follow-up an average of 2.1 years later. RESULTS: At baseline, independent of age, sex, race, height and reported exercise, HR-I (b=-1.02; p&lt.001) and HR-R (b=-1.12; p&lt.001) in separate models were negatively associated with 400m time; that is higher HR was associated with better performance; whereas, for a given 400m time, higher HR-I and HR-R were associated with worse baseline reported walking ability (b=-.007; p=.011 and -.011; p=.002). Longitudinally, higher HR-I and HR-R predicted slower follow-up 400m time and poorer reported walking ability independent of baseline values (b=.19; p=.039 and b=.24; p=.037; b=-.010; p=.007 and -.011; p=.011). No associations were observed between HR-I or HR-R and baseline or

---

Abstracts were prepared by the authors and printed as submitted.

follow-up usual gait speed. CONCLUSION: In well-functioning older adults, better heart rate response equates with better endurance walk performance, but for a given performance, higher heart rate response predicts worse concurrent reported walking ability and poorer future endurance walk performance and reported ability. Including heart rate response to endurance walk testing which is typically collected for safety monitoring may improve predictive models of future functional status.

Relation between Regional and Whole Body Sweat Sodium Concentration and the Effect of Exercise Intensity

Lindsay B. Baker, FACSM, Corey T. Ungaro, Bridget C. Sopeña, Ryan P. Nuccio, Adam J. Reimel, Kelly A. Barnes. *Gatorade Sports Science Institute, Barrington, IL.*

PURPOSE: To determine if exercise intensity has a significant effect on the relation between regional (REG) sweat [Na^+] and whole body (WB) sweat [Na^+].
METHODS: Eleven recreational endurance athletes (7 men, 4 women; 71.5±8.4 kg; 28-40 yr) completed two randomized trials cycling for 90 min at 65% of HR_{max} (LOW, 109±20 Watts) or 85% of HR_{max} (HIGH, 169±27 Watts) in a plastic isolation chamber to determine WB sweat [Na^+] using the washdown technique. REG sweat was collected from the dorsal and ventral forearms, dorsal and ventral wrists, triceps, upper chest, scapulas, lower back, ventral thighs, calves, and forehead using absorbent patches. REG and WB sweat [Na^+] were measured via ion chromatography. An 11-site aggregate of REG sweat [Na^+] was calculated from the surface area weighted mean of all sites. Room temperature (30.1±0.3°C vs. 30.1±0.2°C) and relative humidity (43.0±1.1% vs. 43.6±1.5%) were consistent between trials. Subjects consumed a consistent diet for 48-h and drank 500 mL of water 2 h before trials. Paired t-tests were used to compare measures at LOW and HIGH intensity. Linear regression and Pearson correlation were used to compare REG and WB.
RESULTS: WB sweat rate (0.516±0.077 g/cm²/min vs. 0.764±0.133 g/cm²/min; p<0.001) and WB sweat [Na^+] (32.6±14.3 mmol/L vs. 52.7±14.6 mmol/L; p<0.01) increased from LOW to HIGH. REG sweat [Na^+] increased (p<0.05) from LOW to HIGH at all sites except the thigh (p=0.13) and calf (p=0.18). The ratio between REG and WB sweat [Na^+] was greater at LOW vs. HIGH for the thigh (1.03±0.20 vs. 0.83±0.17; p=0.02) and lower back (1.29±0.25 vs. 1.08±0.19, p=0.04), but there were no differences between intensities at any other site, including the 11-site aggregate (1.28±0.20 vs. 1.22±0.16; p=0.45). There was a significant correlation between REG and WB sweat [Na^+] at each of the 11 sites for both LOW (r=0.70-0.92; p<0.05) and HIGH (r=0.68-0.93; p<0.05).
CONCLUSIONS: These findings suggest that for most sites REG and WB sweat [Na^+] increase proportionally with an increase in exercise intensity. Thus, in general the relation between REG and WB sweat [Na^+] is consistent across exercise intensities. While more research is needed, it seems that regression equations can be used to predict WB sweat [Na^+] from most REG sites irrespective of intensity when exercising between 65 and 85% HR_{max}.

Sport Specific Normative Data for Sweating Rate and Sweat Sodium Loss in Athletes: An Update

Kelly A. Barnes[1], James M. Carter, FACSM[1], Melissa L. Anderson[2], John R. Stofan[1], Matthew D. Pahnke[1], Rebecca K. Randell[3], Lindsay B. Baker, FACSM[1]. *¹Gatorade Sports Science Institute; PepsiCo, Inc, Barrington, IL. ²Gatorade Sports Science Institute; PepsiCo, Inc, Bradenton, FL. ³Gatorade Sports Science Institute; PepsiCo, Inc, Beaumont Park, United Kingdom.*

Previously, we published sweating rate (SR) and sweat sodium concentration ([Na^+]) normative data in 506 athletes. **PURPOSE**: The purpose of this study was to expand the data set and analyses to establish sport-specific normative data for SR and rate of sweat Na^+ loss. **METHODS:** Data from 1303 athletes (1103 male, 200 female) were compiled from field and lab testing. SR was calculated from the difference in pre- to post-exercise body mass, correcting for food/fluid intake and urine/stool loss. A standardized absorbent sweat patch technique was used to determine local sweat [Na^+] and normalized to whole body sweat [Na^+] using published regression equations. Rate of sweat Na^+ loss was determined from the product of whole body sweat [Na^+] and SR. The sport-specific analysis included sports with n>100; endurance (n=255), soccer (n=268), basketball (n=196), American football (n=271), and baseball (n=161). **RESULTS:** Data are mean ± SD. SR differed significantly between sports (ANOVA, Tukey's post hoc; p<0.05); American football displayed the highest SR (1.5 ± 0.7 L/h), followed by endurance (1.3 ± 0.6 L/h), basketball (1.0 ± 0.4 L/h), soccer (0.9 ± 0.4 L/h) and baseball (0.8 ± 0.3 L/h). The rate of sweat Na^+ loss was higher in American football (55.9 ± 36.8 mmol/h) and endurance (51.7 ± 27.8 mmol/h) compared with soccer (34.6 ± 19.2 mmol/h), basketball (34.5 ± 21.2 mmol/h), and baseball (27.2 ± 14.7 mmol/h). The rate of sweat Na^+ loss was higher in soccer than baseball. After accounting for the impact of covariates (age, sex, body mass, temperature, humidity, season, and intensity), there were still significant differences (ANCOVA, Tukey's post hoc; p<0.05) in the adjusted means for SR and rate of sweat Na^+ loss; endurance (1.2 L/h, 43.1 mmol/h), football (1.0 L/h, 38.2 mmol/h) and soccer (1.0 L/h, 35.4 mmol/h) were higher than baseball (0.8 L/h, 25.5 mmol/h), and endurance was higher than basketball (0.9 L/h, 32.0 mmol/h). **CONCLUSION:** This study suggests the potential for significant variation in the rate of sweat fluid and Na^+ losses between sports, with highest values generally occurring in endurance and American football. There are already products targeted to meet the needs of endurance athletes to replace their higher sweat fluid and electrolyte losses; perhaps there is also a need for products and education specific to other sports.

Body Sweat Mapping of Untrained Males during Exercise-Induced Hyperthermia

Caroline J. Smith[1], George Havenith, FACSM[2]. *¹Appalachian State University, Boone, NC. ²Loughborough University, Loughborough, United Kingdom.* (Sponsor: George Havenith, FACSM)

(No relevant relationships reported)

Aerobic training increases gross and regional sweating rates (RSR) allowing improved evaporative heat loss. Variation in RSR are widely recognized, but limited RSR data and implications for thermoregulation are available in untrained individuals. **PURPOSE:** Our aim was to investigate RSR and distribution at 35 sites in young, untrained males (UT) versus endurance-trained male athletes (TR) during exercise-induced hyperthermia in a moderate environment. **METHODS:** Six young, healthy, untrained males (22 ± 3 yrs, VO_{2max} 42.7 ± 7.2 ml.kg⁻¹.min⁻¹) and nine aerobically trained male athletes (23 ± 3 yrs, VO_{2max} 70.2 ± 13 ml.kg⁻¹.min⁻¹) ran for 60 minutes in 25.6 ± 4.5°C, 48.5 ± 0.5% relative humidity, and a 1 m.s⁻¹ air velocity. RSR were measured at two exercise intensities (I1, 60% VO_{2max}; I2, 75% VO_{2max}) using a modified absorbent technique. **RESULTS:** Core temperature was similar between groups at all stages (P>0.05). GSL was significantly higher in TR versus UT at I1 and I2 (I1: TR 365 ± 84, UT 157 ± 66 g.m⁻².h⁻¹, P<0.001; I2 TR 657 ± 119, UT 311 ± 93 g.m⁻².h⁻¹, p<0.001), reflecting a significantly higher absolute work rate in TR versus UT (p<0.01). Absolute RSR were significantly higher in TR versus UT at 28 of 35 regions at I1 and 31 out of 35 regions at I2. Highest RSR were observed on the central mid back in both groups (I1 TR 797 ± 250, UT 277 ± 120 g.m⁻².h⁻¹; I2 TR 1139 ± 364, UT 365 ± 148 g.m⁻².h⁻¹), with lowest values on the palms in TR (I1 98 ± 58, I2 126 ± 53, g.m⁻².h⁻¹) and anterior upper arms in UT (I1 33 ± 24, I2 71 ±30 g.m⁻².h⁻¹). Both groups showed a medial to lateral decrease in RSR on the posterior torso, and proximal to distal increase on the arms. Normalized ratio values were significantly different between groups at 4 and 6 sites out of 35 at I1 and I2, respectively, none of which were significant following Bonferroni correction. No correlation was observed between RSR and local skin temperature in either group. **CONCLUSIONS:** These data provide the most detailed exercise-induced RSR for untrained males, showing large RSR variation. Despite significant differences in GSL and absolute RSR, normalized data suggest no significant differences in distribution of sweat between groups. Male athletes demonstrated superior thermoregulation, with similar Tcore and Tsk values despite a higher absolute workload.

2507   Board #4   June 1 1:00 PM - 3:00 PM

Trapped Sweat in Various Sports Uniforms During Sport-Specific, Laboratory-Based Exercise

Bridget C. Sopena, Kelly A. Barnes, Ryan P. Nuccio, Adam J. Reimel, John R. Stofan, Lindsay B. Baker, FACSM. *Gatorade Sports Science Institute, BARRINGTON, IL.*

Previous research has measured the amount of sweat absorbed in basketball uniforms during exercise, but data are limited in other sports. **Purpose**: To determine the amount of trapped sweat (TS) in various sports uniforms during sport-specific, laboratory-based exercise. **Methods**: Eleven male (30 ± 5 years, 75.7 ± 5.2 kg) and 6 female (29 ± 4 years, 59.9 ± 9.9 kg) moderately-trained athletes completed 3 trials consisting of 120 min intermittent sport-specific exercise in standard uniforms for various sports, including football (n=9 men), basketball (n= 4 men, 5 women), soccer (n=4 men, 5 women), baseball/softball (n=4 men, 4 women), and/or endurance (n=5 men, 4 women) in a temperature-controlled laboratory (basketball: 25°C, 55% rh; all other sports: 30°C, 55% rh). Protocols were designed to simulate the demands of each sport (endurance: $82 \pm 5\%$ HRmax, RPE 13 ± 2; football: $75 \pm 10\%$ HR_{max}, RPE 13 ± 1; soccer: $77 \pm 10\%$ HRmax, RPE 12 ± 1; basketball: $66 \pm 12\%$ HR_{max}, RPE 10 ± 2; and baseball/softball: $59 \pm 3\%$ HR_{max}, RPE 9 ± 2). Sweat loss (SL) was determined from change in nude body mass corrected for fluid intake, urine loss, respiratory water loss, and metabolic mass loss. Nude and clothed body mass were measured pre- and post-exercise to determine TS. Analysis of variance followed by Tukey's post hoc test was used to compare sports. Data are mean $\pm$ SD. **Results**: There were significant differences in SL between sports (p<0.0001): football (2.61 ± 0.36 kg), endurance (2.18 ± 0.53 kg) and soccer (1.99 ± 0.81 kg) > basketball (1.24 ± 0.37 kg) and baseball/softball (1.19 ± 0.38 kg). There were also significant differences in TS (p<0.0001): football (0.58 ± 0.14 kg) > endurance (0.28 ± 0.16 kg) and soccer (0.24 ± 0.18 kg) > basketball (0.11 ± 0.08 kg) and baseball/softball (0.15 ± 0.12 kg). TS as a percentage of SL was significantly (p<0.0001) higher in football ($22.5 \pm 3.8\%$) than endurance ($12.2 \pm 4.7\%$), soccer ($10.9 \pm 3.4\%$), basketball ($9.2 \pm 4.4\%$), and baseball/softball ($10.8 \pm 6.2\%$). **Conclusion**: Sports with higher SL were associated with higher volumes of TS in uniforms. The football uniform (including full pads) led to the most TS and greatest underestimations in SL. Such high volumes of TS are also likely to have ramifications for evaporative heat loss capacity and therefore warrant future research investigating the effects of TS on thermoregulation.

2508   Board #5   June 1 1:00 PM - 3:00 PM

Prolonged Work in the Heat Impairs Heat Loss on the Next day in Older Men

Sean R. Notley, Robert D. Meade, Andrew W. D'Souza, Brian J. Friesen, Glen P. Kenny. *University of Ottawa, Ottawa, ON, Canada.*

(No relevant relationships reported)

Performing prolonged, arduous occupational work in the heat is associated with considerable heat strain, which may be exacerbated on the next work day. Recently, we showed that whole-body heat loss was not modified by prolonged work in the heat on the preceding day in young habitually active men. However, it is unclear whether prolonged heat strain may reduce heat loss on the next day in older workers, who display impaired thermoregulatory function and who recover more slowly from exercise-induced stress compared to young adults. **PURPOSE**: To determine whether prolonged work in the heat impairs whole-body heat loss and exacerbates heat storage on the next day in older men. **METHODS**: Changes in whole-body heat exchange and heat storage were assessed in six older (60 years (SD 5)) men during heat stress tests performed on the same day prior to (Day 1), and on the day following (Day 2), a prolonged work simulation. Each heat stress test involved three, 30-min bouts of cycling performed at increasing, fixed rates of metabolic heat production of 150 (Ex1), 200 (Ex2) and 250 W/m² (Ex3), each separated by 15-min recovery, in hot-dry conditions (40°C, 20% relative humidity (RH)). The work simulation (7.5 h) involved three moderate intensity intermittent work bouts (2 h) each separated by 30-min rest breaks in hot-dry conditions (38°C, 34% RH). Total heat loss (evaporative ± dry heat exchange) and metabolic heat production were measured using direct and indirect calorimetry, respectively. Body heat storage was quantified as the temporal summation of heat production and loss. **RESULTS**: Total heat loss (mean±95% CI) during Ex1 did not differ between Day 1 (149±8 W/m²) and Day 2 (143±6 W/m²; *P*=0.29), but decreased on Day 2 during Ex2 (181±7 W/m²) and Ex3 (219±10 W/m²) relative to Day 1 (191±7 and 230±14 W/m², respectively; both *P*<0.01). As a result, body heat storage across all exercise bouts was 19% greater on Day 2 (364±74 kJ) than on Day 1 (295±50 kJ; *P*=0.02). **CONCLUSIONS**: Prolonged work in the heat impairs whole-body heat loss and exacerbates body heat storage during moderate-to-high intensity work on the next day in older men. These outcomes indicate that older workers may be more vulnerable to heat-related illness when performing consecutive, arduous work shifts.

2509   Board #6   June 1 1:00 PM - 3:00 PM

Heart Failure Modulates Thermoregulatory Control Independently Of Differences In Physical Characteristics And Metabolic Heat Production

Surendran Sabapathy[1], Bryce N. Balmain[1], Ollie Jay, FACSM[2], Kenji Shiino[1], Glenn M. Stewart, FACSM[3], Rohan Jayasinghe[4], Jonathan Chan[4], Norman R. Morris[1]. *[1]Griffith University, Gold Coast, Australia. [2]University of Sydney, Sydney, Australia. [3]Mayo Clinic, Rochester, MN. [4]Gold Coast University Hospital, Gold Coast, Australia.*

(No relevant relationships reported)

PURPOSE: Heart failure (HF) patients appear to exhibit altered thermoregulatory responses during exercise in the heat. However, the extent to which these responses are altered due to physiological impairments independently of biophysical factors associated with differences in metabolic heat production (H_{prod}), evaporative heat balance requirements (E_{req}) and/or body size, is presently unclear. Therefore, we examined thermoregulatory responses in 10 HF and 10 age-matched controls (CON) similar in body size during exercise at a fixed rate of H_{prod}, and thus E_{req}, in a 30°C environment. **METHODS**: Rectal temperature (Trec), local sweat rate (LSR), and cutaneous vascular conductance (CVC) were measured during 60-min of cycle ergometry. Whole-body sweat rate (WBSR) was estimated from pre-post nude body weight corrected for fluid intake. Hprod and Ereq, as well as dry heat loss (Hdry) and evaporative heat loss from the skin (Esk) — assuming all secreted sweat evaporated, were calculated using partitional calorimetry. **RESULTS**: Despite exercising at the same rate of H_{prod} (HF: 338±43; CON: 323±31W, p=0.25), T_{rec} was greater (p<0.01) in HF (0.81±0.16°C) than CON (0.49±0.27°C). In keeping with a similar E_{req} (HF: 285±40; CON: 274±28W, p=0.35), no differences in WBSR (HF: 0.45±0.11; CON: 0.41±0.07L/h, p=0.38) or LSR (HF: 0.96±0.17; CON: 0.79±0.15mg/cm²/min, p=0.50) were observed between groups. Similarly, H_{dry} was comparable between groups (HF: 22.9±3.2; CON: 20.4±5.0W, p=0.14). Consequently, the cumulative body heat storage was similar between groups (HF: 154±106; CON: 196±174kJ, p=0.44). Furthermore, CVC was lower in HF than CON (HF: 0.83±0.42; CON: 2.10±0.79au/mmHg, p<0.01). **CONCLUSIONS**: Collectively, these findings demonstrate that HF patients exhibit an impaired skin blood flow response, but no differences in sweating. Given that HF had similar body heat storage to CON at the same Hprod, their greater rise in core temperature can be attributed to a less uniform distribution of heat between the body core and periphery.

2510   Board #7   June 1 1:00 PM - 3:00 PM

No Evidence Of Thermoregulatory Impairment In Donor Skin During Exercise-induced Hyperthermia

Matthew N. Cramer, Gilbert Moralez, Mu Huang, Craig G. Crandall, FACSM. *Institute for Exercise and Environmental Medicine, Dallas, TX.* (Sponsor: Craig Crandall, FACSM)

(No relevant relationships reported)

According to the US Army's Standards of Medical Fitness (AR 40-501), "Prior burn injury (to include donor sites) involving a total body surface area of 40 percent or more does not meet the standard". While the Standard implies that elevations in skin blood flow and sweating during donor skin during an exercise-induced hyperthermic challenge, this has not been experimentally verified. **PURPOSE:** This study tested the hypothesis that human donor skin retains the capability to increase skin blood flow and sweat production in response to exercise-induced hyperthermia. **METHODS:** Thirteen burn survivors (11 males; aged 36±12 years) with well-healed burn injuries spanning 36.4±17.5% of body surface area (BSA), as well as donor sites covering 18.0±9.8% BSA, cycled for 60 min at a workload eliciting ~50% of maximal aerobic capacity. Environmental conditions were set at 39.5±0.2°C and 21.8±3.8% relative humidity. Immediately prior to and upon completion of exercise, skin blood flow was assessed via laser-Doppler imaging from donor sites and adjacent non-injured skin (n=12). Local sweat rate was also assessed at the same skin sites at 45 min of exercise using absorbent material (n=10). Gastrointestinal temperature was measured using an ingestible temperature sensor. **RESULTS:** At 60 min of exercise, the elevation in gastrointestinal temperature averaged 0.8±0.3°C (P<0.01). At the end of this exercise bout, the magnitude of the increase in skin blood flow was similar between donor and non-injured sites (donor: 103±45 flux units; non-injured: 123±58 flux units; P=0.21). Similarly, local sweat rate did not differ between sites (donor: 0.54±0.29 mg/cm²/min; non-injured: 0.62±0.26 mg/cm²/min; P=0.27). **CONCLUSION:** These data suggest that well-healed donor skin retains the capability to elevate skin blood flow and sweating during exercise in the heat. Therefore, the US Army should exclude donor skin when determining whether the size of a burn injury meets the Standards of Medical Fitness.

Lower-Extremity Vibration Threshold, But Not Proprioception Or Mobility, Distinguishes Non-Progressive From Progressive Multiple Sclerosis Sub-Types

Julia D. Miehm[1], Julianna L. Averill[1], Jongil Lim[1], John Buonaccorsi[1], Carolina Ionete[2], Jane A. Kent, FACSM[1], Richard van Emmerik[1]. [1]*University of Massachusetts Amherst, Amherst, MA.* [2]*University of Massachusetts Medical School, Worcester, MA.*

(No relevant relationships reported)

Multiple Sclerosis (MS) is a demyelinating disease of the central nervous system (CNS). There are two major sub-types of MS: non-progressive (NP) and progressive (P). NP is characterized by intermittent exacerbations of symptoms, followed by a return to near baseline. P is characterized by a steady worsening of symptoms. Many people who are diagnosed as NP will transition to P. Both NP and P result in sensorimotor impairments that can lead to poor mobility and decreased quality of life. **PURPOSE:** A sensitive, non-ambulatory measure of sensorimotor function that can predict the transition from NP to P could be useful in the clinical management of MS. **METHODS:** Sensorimotor function of 19 control (CON; 14 women, 55.6±13.9 yrs), 31 NP (28 women, 52.6±9.9), and 29 P (20 women, 59.4±9.1) participants was assessed. Vibration threshold was measured with a Biothesiometer at three locations on the plantar surface of the non-dominant (CON) or most-affected (NP, P) foot. Proprioception was measured at the ankle with a manipulandum, using a position-matching task. Mobility measures included the 25-foot-walk (25FWT) and the Timed-Up-and-Go (TUG). Data were analyzed across and between groups using a one-factor ANOVA and post-hoc pairwise t-tests, respectively, with significance established as $p < 0.05$. **RESULTS:** There was a main effect of group for all outcome variables. Vibration threshold distinguished NP from P in that these differed across those groups. Neither mobility measure nor proprioception at the ankle distinguished the 2 MS sub-types.

	CON (n=19)	NP (n=31)	P (n=29)	ANOVA p value
Big Toe (v)[b,c]	12.74±10.97	15.63±13.79	26.11±15.52	0.004
5th Metatarsal (v)[b,c]	9.47±7.97	13.97±13.34	27.19±16.92	0.001
Heel (v)[b,c]	12.16±11.85	15.45±12.70	28.07±16.39	0.001
Proprioception (α°)[a,b]	1.85±1.20	4.53±4.48	5.11±3.76	0.001
25FWT (s)[a,b]	5.12±0.50	8.44±4.88	10.07±4.56	0.001
TUG (s)[a,b]	6.89±1.17	11.90±7.10	13.95±5.84	0.001

Table 1. Data are mean±SD. Significant differences: [a]CON vs. NP; [b]CON vs. P; [c]NP vs. P

CONCLUSION: Vibration threshold may be a promising outcome variable for discriminating among individuals with NP and P MS sub-types. This could be useful in a clinical setting for cross-sectional comparisons of NP and P, as well as to detect transitions from NP to P in longitudinal studies.

The Preventive Effect Of A Bounding Exercise Programme On Hamstring Injuries In Amateur Male Soccer

Sander van de Hoef[1], Michel Brink[2], Bionka Huisstede[1], Maarten van Smeden[3], Niels de Vries[4], Edwin Goedhart[4], Vincent Gouttebarge[5], Frank Backx[1]. [1]*University Medical Center Utrecht, Utrecht, Netherlands.* [2]*University of Groningen, Groningen, Netherlands.* [3]*Leiden University Medical Center, Leiden, Netherlands.* [4]*Royal Netherlands Football Association, Zeist, Netherlands.* [5]*Dutch Consumer Safety Institute, Amsterdam, Netherlands.*

(No relevant relationships reported)

Hamstring injuries (HI) are the most common muscle injuries in both professional and amateur soccer. With the introduction of the effective Nordic hamstring exercise (NHE), a decrease of hamstring injuries was expected. Nevertheless, an annual increase of HI is seen in the last decade. This might be due to poor compliance. Arguments for non-compliance are among others, that the NHE is not soccer-specific enough. Therefore, we developed the Bounding Exercise Programme (BEP) as an alternative. It is a sport-specific exercise programme which includes concentric, eccentric and plyometric exercises. **PURPOSE**: To determine the preventive effect of the Bounding Exercise Programme on hamstring injury occurrence in adult amateur male soccer players. **METHODS**: Soccer teams (N=32) competing on first class amateur level, were cluster-randomized to the intervention or control group. Both groups were instructed to perform their regular training programme, and the intervention group was also instructed to perform the BEP during the whole competition. At baseline, player characteristics were gathered from all participants. During the competition 2016-2017 all players weekly registered exposure (minutes) and HI occurrence. Compliance (meters of BEP) was reported by all players in the intervention group. **RESULTS**: 588 male soccer players (24,7 +/-4,5 yrs old) participated in this study. A total of 65 HI were reported within one competition. The overall HI incidence was 1,39 per 1000 soccer hours for the control group and 1,12 per 1000 soccer hours for the intervention group.
Analysis of intention to treat showed no statistical significant difference between both groups in occurrence of HI (OR =0.89, 95% CI 0.459-1.747) and no significant difference in time to first HI (HR =0.90 ,CI = 0.478-1.695). There was also no effect found of adherence to BEP for the occurrence of HI and time to first HI. **CONCLUSIONS**:Our study showed no benefit of BEP over regular soccer on preventing HI in adult amateur soccer players. Compliance for BEP was moderate (on average 71%)

Vigorous Physical Activity And Bone Mineral Density In Anorexia Nervosa Female

Gautier ZUNQUIN. *ULCO, Dunkerque, France.*

(No relevant relationships reported)

Restrictive Anorexia Nervosa (ANR) is a clinical mental disorder defined as abnormal eating behavior and is often associated with physical hyperactivity. There is no consistent cut-off use to define what is considered excessive physical activity in term of duration, frequency and intensity in contrast with healthy physical activity (1). On the other hand, ANR is marked by bone loss and with low Body Mineral Density (BMD)(2). Few data are available in daily patterns of Physical Activity and in the relationship between time spent in moderate to vigorous PA and Bone Mineral Density (BMD) **PURPOSE:** To determine the association between time spent in moderate to vigorous physical activity (MVPA) and BMD in females with anorexia nervosa. **METHODS:** 17 females with anorexia nervosa (22+2 yrs) were included in the study. Body composition was assess by DXA measurements (Hologic QDR-4500W, Waltham, MA). 24h Physical activity levels and sleep time were monitored by using actigraphy (ActiSleep and ActiGraph GT3X, Pensacola, US). **RESULTS:** Females with diurnal higher VPA levels demonstrated an increased in integral Femoral Neck Bone Mineral Density (FNBMD) (0.678 g/cm2 vs. 0.623 g/cm2) compared to those with lower diurnal VPA levels (p<0.05). Time spent in light physical activity (LPA) is associated with a significantly lower total hip BMD (g/cm2)(0.788 ± 0.11 vs 0.873 ± 0.15 ; p< 0.001). CONCLUSION: This investigation shows that ANR females accumulating more total Vigorous Physical Activity presented increased BMDs when compared to their less active peers. These data highlight the importance of VPA in females with AN to counteract their low bone mass and to improve their bone health. High time spent in LPA may be considered to be deleterious for BMD.(1) Achamrah N, Coëffier M, Déchelotte P. Physical activity in patients with anorexia nervosa. Nutr Rev.

Recovery of Lower Extremity Strength and Function following ACL Reconstruction in Skeletally Immature Patients

Dai Sugimoto, Benton Heyworth, Farren Davis, Mininder Kocher, Lyle Micheli, FACSM. *Boston Children's Hospital / The Micheli Center for Sports Injury Prevention, Boston, MA.*
(No relevant relationships reported)

BACKGROUND: Following anterior cruciate ligament reconstruction (ACLR) surgery, lower extremity recovery of the uninjured limb >90% is commonly recommended for clearance to return-to-play (RTP). However, evidence regarding the timing of achieving such a recovery is lacking, especially in skeletally immature populations. **PURPOSE:** To examine the proportion of pediatric ACLR patients (<15 years) who achieve >90% of lower extremity recovery at 6-9 months following ACLR surgery. **METHODS:** Bilateral strength (quadriceps, hamstrings, hip abductor, and hip extensor), Y-balance (anterior, posteromedial, and posterolateral reach), and hop (single, triple, cross-over, and 6 meter timed) tests were assessed. Descriptive statistics (%) were employed. Additionally, sub-groups were analyzed according to sex and technique/autograft type: males with transphyseal quadruple hamstrings (Male-HS), females with transphyseal quadruple hamstrings (Female-HS), and males with extra/intra-compartmental physeal-sparing iliotibial band (Male-ITB) using chi-square (x^2) test with p<0.05. **RESULTS:** A total of 93 pediatric ACLR patients (Male-HS: N=21, age=13.6±1.0, Female-HS: N=33, age=13.4±0.7, Male-ITB: N=39, age=12.5±1.3) were enrolled. Time from ACLR to RTP testing was 6.9±3.4 months. The proportion of pediatric ACLR patients, overall, achieving >90% of strength was: 76.3% in quadriceps, 39.1% in hamstrings, 79.6% in hip abductors, and 82.8% in hip extensors. Y-balance test resulted 82.6% in anterior reach, 83.9% in posteromedial reach, and 89.1% in posterolateral reach. Hop test indicated 62.5% in single hop, 72.9% in triple hops, 56.5% in cross-over hops, and 71.4% in 6 meter timed hops. X^2 analysis identified a difference in hamstrings strength, which showed a lower proportion of >90% recovery in Male-HS (23.8%) and Female-HS (15.6%) compared to Male-ITB (66.7%, p<0.01). **CONCLUSIONS:** Approximately 7 months following ACLR, more than 3/4 of the patients achieved >90% of quadriceps, hip abductor, and hip extensor strength, but not hamstrings strength. While over 4/5 of the patients performed >90% in Y-balance, less than 3/4 achieve >90% on hop tests. Graft type markedly influences hamstrings strength. Less than 1/5 (18.9%) of Male-HS and Female-HS reached >90% compared to 2/3 (66.7%) in Male-ITB patients.

2516   June 1 2:00 PM - 2:15 PM

Long-term Functional Impact of Viscosupplementation Versus True Placebo in Symptomatic Hip Osteoarthritis; A Randomized Control Trial

Jane Konidis[1], Philippe Corbeil[1], Antoine Cantin-Warren[2], Sylvie Turmel[3], Emile Cardinal-Soucy[1], Remi Lacroix[3], Etienne Belzile[3]. *[1]University Laval, Quebec City, QC, Canada. [2]Center for Interdisciplinary Research in Rehabilitation and Social Intergration (CIRRIS), Quebec City, QC, Canada. [3]University Hospital Center of Quebec (CHUQ), Quebec City, QC, Canada.*
(No relevant relationships reported)

INTRODUCTION: Degenerative hip osteoarthritis (OA) is a common progressive disorder causing disability. The injection of exogenous hyaluronic acid (HA), or viscosupplementation (VS), can potentially help restore the properties of synovial fluid. There is little literature available evaluating the long-term effects and the functional impact of VS in hip OA. **PURPOSE:** To determine if a single intra-articular injection of a high-molecular weight (HMW) VS would improve function and decrease pain in persons suffering from hip OA. **METHODS:** A double-blinded randomized control trial was conducted at a University Hospital Center in Canada. Patients were randomly allocated to either the treatment group, an ultrasound guided single intra-articular injection of a HMW HA, or the placebo group, a single extra-articular injection of local anesthetic. Participants underwent evaluations at 2 weeks prior to the injection (T0), and at 1 month (T1), 3 months (T2) and 6 months (T3) post injection. Patients completed two questionnaires; the Hip Disability and Osteoarthritis Outcome Score (HOOS) and the 36-Item Short Form Survey (SF-36). Gait biomechanics were evaluated in a lab. **RESULTS:** Between May 2014 and September 2017, 38 participants were evaluated in this study over the course of 6 months. In the treatment group, N = 19 and in the placebo group, N = 18. The mean age at the time of injection was 55. On the HOOS symptom subscale, the placebo group worsened from T0 to T3 by 6.29% compared to the treatment group. The VS group improved their pain subtotal from T0 to T2 by 4.73%. The control group worsened by 1.22% during that same time and continued to deteriorate by 6.09% at T3. There were also improvements in the activities of daily living subscale from T0 to T3, with the treatment group improving

by 5.29% while the placebo group worsened by 5.15%. The most important change occurred in the sports and recreational subscale of the HOOS. Between T0 and T3, the placebo group worsened by 7.611 points (- 17.82%). The treatment group improved by 6.67%. **CONCLUSION:** Our preliminary results suggest that a HMW VS hip injection for degenerative OA, when compared to true placebo, may lead to long-term improvements in pain relief, increase in function and in activity participation. **NIH Clinical Trials Registry:** NCT02086474

The Prevalence Of Obstructive Sleep Apnea Within A Professional Rugby League Team: An Exploratory Study

Johnpaul Caia[1], Andrew Scott[2], Shona L. Halson[3], Vincent G. Kelly[1]. *[1]University of Queensland, Brisbane, Australia. [2]Wesley Hospital, Brisbane, Australia. [3]Australian Institute of Sport, Canberra, Australia.*
(No relevant relationships reported)

Obstructive sleep apnea (OSA) is a disorder characterized by recurrent episodes of partial or complete obstruction of the upper airway. This results in non-restorative sleep leading to daytime sleepiness and decreased quality of life. It is estimated that 1-5% of the worldwide population suffer from OSA, however the prevalence within athletes is largely unknown. **PURPOSE:** To characterize the prevalence of OSA within a team of professional rugby league athletes. **METHODS:** 22 professional rugby league athletes underwent one night of home-based polysomnography, with apnea-hypopnea index (AHI) used to indicate the presence and severity of OSA. Linear models were used to determine if playing position (back, forward), ethnicity (European-Australian, Polynesian) or body composition influenced the prevalence or severity of OSA. **RESULTS:** 10 cases of OSA were found. When considering ethnicity, a likely moderate difference was observed between Polynesians and European-Australians for AHI during rapid eye movement sleep (ES = 0.94; ±0.77, p<0.05). Differences between forwards and backs were unclear (ES = 0.44; ±0.77, p>0.05). Increased BMI (ES = 0.83; ±0.77, p<0.05) and skinfold thickness (ES = 0.87; ±0.49, p<0.05) were associated with increased AHI. **CONCLUSION:** Within professional rugby league athletes, Polynesians may be more susceptibility to OSA than European-Australians. Furthermore, our data suggests that athletes with greater BMI and skinfold thickness may be predisposed to the existence of OSA.

2518   June 1 2:30 PM - 2:45 PM

Cardiovascular Risks For Participation In Marathon Among The Adolescent Athletes In Sri Lanka - A Pilot Study

Sanka Thebuwanaarachchi. *Teaching Hospital Karapitiya, Galle, Sri Lanka.*
(No relevant relationships reported)

Undetected cardiovascular abnormalities are one of the major causes of sudden death in young athletes. Currently we lack data on this field in Sri Lanka.
PURPOSE :To determine the prevalence, the associated factors of cardiovascular disease among the adolescent players and the cardiovascular risks for participating in marathon. **METHODS:** Research was conducted in three sports medicine clinics selected from the hospitals of three main provinces in the country including Western, Southern and Central provinces where sports medical officers' conducted pre participation medical screening of players and documented in Pre participation Examination (PPE) forms. Study population consisted of adolescent players aged between 10 to 19y who attended previously mentioned clinics for medical clearance prior to the marathon run . Physically challenged players were excluded. Sample was selected from January 2015 to August 2015. The sample size was 900. Convenient cluster sampling method was incorporated. Pretesting was done which lead to the amendments in the Data extraction sheet. Secondary data were collected from the PPE forms from the clinics. A cross-sectional analytical study was conducted to determine the prevalence and the associated factors of cardiovascular disease: **RESULTS** : Prevalence of cardiovascular diseases among adolescent players in Sri Lanka according to our study was 2%. Most common cardiac abnormality was Mitral Valve Prolapse. Mitral Stenosis, Ventricular Septal Defect and Aortic Stenosis were the other cardiac abnormalities detected. Important incidental finding of our study was a higher prevalence (6%) of bronchial asthma among adolescent players which was more than the cardiovascular disease. **CONCLUSION** : Properly conducted Pre Participation screening reveals underlying cardiovascular disease and it may be used as a tool to identify cardiovascular risks for participation in marathon among adolescent players and hence reduce sudden cardiac death incidents.

Abstracts were prepared by the authors and printed as submitted.

Immune and Hormones Levels Responses Before and After Specific Maximal Protocol of Brazilian Olympic Athletes

Hugo Tadashi Kano, Layene Peixoto Barros, Franz H. Burini, Roberto C. Burini. *UNESP Medical School, Botucatu, Brazil.* (Sponsor: Roberto C Burini, FACSM)

(No relevant relationships reported)

Athletes are overexposed to stress factors such as training routine, sleep and dietary pattern, wich may influence immune function and hormones patterns modulating health and performance. Immune supression after sport metabolic overload is an issue for elite athletes and should be considered during training log. **Purpose:** The purpose of this study was to evaluate Leukocytes, Testosterone and Cortisol responses to specific maximal protocol of elite brazilian atheltes, and their relations dynamically. **Methods:** We evaluated 55 elite athletes (16 judo, 10 boxing and 29 rowing olympic national athletes; 38 males and 17 females; 24.2±6yrs) for leukocytes (Leuk) and hormones levels such as Testosterone (T) and Cortisol (C) taken blood samples before and after specific maximum effort protocol. **Results:** Leukocytes values before and after test were 7.42±1,3 and 10.02±1,7x10³/mm3 (pre *vs* post 2,6 x10³/mm³); Cortisol levels were 15.3±2,7 and 16.2±1,9mg/dL (pre *vs* post 0.9mg/dL) and Testosterone 371.5±57,2 and 362.1±73,1mg/dL. Analysing genders separately, post *vs* pre difference of Leukocytes, Testosterone and Cortisol levels for males and females were 2.4x10³/mm³, -18.8mg/dL, 0.5mg/dL; 3.1x10³/mm³; 2.2mg/dL and 1.7mg/dL respectively. **Conclusions:** Leukocytes elevation after maximum effort were observed on males and females athletes despite sport modality, and these elevations were not associated with Testosterone or Cortisol variations during this protocol. Leukocytes response may be a primary indicator of imune response integrity compared with Testosterone declines or Cortisol elevations in response to sport induced stress protocol.Health issues, specially upper respiratory tract infections, has been associated with imune supression after metabolic overload and should be focused besides sports adaptation to training log and competition.

Oral Consumption of Bisphenol A Increases Glucose Responses in Adults

Sean Stanelle, Alyssa Bird, Leana Mosesian, Garrett Grant, Julie Pollard, Eduardo Uribe, Dana Williams, Suzanne Phelan, Todd Hagobian, FACSM. *California Polytechnic State University San Luis Obispo, San Luis Obispo, CA.* (Sponsor: Todd Hagobian, FACSM)

(No relevant relationships reported)

Previous observational studies have shown a correlation between urinary bisphenol A (BPA) and type 2 diabetes, however the direct effects of BPA on risk markers in the pathogenesis of diabetes are unknown. **PURPOSE:** To determine the effects of oral ingestion of BPA on glucose, insulin, and estrogen responses. **METHODS:** After an overnight fast, ten healthy college students (7W, 3M; 40% Hispanic, 21.0 ± 0.8 yrs; 24.2 ± 3.9 kg/m²) were block randomized, in a double-blinded fashion, to oral consumption of Placebo (PL), BPA at 4 µg/kg BW (BPA-Low), and BPA at 50 µg/kg BW (BPA-High). Blood glucose, insulin, and estrogen concentrations and calculated area under the curve (AUC) were assessed at baseline, minutes 15, 30, 45, 60, and then every 30 minutes for the next 2 hours in response to a 75g oral glucose tolerance test using a repeated measures ANOVA. **RESULTS:** Compared to PL, BPA AUC was significantly higher (p < 0.05) in BPA-Low and BPA-High (295 ± 139, 2239 ± 1255, 14030 ± 4350 ng/mL*min). Compared to PL, glucose AUC tended to be higher (p = 0.08) in BPA-Low and was significantly (p = 0.04) higher in BPA-High (1150 ± 23, 1232 ± 24, 1245 ± 30 mmol/L*min). Insulin AUC (6360 ± 382, 6527 ± 400, 5683 ± 462 ug/mL*min) and estrogen AUC (12154 ± 2752, 12161 ± 2326, 11145 ± 2263 pg/mL*min) were not significantly different between conditions (p > 0.05). **CONCLUSION:** Oral BPA consumption of 50 µg/kg BW significantly increased glucose AUC, but not insulin or estrogen. These data provide the first direct evidence in humans that consumption of BPA alters a risk marker in the pathogenesis of type 2 diabetes.

2522 June 1 1:15 PM - 1:30 PM

The Influence of Metabolic Syndrome on Carotid Intima Media Thickness in Children

Robert E. Downing, Rebecca Place, Paul Visich. *University of New England, Biddeford, ME.*

(No relevant relationships reported)

Increased carotid intima-media thickness (CIMT) is accepted as an early indicator for the development of atherosclerotic coronary artery disease (CAD). The presence of metabolic syndrome (MetS) in adults is shown to have a negative influence on CIMT and thus CAD. As obesity rates increase in children, which elevates the risk of MetS, it is unclear how this might alter a child's CIMT.
PURPOSE: To determine if children with MetS are at a greater risk of an increased CIMT.
METHODS:Two hundred and twenty-one children had their CIMT assessed. In addition, all subjects completed a fasting blood lipid and glucose profile, waist circumference (WC) and resting blood pressure to evaluate MetS risk factors. A licensed sonographer completed scans on the right and left common carotid artery using the Terason t3200 ultrasound unit with a linear transducer probe. CIMT was measured using the software The Carotid Analyzer for Research Version 6. To evaluate the effect of MetS on CIMT, the students were categorized into three groups: 0 MetS Risk Factors (n=73), elevated WC (≥90th%, n=31) only and MetS (n=11). A random sample of 11 subjects were chosen from the first two groups.
RESULTS: A total of 33 students with an age of 10.5±0.51, height 150.0±8.0cm, and weight 55.7±16.1kg participated in the study. An increase in the right, left and combined CIMT's were observed in children with MetS (0.554±0.023 (p<0.005), 0.552±0.019 (p<0.005), and 0.552±0.016 (p<0.0001), respectively) and elevated WC only (0.552±0.017, (p<0.005), 0.551±0.023 (p<0.003), and 0.551±0.018 (p<0.005), respectively) Vs children with 0 risk factors (0.532±0.004, 0.531±0.009, and 0.531±0.005, respectively). When comparing the elevated WC only group to the MetS group, there was no differences in CIMT.
CONCLUSIONS: It appears MetS negatively impacts CIMT, however an elevated WC by itself negatively impacts CIMT. Early identification of children with an elevated WC may be beneficial in identifying children at risk for premature cardiovascular disease. Assessment of CIMT in children with an elevated WC may help motivate families to make positive lifestyle modifications.

2523 June 1 1:30 PM - 1:45 PM

Combining Short-Term Interval Training With Caloric-Restriction Improves ß-Cell Function In Obese Adults

Monique E. Francois, Nicole M. Gilbertson, Natalie Z.M Eichner, Emily M. Heiston, James H. Mehaffey, Taryn E. Hassinger, Peter T. Hallowell, Steven K. Malin, FACSM. *University of Virginia, Charlottesville, VA.* (Sponsor: Steve Malin, FACSM)

(No relevant relationships reported)

Background: Obese adults have an increased risk of type 2 diabetes (T2D). Although insulin resistance is a key etiological factor, the progressive loss of ß-cell function causes T2D. Lifestyle therapies, such as caloric-restriction and interval exercise training (INT) have separately been shown to improve insulin secretion; however, the impact of these therapies combined on ß-cell function prior to meaningful weight loss is unknown.
Purpose: To examine the impact of a low-calorie diet (LCD), with and without INT, on ß-cell function in obese adults.
Methods: Twenty-two, middle-aged obese (Age: 46±12 y; BMI 38±6 kg/m²) adults were randomized to either 2-wks of a LCD (~1200 kcal/day) or an energy matched LCD+INT intervention (supervised: 60-min/d alternating 3-min at 90 and 50% HRpeak). VO₂peak and body fat were assessed before and after interventions. After an overnight fast, a 120-min 75g oral glucose tolerance test (OGTT) with blood samples every 30-min was performed, and glucose, insulin, and C-peptide were used to define glucose-stimulated insulin secretion ([GSIS: Δinsulin/Δglucose]), hepatic clearance (HC: AUC_{insulin}/AUC_{c-peptide}), and ß-cell function (Disposition Index [DI: IGI x Matsuda Index]) for early- (0-30-min) and total-phase (0-120-min) responses. GLP-1_{active} was also measured during 0, 30 and 60-min of the OGTT to assess incretin effects.
Results: Neither intervention altered body fat % (Time: *P*=0.74), and only LCD+INT increased VO₂peak (Interaction: *P*=0.03). LCD+INT reduced glucose total area under the curve (tAUC) when compared with LCD (Interaction: *P*<0.05). While both interventions increased insulin sensitivity by ~13% (Time: *P*=0.04), only LCD+INT elevated early-phase GSIS (Interaction: *P*=0.05) with no change in HC (Time: *P*=0.11). LCD+INT tended to increase early-, but not total-phase, ß-cell function to a greater extent when compared with LCD (Interaction: *P*=0.06). GLP-1_{active} tAUC increased similarly after LCD+INT and LCD (Time: *P*<0.05) by ~28%.

Conclusions: Independent of insulin sensitivity and GLP-1, INT combined with LCD improved early-phase pancreatic function in obese adults when compared to an energy matched diet. Additional work is required to elucidate the mechanism(s) by which INT improves insulin secretion during weight loss to optimize diabetes prevention.

2524   June 1 1:45 PM - 2:00 PM

Exercise-induced Energy Deficit Lowers Glycemia At Breakfast The Next Day, But Not Over 24-hours.

Michael Schleh, Lisa Guth, Haojia Jing, Jeffrey F. Horowitz, FACSM. *University of Michigan, Ann Arbor, MI.*

(No relevant relationships reported)

Several studies have reported improved glycemic control the day after a session of exercise, but it is unclear if this is a direct effect of exercise or an indirect effect of the exercise-induced energy deficit. **Purpose:** Determine the effect of energy deficit after acute exercise on free-living glycemic control the next day. **Methods:** 12 healthy subjects (male=4, female=8, age=28±6 yrs, BMI=24.6±3.2 kg•m^{-2}, VO_{2max}=36±10 ml•kg^{-1}•min^{-1}) completed two experimental trials, which were identical other than the energy content of the meals consumed after exercise. Before each trial, continuous glucose monitoring (CGM) probes were inserted in the abdominal region. On day 2, subjects were provided a standardized breakfast and lunch, then they exercised in the afternoon at 65% VO_{2max} until 350 kcals were expended (~50 min). After exercise on one occasion, subjects consumed meals (~55% CHO, ~30% Fat, ~15% PRO) supplemented with calories to replenish the energy expended during exercise, thereby achieving energy balance (EB). On the other occasion, the meals after exercise were not supplemented with extra calories, inducing a 350 kcal energy deficit (ED). Throughout the next day, subjects ate identical meals in both the EB and ED trials, and free-living glycemic control was compared between trials starting at 0800h. **Results:** 3-hour post-prandial area under curve (AUC) was significantly lower after breakfast in ED compared with EB (27.5±3.5 vs. 29.3±4.0 mM•h^{-1}, P=0.03), but not different after lunch (28.8±4.2 vs. 27.9±3.3 mM•hour^{-1}, P=0.38), dinner (28.7±3.3 vs. 27.3±3.3 mM•hour^{-1}, P=0.50), or evening snack (27.8±3.3 vs. 26.8±2.1 mM•hour^{-1}, P=0.45). Similarly, average postprandial glucose (3-hour) was lower after breakfast in ED vs. EB (5.6±0.7 vs. 6.0±0.8 mM, P=0.02), and not different between trials after the other meals. Despite differences in the glycemic response to breakfast, average 24-hour glycemic response did not differ between ED and EB (24-hour AUC: 27.2±2.5 vs. 26.5±2.1 mM•h^{-1}, respectively; P=0.2). **Conclusion:** Compared with eating meals that replenish the energy expended during exercise, an exercise-induced energy deficit lowered the glycemic response to breakfast the next day - but this energy deficit did not impact total 24-hour glycemia the day after exercise. **Supported by NIH GRANT#** R01 DK077966

Components of Metabolic Flexibility Improved 48 hours After High Intensity Interval Exercise.

Timothy D. Allerton[1], Brian Irving[2], Guillaume Spielmann[2], Stefany Primeaux[3], Arnold Nelson, FACSM[2], Dennis Landin[4], Neil Johannsen[2]. *[1]Pennington Biomedical Research Center, Baton Rouge, LA. [2]Louisiana State University, Baton Rouge, LA. [3]LSU Health Sciences Center, New Orleans, LA. [4]Louisisana State University, Baton Rouge, LA.* (Sponsor: Arnold Nelson, FACSM)

(No relevant relationships reported)

The inability to switching between fuel sources (fat and carbohydrates), termed metabolic inflexibility, plays a prominent role in the development of type 2 diabetes and obesity. Evidence suggests that chronic exercise interventions and weight reduction improve metabolic flexibility (MF). However, little is known about the impact of a single bout of high-intensity interval exercise (HIIE) on MF. **Purpose:** To assess the impact that HIIE has on MF and blood flow in response to a mixed meal tolerance test (MMTT) performed without exercise (BL) or following 1H or 48H post-HIIE. **Methods:** Participants (n=16, aged 21.2 ± 1.2 y, BMI 22.6 ± 2.7 kg/m^2) completed 3 mixed meal tolerance tests (MMTT; 412.2 ± 71.5 kcal) (BL, 1H and 48H) lasting 180 minutes. Indirect calorimetry measurements were taken prior to the mixed meal (0 min), 60 min, and 120 min post mixed meal. MF was determined by subtracting RER 60 min - RER 0 min and analyzing the rate of carbohydrate and fat oxidation/suppression (FatOx). HIIE was 10 x 60s intervals at 90% (154.6 ± 35.6 W) of power output achieved at VO_{2peak}, followed by 60s of recovery. Additionally, we measured blood flow in the vastus lateralis (VL) every 30-min utilizing near-infrared spectroscopy (NIRS). **Results**: Fasting FATox was elevated 48H post-exercise compared to BL (1.31 ± 0.39 mg/kg/min vs.0.96 ± 0.32 mg/kg/min, p=0.04). The ability to suppress FATox at the 60-min time-point of the MMTT was significantly higher 48H post-exercise compared to BL (~20% vs. ~12%, p=0.01). Increased VL blood flow was detected 120-minutes into the MMTT during BL. When compared to BL, 1H post-exercise VL blood flow changes were significantly higher at 60 (1.8 fold, p=0.03) and 120-min (2.0 fold, p=0.04) time points. **Conclusions:** Our results suggest, a single bout of HIIE improves MF up to 48H post-exercise, which is characterized

by higher fasting and meal-induced suppression of FATox. Postprandial VL blood flow was also stimulated to a greater degree 1H post-exercise when compared to the BL postprandial measurement. The impact of acute HIIE demonstrates MF can be improved acutely, prior to chronic adaptations.

Relationship between Cardiorespiratory Fitness and Relative Gut Microbiota Composition in Healthy Adults

Ryan P. Durk[1], Esperanza Castillo[1], Leticia Márquez-Magaña[1], Gregory J. Grosicki[2], Nicole Bolter[1], C. Matthew Lee[1], James R. Bagley[1]. *[1]San Francisco State University, San Francisco, CA. [2]Tufts University, Boston, MA.*

(No relevant relationships reported)

PURPOSE: Bacteria residing in the human gastrointestinal tract has a symbiotic relationship with its host. Animal models have demonstrated a relationship between exercise and gut microbiota composition. The purpose of this study was to explore the relationship between cardiorespiratory fitness and relative gut microbiota composition, measured by the ratio of Firmicutes to Bacteroidetes (F/B ratio) in healthy adults. **METHODS**: Twenty-one males and 19 females (Age=26.1 ± 2.8 y; BMI=24.0 ± 4.2 kg/m^2), who did not take antibiotics in the last 6 months, volunteered for this study. Participants completed a 3-month exercise recall, tracked their nutritional intake for 7 days (via MyFitnessPal®), and collected their stool sample with an OMNIGENE Gut® home stool collection kit. Body composition and maximal cardiorespiratory fitness (VO_{2max}), were measured via air displacement plethysmography using the Bod Pod® and a symptom-limited graded treadmill test, respectively. Relative microbiota composition was determined by analyzing DNA extracted from stool samples using a Quantitative Polymerase Chain Reaction (qPCR) approach that specifically measured the amount of a target gene (16s RNA) found in Firmicutes and Bacteroidetes. Relationships between F/B ratio and potentially related dietary, anthropometric, and fitness variables were assessed using correlation analyses with appropriate Bonferroni adjustment ($p<0.004$). **RESULTS**: Average F/B ratio in all participants was 0.94 and average VO_{2max} was 45.8 ± 8.8 ml/kg/min. F/B ratio was significantly correlated to VO_{2max} ($r=0.45$, $p<0.004$), but no other fitness, nutritional intake, or anthropometric variables ($p>0.004$). **CONCLUSIONS**: VO_{2max} was responsible for ~20% of the variance of an individual's relative gut bacteria as determined by F/B ratio. These data support animal findings by demonstrating a relationship between relative human gut microbiota composition and cardiorespiratory fitness in healthy adults. Future investigations should confirm this relationship in heterogenous populations and investigate the utility of exercise training as medium to promote beneficial changes in gut microbiota.

Effects of Maternal Exercise on Hepatic Steatosis in Young Adult Rats

Rory P. Cunningham[1], Grace M. Meers[1], Greg Ruegsegger[2], Frank Booth, FACSM[2], R. Scott Rector, FACSM[1]. *[1]University of Missouri & Truman VA, Columbia, MO. [2]University of Missouri, Columbia, MO.* (Sponsor: R. Scott Rector, FACSM)

(No relevant relationships reported)

Introduction: Maternal high fat diets (HFD) result in excess fat accumulation in the liver of offspring, known as hepatic steatosis. Maternal exercise during this crucial period of fetal development can be protective against hepatic steatosis in older offspring. However, it is unknown whether these protective effects can be seen in younger offspring. Here we sought to determine whether maternal exercise would attenuate maternal HFD-induced steatosis in young adult rats. **Methods:** Female Wistar rats (7-8 weeks of age) were randomized into one of four groups: HFD (42% fat, 10% sucrose) or normal chow diet (ND) with either exercise (RUN) or sedentary (SED) for each group. All dams returned to ND/SED conditions following parturition. Post-weaning, all offspring were maintained in ND/SED conditions for 18 weeks. **Results:** Male offspring had increased body mass compared with females (p<0.05). Maternal HFD-induced increases in male offspring body mass was attenuated in the HFD/RUN offspring (p<0.05). Maternal HFD feeding significantly increased hepatic steatosis in male (but not female offspring), which was not attenuated by maternal RUN. However, maternal RUN increased (p<0.05) hepatic markers of mitochondrial biogenesis and mitophagy (TFAM, PPARγ, NRF2) in all offspring and the mitophagy marker BNIP3 in HFD-RUN offspring. Interestingly, hepatic markers of de novo lipogenesis (FAS, ACC), mitophagy (ATG12:5, BNIP3, P62, LC3 II/I), and mitochondria biogenesis/content (TFAM, OX PHOS-Complex II) were significantly increased in female vs. male offspring. **Conclusion:** Although maternal exercise did not attenuate maternal HFD-induced hepatic steatosis as has been previously reported in older adult offspring, it did significantly increase hepatic markers of mitochondrial biogenesis and autophagy/mitophagy. Furthermore, female offspring had elevated hepatic markers of mitochondrial health which may possibly explain why female

---

Abstracts were prepared by the authors and printed as submitted.

rats are protected against maternal HFD-induced hepatic steatosis. Future studies are warranted to shed light on the timeline of hepatic steatosis development under the influence of maternal exercise.

Physical Activity during Pregnancy Alters Gene Expression in Neonatal Tissue

Leryn J. Reynolds[1], Niraj R. Chavan[2], Brittany B. Rice[2], Hannah F. Maddox[2], Joshua D. Preston[2], Logan B. DeHoff[2], Kevin J. Pearson[2]. *[1]Old Dominion University, Norfolk, VA. [2]University of Kentucky, Lexington, KY.* (Sponsor: David Swain, FACSM)
(No relevant relationships reported)

Offspring born to mothers who exercise during pregnancy have been shown to have reduced birth weight and body weight during adolescence; however, mechanisms to explain this phenomenon are lacking. **PURPOSE:** This study examined whether male infants born to mothers with low levels of naturally occurring physical activity during pregnancy (<6,000 steps/day; <6K) had altered expression of genes related to glucose metabolism and adipogenesis compared to infants born to mothers with greater than 6,000 steps/day (>6K). **METHODS:** Physical activity levels were assessed via Fitbit Flex during the second and third trimester of pregnancy. The dartos layer of the foreskin was collected following circumcision in full term, singleton, male neonates (n = 6 per group). Tissue was homogenized, RNA isolated, and a NanoString code set run to quantify a panel of genes related to glucose metabolism and adipogenesis, as well as housekeeping genes. **RESULTS:** Peroxisome proliferator-activated receptor alpha (<6K: 86.4±9.2 vs. >6K: 59.4±5.0) and cAMP responsive element binding protein 1 (<6K: 285.7±36.8 vs. >6K: 197.4±12.1), genes encoding proteins that are involved in partially regulating adipogenesis, and DNA methyltransferase 1 (DNMT1) (<6K: 132.2±6.4 vs. >6K: 112.5±3.7), a gene coding an enzyme involved in the regulation of DNA methylation patterns, were significantly decreased in the infants born to mothers with higher levels of physical activity during pregnancy (p<0.05). Adiponectin receptor 1 (<6K: 490.1±38.1 vs. >6K: 743.3±99.7), a receptor that is downregulated in obese, insulin resistant populations, and glucose transporter 1 (<6K: 88.0±15.7 vs. >6K: 153.3±13.0), a glucose transporter responsible for basal levels of glucose uptake in most cells, were significantly increased in the tissue of neonates born to mothers with higher levels of physical activity (p<0.05). **CONCLUSION:** These preliminary data suggest that low levels of physical activity during pregnancy are associated with increased gene expression of markers of adipogenesis and decreased markers involved in insulin sensitivity and glucose uptake. Further, these adaptations or other gene expression changes may be epigenetically regulated as DNMT1 levels were significantly lower in the lower physical activity group.

Exercise Training Alters Expression of Acid Sensing Ion Channels (ASICs) in Sensory Pathways

Tahsin Khataei[1], Anne Marie S. Harding[2], Mahyar Janahmadi[3], Hamid Agha alinejad[1], Christopher J. Benson[2]. *[1]Tarbiat Modares University, Tehran, Iran, Islamic Republic of. [2]University of Iowa, Iowa city, IA. [3]Shahid Beheshti University of Medical Sciences, Tehran, Iran, Islamic Republic of.*
(No relevant relationships reported)

Exercise is an effective therapy for numerous pathological conditions that are associated with elevated metabolites and inflammatory factors. These chemicals can activate receptors on peripheral sensory neurons, such as Acid Sensing Ion Channels (ASICs) and Transient Receptor Potential Vanilloid 1 (TRPV1). High-intensity exercise can induce release of protons, metabolites, and inflammatory factors, which are known to activate ASICs and TRPV1 and elicit reflex-mediated changes in hemodynamics and respiration, as well as pain perception and fatigue.
Purpose: Does exercise training alter the expression of ASICs and TRPV1 in skeletal muscle afferents and carotid body (CB)?
Methods: Female C57BL/6 mice were divided into sedentary (SED), low intensity training (LIT) and high intensity interval training (HIIT) groups. HIIT was trained on treadmill every other day for 4 weeks (4 bouts of 6 min intervals at 80-90% of

maximum velocity (V_{max}) with 4 min of active rest), whereas LIT trained at 40-50% of V_{max} for the same distance. SED mice were placed on the treadmill for similar periods of time. After 4 weeks, all groups underwent an incremental treadmill test for maximal exercise performance. Lumbar dorsal root ganglia (DRG) and CB were collected 48 hrs after maximal exercise, and mRNA levels of ASICs and TRPV1 determined by RT-qPCR.
Results: HIIT had higher exercise performance (V_{max}, time to exhaustion and workload) compared to LIT and SED (p ≤ 0.05), while there was no significant difference between LIT and SED groups. Body composition, as measured by NMR, did not change significantly between groups after 4 weeks of training. HIIT showed reductions (p ≤ 0.05) of ASIC1b, ASIC2, ASIC3, TRPV1 mRNA levels in DRG, as well as reductions (p ≤ 0.05) in ASIC1b, ASIC2 in CB compared to SED. Paradoxically, LIT showed an upregulation (p ≤ 0.05) of ASIC3 and ASIC1a in DRG and CB.
Conclusion: HIIT improves exercise performance and lowers ASICs and TRPV1 mRNA in sensory pathways. We suggest that ASICs and TRPV1 downregulation could contribute to enhanced exercise performance by diminishing sensations of pain and fatigue. Diminishment of these sensory pathways might contribute to the benefits of exercise in disease conditions by reducing deleterious sympathoexcitation and associated inflammation.

Functional Brain Plasticity Following Physical Training in Amnestic Mild Cognitive Impairment: A Neuroimaging Study

Tamir Eisenstein, Galit Yogev-Seligmann, Nir Giladi, Elissa Ash, Talma Hendler, Yulia Lerner. *Tel Aviv Sourasky Medical Center, Tel Aviv, Israel.*
(No relevant relationships reported)

Amnestic mild cognitive impairment (aMCI) is the typical prodromal stage of Alzheimer's disease (AD). To date, pharmacological treatments in aMCI are of modest efficacy. Evidence suggest that physical exercise may promote structural and functional brain changes in healthy adults and clinical settings. However, the extent to which comparable effects can be observed in aMCI remains unclear. **PURPOSE:** Identify brain mechanisms underlying neurocognitive effects of aerobic training in aMCI. **METHODS:** 23 subjects with aMCI (age 70.9±5.6) were assigned to aerobic (AT, n=11) or balance and coordination (BAC, n=12) groups. Intervention lasted 16 weeks, 3 sessions/week. AT intensity gradually increased to 70-80% of heart rate reserve (HRR), while BAC was kept below 30%. HRR and peak oxygen consumption (Vo2peak) were determined using cardiopulmonary exercise test. Subjects underwent fMRI sessions, evaluating neural pattern during tasks, known to be sensitive in aMCI (i.e. face-name associative memory and processing of complex auditory information). Neuropsychological assessments were performed to evaluate changes in cognitive domains including verbal and spatial memory, and executive functions. **RESULTS:** Increased activity in bilateral hippocampi was found in the AT group post intervention (p<0.007), while increased activity in left fusiform gyrus was shown in the BAC group (p<0.008), during memory encoding. During information processing, both groups demonstrated increased responses in high-order cognitive and language areas (e.g. temporo-parietal junction and inferior frontal gyrus), representing greater resemblance to normal aging patterns, compared to pre-training [q(FDR)<0.05]. Changes in Vo2peak were correlated with changes in executive functions in the AT group, including semantic verbal fluency (r=0.819, p<0.002) and phonemic verbal fluency (r=0.611, p<0.03). Improvements in immediate recall (normalized Z-score change 0.74±0.89, p<0.015) and delayed recall (0.71±0.71, p<0.005) of verbal information (1st & 8th repetitions of the Rey auditory verbal learning test) were demonstrated in the BAC group. **CONCLUSION:** Both aerobic and non-aerobic (low-intensity balance and coordination) training modalities may promote neuroplastic changes in older individuals with aMCI and high risk of AD.

The Impact of Imperceptible Vibratory Noise on the Spinal Motor Reflex

Matthew S. Tenan, Maxwell Alander, Courtney A. Haynes, Antony D. Passaro. *U.S. Army Research Laboratory, Research Triangle Park, NC.*
(No relevant relationships reported)

Imperceptible noise stimulation has been shown to increase agility, stability and decrease muscle tremor. Previous research has shown that this effect is mediated via decreases in motor unit discharge variability and decreased motor unit synchronization. However, whether these motor unit effects arise from a spinal or cortical mechanisms is unknown and may change how these technologies are implemented to enhance human performance.
PURPOSE: Determine the effect of imperceptible vibratory noise on the spinal motor reflex (Hoffman Reflex).

METHODS: 12 males participated in the collection of a Hoffman reflex (H-reflex) recruitment curve and underwent either a randomized STIM (noise applied) trial or SHAM (control). The H-reflex recruitment curve was obtained from the median nerve of the subject's dominant arm. The intensity that elicited the onset of the M-wave was used to standardize the H-reflex stimulation intensity. The STIM trial was performed by introducing a random imperceptible vibratory noise 3 seconds before the collection of the H-reflex. The test was repeated for a total of 10 stimulations with six seconds of rest between stimulations. The resulting H-reflex amplitudes were then normalized to the maximal M-wave (Mmax) found during the H-reflex recruitment curve. Data were assessed with a generalized estimating equation, clustering for multiple observations. **RESULTS**: The H-reflex was 19.1% (SE±2.42) of Mmax in the STIM trials and 17.4% (SE±2.66) in the SHAM trials, showing a significant increase of 1.73% with STIM ($p = 0.0016$). **CONCLUSIONS**: Subjects showed an increase in spinal excitability while undergoing STIM. The results demonstrate that the spinal reflex plays a role in the motor adaptation response to imperceptible vibration. This increase in spinal excitability suggests that the performance benefits of imperceptible noise stimulation may have a rapid onset, on the order of 10-20 milliseconds, in contrast to cortical mechanisms which are greater than 100 milliseconds. Determining which motor centers mediate the behavioral response to noise stimulation, and to what degree, will help define the optimal parameters for the application of noise stimulation.

Aerobic Exercise and Cerebral White Matter Integrity in MCI Patients: A 1-Year Randomized Controlled Trial

Takashi Tarumi[1], Binu P. Thomas[1], Ciwen Wang[2], Tsubasa Tomoto[2], Evan Pasha[2], Rong Zhang[1]. [1]The University of Texas Southwestern Medical Center, Dallas, TX. [2]Texas Health Presbyterian Hospital Dallas, Dallas, TX.
(No relevant relationships reported)

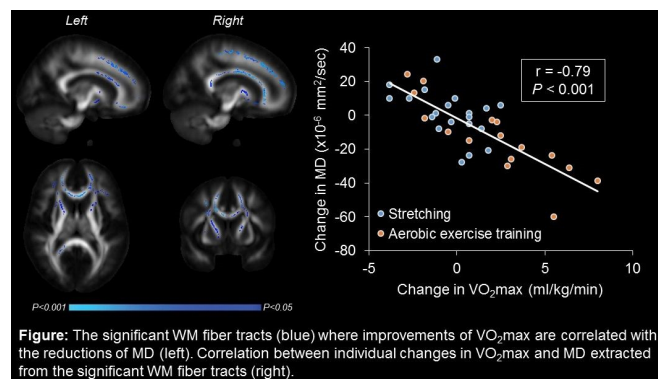
Cerebral white matter (WM) represents the structural substrate of neuronal communications and is damaged in dementia patients. Aerobic exercise training (AET) may improve cerebral WM integrity in healthy older adults, but its effect in populations at risk for dementia remains unclear. **PURPOSE:** To determine the effect of AET on cerebral WM integrity in patients with amnesic mild cognitive impairment (MCI) **METHODS:** We conducted a 1-year, single-blinded, parallel randomized controlled trial of AET and stretching intervention programs in patients with MCI. At baseline and post intervention, diffusion tensor images (DTI) were acquired to estimate fractional anisotropy and mean diffusivity (MD) that are analyzed by tract-based spatial statistics (TBSS) and compared among the major WM fiber tracts. High-resolution T1-weighted images were also acquired to measure the volumes of cerebral WM and WM hypointensities. Maximal oxygen consumption (VO$_2$max) was measured at pre and post intervention. **RESULTS:** Thirty-six MCI patients completed AET (n=16) or stretching (n=20) program with the baseline and post-intervention MRI scans. After intervention, participants in AET program improved VO$_2$max while those in stretching group showed slight declines (time × treatment: $P=0.008$). The volumes of WM and WM hypointensities did not show treatment effects over time (time × treatment: $P>0.05$). However, TBSS analysis demonstrated that improvements of VO$_2$max with AET are correlated with the reductions of MD among the major WM fiber tracts (Figure). **CONCLUSIONS:** In patients with amnesic MCI, AET did not improve cerebral WM volume and integrity between the intervention and control groups. However, individual improvements of VO$_2$max were associated with the reductions of MD. These findings suggest that benefits of AET on cerebral WM integrity depend on the magnitude of cardiorespiratory fitness gains. *This study was supported by the NIH (R01AG033106 and K99HL133449).*


Figure: The significant WM fiber tracts (blue) where improvements of VO$_2$max are correlated with the reductions of MD (left). Correlation between individual changes in VO$_2$max and MD extracted from the significant WM fiber tracts (right).

2534   June 1 2:00 PM - 2:15 PM

Aerobic Exercise Regulates Synaptic Transmission by Attenuating Oxidative Stress in the Paraventricular Nucleus of Spontaneously Hypertensive Rats

Li ZHAO, Yan LI, Boya GU, Yuanyuan LV. *Beijing Sport University, Beijing, China.*
(No relevant relationships reported)

PURPOSE: Synaptic transmission in the hypothalamic paraventricular nucleus (PVN) plays a key role in the control of sympathetic outflow. Whether exercise training associated with reduced sympathetic activity and oxidative stress in hypertension is implicated in changes in sympathetic drive in the PVN remain unclear.
METHODS: In the present study, spontaneously hypertensive rats (SHRs) were subjected to exercise training for 8 weeks, five times per week, and Westar Kyoto (WKY) rats as cohort control. Miniature excitatory and inhibitory postsynaptic currents (mEPSCs and mIPSCs) were recorded from PVN in *ex vivo* hypothalamic slice preparations obtained after the last training, and biomarkers of oxidative stress and physical indexes were observed.
RESULTS: The mean frequency and amplitude, as well as the rise time and the decay time constant of mIPSCs, were significantly decreased in 20-wk-old SHRs compared with WKY 20-wk-old controls. In contrast to mIPSCs, only the mean mEPSCs frequency was higher, and there were no other changes in mEPSCs in comparison to the control group. SHRs exhibited higher ROS, 8-OHdG, and MDA, and lower SOD1, SOD2, CAT, Ogg1, and SOD activity, CAT activity in the PVN. These SHRs also had a significant increase in heart rate, blood pressure and sympathetic nerve activity, and higher levels of norepinephrine (NE). Exercise training ameliorated all these changes, resulting in an increase in the mean frequency, amplitude and the kinetics of mIPSCs, accompanied by a decrease in the mean frequency of mEPSCs in the PVN.
CONCLUSIONS: This study demonstrates that moderate intensity, high frequency exercise training induces antioxidant-related adaptations in the PVNs of SHRs, which in studies resulted in a selective enhancement of inhibitory synaptic transmission partly to recue autonomic nerves and reduce blood pressure in hypertension.

2535   June 1 2:15 PM - 2:30 PM

Effect of Acute Exercise on Salience Network Functional Connectivity and Affect in Healthy Older Adults

Alfonso J. Alfini[1], Lauren R. Weiss[2], Junyeon Won[2], Corey Michelson[2], Daniel Callow[2], Caroline Simon[2], Adam P. Spira[1], J. Carson Smith, FACSM[2]. [1]Johns Hopkins University, Baltimore, MD. [2]University of Maryland, College Park, MD. (Sponsor: Dr. J. Carson Smith, FACSM)
(No relevant relationships reported)

Mood and anxiety disorders are the most prevalent mental disorders among older adults and are associated with poor health outcomes. Exercise may be a useful means of treating or preventing these disorders, but the mechanism by which it does so is unclear. The salience network (SN), which connects the prefrontal cortex with several limbic brain regions, plays a primary role in emotion regulation. While several cross-sectional studies have demonstrated a link between increased SN resting-state functional connectivity (SN-RSFC) and mood and anxiety symptoms, none have examined the effect of acute aerobic exercise on SN-RSFC and affective measures in a sample of healthy older adults.
PURPOSE: To determine the effect of acute aerobic exercise on self-reported affect and SN-RSFC among healthy older adults. We hypothesized that exercise would enhance positive affect and decrease negative affect and SN-RSFC.
METHODS: Using a crossover repeated measures design, 21 participants (mean ±SD = 65.6 ±8.0; range 55-85) completed two study visits with 30-min of moderate-intensity bicycle exercise or seated rest, immediately followed by a resting-state fMRI scan. They completed the Positive and Negative Affect Schedule before and after each condition. We performed a seed-based analysis (AFNI v.17.3.01; seeds = L and R insula; 34, 22, -2) to determine changes in SN-RSFC.
RESULTS: Compared to rest, 30-min of moderate-intensity exercise increased positive affect ($p = 0.015$) and led to notable, but non-significant, decreases in negative affect ($p = 0.059$). Exercise also significantly decreased SN-RSFC in three limbic brain regions: L hippocampus, L amygdala, and L middle temporal gyrus ($p < 0.01$).
CONCLUSIONS: Acute aerobic exercise enhanced positive affect and decreased SN-RSFC in healthy older adults. Results suggest that exercise-induced changes in functional connectivity within the brain's salience network may drive the effects of exercise on mood and anxiety in this population. Further studies are needed to test different doses of acute and chronic exercise on these outcomes.

Probing the Therapeutic Potential of Brain Stimulation for Functional and Corticospinal Deficits Following Traumatic Musculoskeletal Injury

Shawn Flanagan. *University of Pittsburgh, Pittsburgh, PA.*
(Sponsor: WIlliam Kraemer, FACSM)
(No relevant relationships reported)

Background: Traumatic anterior cruciate ligament (ACL) rupture can lead to bilateral deficits in balance, skilled movement, and force production. Such deficits persist for years independent of knee musculature or joint translation. Recently, others have demonstrated reduced cortical sensorimotor excitability and hemodynamic activity in conjunction with increased cortical inhibition and normalized spinal inhibition. The consequences of traumatic musculoskeletal injury (MSI) appear to extend to the brain, with maladaptive neuroplasticity contributing to disability. Non-invasive brain stimulation (NIBS) represents a promising strategy to modulate corticospinal activity after traumatic MSI, but therapeutic efficacy is untested. **Objective:** To examine the influence of NIBS on behavioral and neurophysiological activity after ACL rupture. **Methods:** Twenty women participated in a randomized, sham-controlled, double-blind, cross-over study. Nine experienced traumatic ACL rupture and reconstruction within five years of the study (ACL: N=9, age 20.6±2.3yr, height 166.1±8.0cm, weight 68.1±9.1kg). Eleven matched participants with no history of lower body injury served as controls (CON: N=11, 20.3±1.4yr, 165.0±5.3cm, 65.7±8.4cm). Participants completed a familiarization visit followed by two treatment visits with active or sham intermittent theta-burst stimulation (iTBS) applied to the injured (or non-dominant) motor cortex (M1) leg representation. Voluntary activation, force production, and corticospinal dynamics were examined. **Results:** The protocol was well tolerated. Active stimulation increased voluntary activation (4.2±1.4%, $p = 0.01$), relative force (44.22±14.21N, $p = 0.01$), and MEP amplitude (10.9±3.1%, $p = 0.00$) in the injured leg. Stimulation normalized superimposed twitch force (0.28±3.02N, $p = 0.93$) and contralateral silent period duration (-10.91±5.13ms, $p = 0.05$). **Conclusions:** One bout of NIBS was sufficient to normalize behavioral and corticospinal dysfunction 3.2±1.1yr after MSI, with distinct effects on the interhemispheric motor system network. Future work on the effects of repeated treatments, injury characteristics, and timing is needed. Nevertheless, traumatic MSI may be added to the list of conditions with neurological aspects responsive to NIBS.

2537   June 1 2:45 PM - 3:00 PM

Are Exercise Effects on Valence-Modulation of the Acoustic Startle Eyeblink Response Trait Dependent?

Kathryn Elizabeth Wilson[1], Jianchun Yin[2], Rodney King Dishman, FACSM[3]. *[1]University of Nebraska Medical Center, Omaha, NE. [2]Shanghai Normal University, Shanghai, China. [3]University of Georgia, Athens, GA.* (Sponsor: Rodney K. Dishman, FACSM)
(No relevant relationships reported)

Studies using objective probes for emotional state conclude no effect of exercise on affective processing. However, these studies fail to control for trait differences in sensitivity to affective cues and have been primarily restricted to prescribed (rather than self-selected) exercise intensities. It is possible that effects of exercise on affective processing of appetitive and aversive stimuli are moderated by motivational dispositions (approach/avoidance) reflective of individual differences in functioning of neural systems responsible for behavioral inhibition and behavioral activation (BIS/BAS traits). It is also possible that effects are influenced by perceived control of the exercise intensity.
PURPOSE: This laboratory experiment tested the hypotheses that 1) changes in sensitivity to emotional stimuli would manifest for those stimuli to which one is naturally predisposed to attend (i.e., aversive stimuli for BIS-dominant, and appetitive stimuli for BAS-dominant individuals), and 2) effects would be enhanced following exercise at a self-adjusted intensity.
METHODS: We examined valence-modulation of the acoustic startle eyeblink response during affective picture viewing before and after moderate intensity exercise with and without the opportunity to adjust intensity, or quiet rest among 58 undergraduates scoring high or low for BIS/BAS traits.
RESULTS: A 4 way mixed-model ANOVA indicated a main effect for valence [$F(2, 108) = 16.21$, $p < .01$, $\eta^2 = .23$, $\varepsilon = .97$], consistent with expected effects of picture content. There were no effects of personality group ($p \geq .18$, $\eta^2 \leq .08$). Helmert contrasts revealed a 3-way quadratic interaction between valence, condition and time [$F(1, 54) = 6.2$, $p = .02$, $\eta^2 = .10$]. Follow-up RM-ANOVAs revealed a quadratic valence X time interaction during the prescribed exercise condition [$F(1, 57)=7.38$, $p=.01$, $\eta^2 = .12$]; the reduction in ASER magnitude in response to neutral stimuli was greater than that in response to unpleasant or pleasant stimuli. These effects were not observed in the adjustable exercise or control conditions.
CONCLUSIONS: Results confirm that cycling exercise does not alter emotional response to affective pictures, regardless of motivational disposition, and extend the evidence to conditions in which participants can alter the exercise intensity.

Effect Of Forefoot Type On Self-reported Pain In Minimalist and Traditionally Shod Runners

Jean L. McCrory, FACSM[1], Lauren K. Cline[1], Erica Casto[2], Kyla M. Galbreath[1]. *[1]West Virginia University, Morgantown, WV. [2]University of Massachusetts, Amherst, MA.*
(No relevant relationships reported)

Distance running is a popular recreational activity despite high rates of overuse injury. The efficacy of wearing minimalist shoes to prevent injury has been debated. We previously reported that minimalist runners are more likely to experience site-specific lower extremity pain; however, no clear relationship has been established between shoe type, forefoot (FF) shape (Egyptian, Morton's, or square), and pain. Therefore, the **purpose** of this study is to examine self-reported pain in the lower limbs in minimalist and traditionally shod runners with various forefoot types. **Methods:** Following consent, 48 experienced runners (age: 27.5 ±9.3 yrs, hgt: 172.2 ±10.2 cm, mass: 70.6 ±15.6 kg, gender: 18M/30F) who reported running at least 10 miles a week for the past three months, completed a visual analog scale (VAS) about pain they experience in five common sites of injury: knee, ankle, calf, shin, and foot. A score of ≥ 3 on the VAS was considered pain. Shoes were categorized as either minimalist (n=40 feet, midsole drop <4mm) or traditional (n=56 feet, midsole drop>4mm). Superior view photographs were taken of the FF and were categorized as Egyptian (EF) (n=73 feet, typical foot with Hallux the most distal toe), Morton's (MF) (n=10 feet, 2nd toe longer than Hallux), or square (SQ) (n=13 feet, Hallux and 2nd toe equal length). Separate three-factor chi-square analyses determined if shoe type (minimalist, traditional) and forefoot type (EF, MF, SQ) were related to pain (yes, no). (α=0.05). **Results:** More minimalist runners with EF reported pain (61.8%; p=0.004) when compared to MF (50%) or SQ (20%). More minimalist runners with EF reported calf pain (77.8%; p=0.028) than those with MF (0%) or SQ (20%). FF type did not relate to pain at any other site. **Conclusion:** Runners with EF are more likely to report pain in at least one location, and specifically in the calf, than runners with other FF shapes when wearing minimalist vs traditional shoes. Minimalist shoes encourage the runner to strike the ground with the forefoot; however, this requires more eccentric loading of the calf musculature and Achilles tendon. Our minimalist runners with EF reported more calf pain than those with other FF types. Other FF types may be better able to absorb the foot contact and muscle forces better than a more typical foot when wearing minimalist shoes.

Sagittal Plane Gait Mechanics are Associated with Femoral Cartilage Thickness After ACL Reconstruction

Derek N. Pamukoff[1], Tyler J. Moffit[1], Michael N. Vakula[2], Skylar C. Holmes[1], Steven A. Garcia[1], Melissa M. Montgomery[1]. *[1]California State University, Fullerton, Fullerton, CA. [2]Utah State University, Logan, UT.* (Sponsor: Daniela Rubin, FACSM)
(No relevant relationships reported)

Individuals with ACL reconstruction (ACLR) are at greater risk for knee osteoarthritis (OA) due to aberrant walking biomechanics. Cartilage morphology is typically imaged using magnetic resonance imaging, but ultrasonography may provide a cost-effective alternative method. **PURPOSE**: To evaluate the association between sagittal plane knee mechanics and femoral cartilage thickness in individuals with ACLR. **METHODS**: 33 individuals with primary unilateral ACLR (age=22.2±2.9 years; body mass index=24.2±4.5 kg/m²; time since ACLR=55.8±31.6 months; 73% Female; IKDC=85.7±9.5; 16 patellar tendon; 8 hamstring tendon; 9 allograft) participated in this study. Femoral cartilage thickness was assessed at the medial (MC) and lateral (LC) femoral condyle, and intercondylar (IC) notch using ultrasonography in 140° of knee flexion. Participants completed 5 walking trials at a self-selected speed while striking consecutive force plates, and data were extracted from the first 50% of stance phase. Kinematic variables included the peak knee flexion angle (KFA), knee flexion angle at heel contact (KFHC), and knee flexion excursion (KFE). Kinetic variables included the peak external knee flexion moment (KFM) and angular impulse (KFI). Partial correlation adjusted for gait speed and time since ACLR was used to analyze the relationship between ultrasound and gait variables (α=0.05). **RESULTS**: After adjusting for gait speed and time since ACLR, greater KFI was associated with thicker MC cartilage (r=0.46, p=0.006). Trends were observed between greater KFI and

thicker LC cartilage (r=0.26, p=0.08) and thicker IC cartilage (r=0.28, p=0.07). Larger KFE was associated with thicker MC cartilage (r=0.34, p=0.04), thicker LC cartilage (r=0.39, p=0.02), and thicker IC cartilage (r=0.38, p=0.02). Larger KFA was associated with thicker MC cartilage (r=0.29, p=0.05) and thicker IC cartilage (r=0.36, p=0.03). No relationships were found between cartilage thickness measures and KFHC or KFM. **CONCLUSIONS**: These data suggest that sagittal plane knee mechanics during gait are associated with thicker femoral cartilage in individuals with ACLR. Knee flexion is used to attenuate ground reaction force during gait. As such improving sagittal plane knee mechanics during gait may alleviate knee OA risk in individuals with ACLR.

Intrinsic and Extrinsic Muscle Function in Rearfoot Strikers During Barefoot and Shod Treadmill Running

Summer Neborsky, Monika Patel, Nathan Ratner, Kahleigh Quinn, Thomas Martin, Juan C. Garbalosa. *Quinnipiac University, Hamden, CT.*

(No relevant relationships reported)

Barefoot/minimalist running is theorized to cause an increase in the activity of intrinsic and extrinsic foot muscles. Although studies have shown an increase in the activity of extrinsic foot muscles during barefoot running very little data exists documenting the effects of barefoot running on intrinsic foot muscles. **PURPOSE**: To compare the activity of select extrinsic and intrinsic muscles during barefoot and shod running in rearfoot strikers.
METHODS: A convenience sample of 21 recreational runners were assigned to run both shod and barefoot in a random order. Electrodes were placed on the subjects' dominant lower extremity over the peroneus longus (PL), tibialis anterior (TA), and abductor hallucis (AH) muscles. Subjects participated in a treadmill running protocol consisting of running at 8.0 and 9.7 kph while lower extremity kinematics and electromyographic (EMG) activity of the muscles were recorded using an 8 camera motion analysis system in both footwear conditions. The EMG data were filtered with a fourth order, band pass filter with 10 and 350 Hz cutoffs. Using a 250 ms window, the root mean square (RMS) of the filtered data was obtained. The RMS was normalized to the peak EMG activity of the 8.0 kmh barefoot trials. Using the marker displacement data, the stance phases of the amplitude normalized 9.7 kmh trials were extracted. The average RMS value of the PL, TA, and AH during the stance phase of these trials were obtained and grouped according to running speed and muscle. A two factor, fixed effects ANOVA model was used to determine the effect of footwear condition and muscle on the mean RMS values.
RESULTS: The mean (± 1 S.E.) amplitude normalize RMS value during the barefoot condition for the TA, PL, and AH was 50 (± 4.7), 109 (± 17.9), and 123 (± 18.4) percent, respectively. During the shod condition the mean (± 1 S.E.) amplitude normalize RMS value for the TA, PL, and AH was 52 (± 6.1), 103 (± 17.3), and 130 (± 16.8). A significant effect was noted only for muscle (p < .001). Both the PL and the AH exhibited significantly greater activity than the TA in both the shod and barefoot conditions. A significant effect of footwear condition was not present (p = .923).
CONCLUSIONS: In rearfoot strikers, footwear does not appear to affect the EMG activity of the TA, PL, or AH.

Barefoot Gait Adaptations Remain With Use of the Barefoot Orthotic

Melissa Thompson[1], Christopher Bent[1], Kelsey Pryor[1], Kristine Hoffman[2]. *[1]Fort Lewis College, Durango, CO. [2]Denver Health Medical Center, Denver, CO.*

(No relevant relationships reported)

Orthotics are used to treat a number of foot and ankle pathologies, but require the use of supportive footwear. Alternatively, the barefoot condition enhances sensation from the plantar foot leading to gait adaptations that may influence injury prognosis and incidence. Recently, a barefoot orthotic (Hozhoni Balance Rail®) was designed to adhere to the plantar surface rather than being secured inside footwear; thus, potentially allowing for the benefits of the barefoot gait, while also providing the stability of an orthotic. **PURPOSE:** To determine if the commonly observed barefoot gait adaptations were found when walking and running with the barefoot orthotic. **METHODS**: 12 healthy habitually shod runners (7 men and 5 women, age: 25 ± 3.8 yr; height: 1.58 ± 0.15 m; mass: 68.1 ± 8.9 kg) participated in this study. Gait kinematics and kinetics were analyzed as participants performed 10 over-ground trials of running and walking in running shoes (SHOD), barefoot (BF), and while wearing the barefoot orthotics (BF ORTHO). Kinematic data was obtained via 3D motion analysis and ground reaction force (GRF) data were captured as subjects ran across a runway with an embedded force plate. Kinematic and kinetic differences between the SHOD, BF and BF ORTHO conditions for both walking and running were analyzed using repeated measures ANOVA tests. **RESULTS**: There were no significant differences between the BF and BF ORTHO conditions in terms of gait kinematics or kinetics in either walking or running, indicating that the barefoot orthotic does not interfere with the natural barefoot gait. Consistent with previous research,

subjects exhibited decreased stride lengths in the BF and BF ORTHO conditions when walking (BF: 1.38±0.20 m, BF ORTHO: 1.43±0.19 m, SHOD: 1.54±0.17 m, p<0.05 compared to SHOD) and running (BF: 1.98±0.27 m, BF ORTHO: 2.06±0.30 m, SHOD: 2.16±0.31 m, p<0.05 compared to SHOD). Additionally, the BF and BF ORTHO conditions were associated with reduced peak vertical GRFs in walking (BF: 1.16±0.10 m, BF ORTHO: 1.19±0.12 m, SHOD: 1.29±0.11 m, p<0.05 compared to SHOD) and running (BF: 2.29±0.26 m, BF ORTHO: 2.27±0.21 m, SHOD: 2.48±0.22 m, p<0.05 compared to SHOD). **CONCLUSION**: The barefoot orthotic does not interfere with the natural barefoot gait, indicating the potential for clinical use while barefoot or without supportive footwear.

The Influence of Maximal Running Shoes on Biomechanics Prior to and Following a 5K Run

Christine D. Pollard, Justin Ter Har, JJ Hannigan, Marc F. Norcross. *Oregon State University-Cascades, Bend, OR.*

(No relevant relationships reported)

Lower extremity injuries are a common occurrence among runners. Recent footwear trends have included minimal and maximal running shoe types. Maximal running shoes are unique because they provide the runner with a highly cushioned midsole in both the rearfoot and forefoot. Little is known about how maximal shoes influence running biomechanics. **PURPOSE**: To examine the influence of maximal running shoes on biomechanics prior to and following a 5K run as compared to neutral running shoes. **METHODS**: : Fifteen female runners participated in two testing sessions (neutral shoe session and maximal shoe session) with 7-10 days between sessions. Three-dimensional kinematics and kinetics were collected while subjects ran along a 10 meter runway. After five running trials, they completed a 5K treadmill run, and then completed five additional running trials. Variables of interest included impact peak of the vertical ground reaction force, loading rate, and peak eversion. Differences were determined by using a series of two-way repeated measures ANOVA models (shoe x time). **RESULTS**: There was a significant main effect for shoe type for impact peak and loading rate. Comparing the neutral shoe to the maximal shoe prior to and following running a 5K, subjects exhibited an increased loading rate [(pre-neutral: 60.83 BWs/sec; pre-maximal: 81.15 BWs/sec) p=0.000, (post-neutral: 61.22 BWs/sec; post-maximal: 79.10 BWs/sec) p=0.008], and increased impact peak [(pre-neutral: 1.58 BWs; pre-maximal: 1.76 BWs) p=0.004, (post-neutral: 1.55 BWs; post-maximal: 1.79 BWs) p=0.003] in the maximal shoe condition. There were no shoe-time interactions and no significant findings for peak eversion. **CONCLUSIONS**: Runners exhibited increased impact forces and loading rate when running in a maximal versus neutral shoe. Since increases in these variables have been associated with an increased risk of running related injuries, runners who are new to running in a maximal shoe may be at an increased risk of injury. Therefore, runners should be cautious when switching from a neutral shoe to a maximal shoe; however, further work is necessary to better understand the longer-term impact.

Kinematics And Muscle Activity While Running In Minimalist, Neutral, And Ultra-cushioning Shoes

James Becker[1], Brianne Borgia[2]. *[1]Montana State University, Bozeman, MT. [2]University of Nevada, Las Vegas, Las Vegas, NV.*

(No relevant relationships reported)

While several studies have compared muscle activity in minimalist and traditional running shoes, to date it is unknown how muscle activity changes when running in ultra-cushioning shoes. **PURPOSE:** To evaluate differences in kinematics and muscle activity while running in minimalist (Min), traditional (Trad), and ultra-cushioning (Ultra) shoes. **METHODS:** Participants included 13 runners (sex: 5 M; 8 F; age: 22 ± 5.4 years). Whole body kinematics were recorded using a 12-camera motion capture system while participants ran in each shoe. Ankle, knee, and hip range of motion (ROM) during stance phase were calculated in all three planes. Muscle activity was recorded from seven lower extremity muscles. Differences in kinematics and average root mean square (RMS) amplitude during stance were evaluated using one-way repeated measures ANOVAs. **RESULTS:** Mean values for variables with significant differences are shown in Table 1. Post hoc comparisons revealed hip internal rotation ROM was higher in the Ultra shoes than in either the Trad (p=.033) or Min (p=.047) shoes. Ankle dorsiflexion ROM was lower in the Ultra shoes than in either the Trad (p=.007) or Min (p=.038) shoes. Mean gluteus medius RMS was higher in the Ultra shoes than in either the Trad (p=.013) or Min (p= .017). Mean RMS for the tibialis anterior was also higher in the Ultra shoes than in either the Trad (p=.033) or Min (p=.029). Finally, mean RMS for the peroneus longus was higher in the Ultra shoes than the Trad shoes (p=.046). **CONCLUSION:** The minor differences in kinematics suggest individuals maintained their preferred movement path in all three shoes. However, the increased muscle activity may indicate the neuromuscular system was working harder to maintain the preferred path in the Ultra shoes.

Table 1. Mean (± standard deviation) for variables which were significantly different between shoe conditions. *F* and *p* values refer to omnibus tests. For post hoc values see text.

	Min	Trad	Ultra	$F_{2,24}$, p
Hip int. rotation ROM (°)	7.0 ± 5.6	6.4 ± 4.4	8.4 ± 5.9	4.82, .017
Ankle dorsiflexion ROM (°)	20.8 ± 3.6	20.7 ± 4.2	18.3 ± 3.7	6.69, .005
Mean GM RMS (mV)	3.6 ± 1.2	2.6 ± 0.7	6.5 ± 2.4	5.15, .014
Mean TA RMS (mV)	6.4 ± 3.1	5.0 ± 4.6	7.1 ± 4.5	4.50, .036

2545   June 1 2:30 PM - 2:45 PM

Sex and Speed Influence Frontal Plane Kinematics During Running

Mikel R. Stiffler-Joachim, Herman J. Feller, Christa M. Wille, Bryan C. Heiderscheit. *University of Wisconsin - Madison, Madison, WI.*

(No relevant relationships reported)

Frontal plane mechanics, such as hip adduction angle and base of gait (BOG), have been implicated as causes for running-related injuries such as iliotibial band syndrome and patellofemoral pain. While modification of frontal plane variables may be a way to alter injury risk, the effect of speed and sex on frontal plane mechanics has not been investigated. Describing these effects may facilitate more appropriate prescription of gait retraining to reduce injury risk. **PURPOSE**: To determine the influence of sex and speed on frontal plane kinematics during running. **METHODS**: Whole body kinematics and ground reaction forces were collected for 99 NCAA Division I collegiate athletes (52 males) during treadmill running at 2.68, 3.35, and 4.47 m/s. Athletes were healthy at time of testing and had no history of lower extremity surgery. BOG at midstance (cm), hip adduction at initial contact (ADD_{IC}, deg), peak hip adduction (ADD_{PK}, deg), and peak contralateral pelvic drop (PEL_{PK}, deg) for the right limb were compared between sex and speed using 2-way repeated measures ANOVAs. **RESULTS**: A significant sex by speed interaction (p < 0.01) for BOG was observed. BOG decreased significantly (p < 0.01) with speed for both sexes. Females exhibited larger BOG than males at 3.35 and 4.47m/s (females: 0.6 ± 1.5 cm and -0.1 ± 1.5 cm, males: 0.2 ± 2.4 cm and -0.9 ± 2.5 cm for 3.35 and 4.47 m/s, respectively). No significant interactions (p ≥ .40) were observed for ADD_{IC}, ADD_{PK}, or PEL_{PK}. There was a significant speed main effect for ADD_{IC}, ADD_{PK}, and PEL_{PK}. ADD_{IC} and ADD_{PK} increased significantly with speed (p < 0.01). PEL_{PK} at 2.68m/s was significantly less than 3.35 and 4.47m/s (p < 0.01, mean difference = 0.5 deg). Females demonstrated greater ADD_{IC} and ADD_{PK} than males (p < 0.01, mean difference = 2.0 deg for both ADD_{IC} and ADD_{PK}). **CONCLUSIONS**: Females demonstrate a wider BOG than men at faster running speeds. Females also demonstrate greater hip adduction than men at the same running speed. As a result, both sex and speed must be considered when assessing frontal plane kinematic variables, particularly with regard to identifying excessive motion which may be related to injury.

2546   June 1 2:45 PM - 3:00 PM

Lower Extremity Strength & Kinematic Variability in Healthy Runners During a Prolonged Run: Preliminary Analysis

Amanda Estep[1], Steven Morrison[2], Shane Caswell[1], Nelson Cortes[1]. *[1]George Mason University, Manassas, VA. [2]Old Dominion University, Norfolk, VA.*

(No relevant relationships reported)

BACKGROUND: To date limited studies incorporating prolonged runs in healthy runners have produced conflicting results. Furthermore, kinematic variability of the ankle, knee and hip have not been assessed, nor has hip strength been measured simultaneously. Rather previous studies have focused on foot contact angle variability and stride time variability.
PURPOSE: To compare changes in lower limb strength & kinematic variability after a prolonged run in healthy runners.
METHODS: 7 healthy subjects (25±2.5 years, 1.77±0.12 m, 65.2±19.9 kg) volunteered for this study. Subjects ran on a motorized treadmill for an average of 44.3±1.9 minutes at a self-selected training pace. 3D kinematic data were collected after 5 minutes of running and again at the end of the run at 200Hz using reflective markers placed on the lower body with 6 infrared cameras. Variables of interest included ankle, knee and hip sagittal, frontal and transverse plane angles. Standard deviation (SD) and coefficient of variation (CV), were calculated for each dependent variable (DV) at the beginning and end of run. Approximate entropy (ApEn) was also calculated for each DV at both time intervals. Hip strength was assessed in the sagittal, frontal and transverse planes of motion before and after the run using a handheld dynamometer. Each subject performed 3 maximum voluntary isometric contractions (MVICs) for each motion. The highest number for each motion was recorded.

Additionally, heart rate (HR) and rate of perceived exertion (RPE) was recorded at the beginning and end of run. A paired samples T-test was conducted to compare all DVs. Alpha level was set at 0.05.
RESULTS: Average running speed: 2.63±.26 m/s. Only hip front plane SD was significantly different from the beginning to the end of the run (t=-2.93, p=.03). Specifically, SD increased from 7.42±1.63 to 8.21±1.44. All other DVs, including all strength measures, remained unchanged from the beginning to end of run (p>0.05).
CONCLUSIONS: Based on our preliminary results, a prolonged run had minimal impact on kinematic variability and hip strength. Despite subjects reaching a fatigued state (RPE 17; 85% HR max), each subject was able to maintain their preferred running pattern. Perhaps it is not the running time that affects kinematic variability, but the combination of both time and intensity of the run.

F-13   Free Communication/Slide - **Physical Activity, Sedentary Behavior and Health: New Epidemiologic Findings**

Friday, June 1, 2018, 1:00 PM - 3:00 PM
Room: CC-101CD

Mortality Attributable to Sedentary Behavior and Physical Inactivity in the United States

Peter T. Katzmarzyk, FACSM, Emily F. Mire. *Pennington Biomedical Research Center, Baton Rouge, LA.*

(No relevant relationships reported)

In addition to the health hazards associated with lack of moderate-to-vigorous physical activity (MVPA), sedentary behavior (i.e. sitting) has recently been identified as potential risk factor for premature mortality. **PURPOSE:** To estimate the population attributable fraction [PAF%] for all-cause mortality in the United States associated with combined categories of sedentary behavior and MVPA. **METHODS:** Data on the prevalence [P] of combined sedentary behavior and MVPA categories were obtained from self-report questionnaires in the 2013-14 U.S. National Health and Nutrition Examination Survey [N= 5,926 non-pregnant adults 18+ y of age]. Sedentary behavior was operationalized as daily sitting time in the following categories (h/day): <4, 4-5.9, 6-8, and >8. Total MET-h per week of MVPA was computed and categorized into 4 groups: ≤2.5, 2.51-16, 16.01-34.5, and ≥34.51. Hazard ratios (HRs) for all-cause mortality associated with the combined sedentary behavior and MVPA categories were obtained from a published pooled analysis of 1,005,791 adults [Ekelund et al. The Lancet 2016;388:1302-10]. The PAF% [((P[HR-1])/(P[HR-1]+1))X100] for all 16 combinations of sedentary behavior and MVPA were computed and summed across groups to determine the overall PAF% associated with sedentary behavior and physical inactivity. **RESULTS:** Population prevalence in the combined categories sitting and MVPA ranged from 2.3% to 19%, with the highest prevalence observed in the low MVPA/high sitting groups. The overall PAF% associated with sitting and physical inactivity was 25.8%. **CONCLUSION:** Approximately 26% of premature deaths in the United States can be attributable to excessive sitting and physical inactivity.

2549   June 1 1:15 PM - 1:30 PM

Physical Activity Throughout Adulthood And Medicare Expenditures In Us Adults

Diarmuid Coughlan[1], Pedro Saint-Maurice, FACSM[1], Susan Carlson[2], Janet Fulton, FACSM[2], Charles E. Matthews, FACSM[1]. *[1]National Cancer Institute, Bethesda, MD. [2]Centers for Disease and Prevention, Atlanta, GA.*

(No relevant relationships reported)

PURPOSE: To examine the relationship between moderate-to vigorous physical activity (MVPA) participation throughout adulthood and Medicare health care expenditures later in life.
METHODS: NIH-AARP Diet and Health Study respondents' data were linked to Medicare claims data (N=21,750 US adults) to estimate health care utilization and costs prospectively after age 65 yrs. The analytical cohort, retrospectively reported their MVPA participation (never/rarely, <1, 1-3, 4-7, and >7 hrs/week) for ages 15-18, 19-29, 35-39 and 43-64 years, from a single time-point prior to Medicare eligibility. 10 distinct MVPA trajectories were identified, and a two-part multivariable model was used to estimate the association between trajectories and average annual Medicare expenditures.

RESULTS: The mean number of accumulated years of health care expenditures was 6.2 years, and the average annual total health care cost was $7,813/person/year. After adjustment, average annual expenditures were lower for adults who were consistently active (i.e., 7 hrs/week MVPA throughout adulthood), aggressive improvers (i.e., very little activity during adolescent but consistent 7 hrs/week during adulthood), and with a lull in 20-30s (i.e., very active during adolescent, moderately active in 20-30s, very active in mid-life) when compared to those who did no MVPA in any life-period (i.e., consistently inactive) (See Table). Detailed sensitivity analyses did not reveal evidence of confounding or effect modification.

CONCLUSION: Adults that are consistently active or show substantial MVPA improvement throughout adulthood have lower health care expenditures after age 65. Strategies that promote physical activity throughout adulthood may help reduce Medicare expenditures.

Table: Medicare expenditures based on MVPA trajectory throughout adulthood

Trajectory (N)	Average marginal decrease (per person/year) (95% CI)	
	Age-adjusted	Multivariable
Consistently inactive (743)	Referent	Referent
Moderate improver (1,988)	-$1,116 (-$1,185, -$1,047)	-$818 (-$2061, $425)
Consistent 1hr (3,273)	-$152 (-$221, -$83)	-$48 (-$1249, $1,154)
Aggressive improver (1,168)	-$2,310 (-$2,382, -$2,237)	-$1,896 (-$3,178, -$616)
Early improver & late decliner (1,128)	-$1,044 (-$1,122, -$965)	-$819 (-$2,106, $467)
Moderate decliner (2,028)	$255 ($176, $335)	-$101 (-$1,357, $1,155)
Fast decliner (1,676)	-$319 (-$393, -$247)	-$250 (-$1,518, $1,018)
Consistently active (5,220)	-$1,421 (-$1,488, -$1,354)	-$1,165 (-$2,299, -$31)
Steady decliner (1,802)	-$37 (- $144, +$39)	-$115 (-$1,389, $1,160)
Lull in 20-30s (2,724)	-$1,607 (-$1,675, -$1,540)	-$1,423 (-$2,602, -$244)

2550   June 1 1:30 PM - 1:45 PM

Sitting Time And Quality Of Life In Office Workers Undergoing A Sedentary Behavior Intervention

Nirjhar Dutta[1], Nathan R. Mitchell[1], Sarah A. Rydell[1], Meynard L. Toledo[2], Sarah L. Mullane[2], Miranda L. Larouche[2], Matthew P. Buman, FACSM[2], Mark A. Pereira[1]. *[1]University of Minnesota, Minneapolis, MN. [2]Arizona State University, Phoenix, AZ.*
(Sponsor: Matthew P. Buman, FACSM)
(No relevant relationships reported)

PURPOSE: The purpose of this study was to investigate the association of changes in occupational sitting time and self-rated quality of life (QOL) in adult sedentary office workers undergoing a sedentary behavior intervention. **METHODS**: Data were derived from the ongoing study 'Stand & Move at Work', a group randomized trial aimed at reducing employee sedentary time through individual, environmental, and policy level changes. Physical functioning and mental health QOL scores were assessed with the SF-12 questionnaire. Sitting time (min/day) throughout the work day was assessed by the activPal accelerometer/inclinometer with seven days of continuous wear. Work logs were used to isolate sitting minutes at work. These measures were assessed at baseline and at the three month time-point during the intervention. Change over time was computed for all variables by subtracting the individual 3-month value from the baseline value. The correlations between change in sitting time and changes in physical functioning and mental health were estimated by Pearson's correlation coefficient. **RESULTS**: A total of 344 men and women were available for these analyses, of whom 24% were male and the average age was 45 +/- 11 yr. The mean baseline sitting time was 70 +/- 16% of the workday. Change in sitting time was inversely correlated with the physical functioning score (r=-0.13, p <0.05), whereas sitting time was not associated with the mental health score (r=-.042, p = 0.44). **CONCLUSIONS**: Decreases in sitting time were associated with improvement in self-reported physical functioning quality of life but not in mental health quality of life. Longer term results over 12 months of intervention and comparisons between the two different intervention arms may shed more light on the robustness and interpretation of the possible link between sitting time and quality of life domains.

10-year Changes In Accelerometer-determined Physical Activity And Sedentary Time During Midlife: CARDIA

Kelley Pettee Gabriel, FACSM[1], Steve Sidney[2], David R. Jacobs, Jr.[3], Mercedes Carnethon[4], Cora E. Lewis[5], Pamela Schreiner[3], Raja Malkani[1], James M. Shikany[5], Kara M. Whitaker[6], Jared P. Reis[7], Barbara Sternfeld, FACSM[2]. *[1]University of Texas Health Science Center at Houston School of Public Health, Austin, TX. [2]Kaiser Permanente Northern California, Oakland, CA. [3]University of Minnesota, Minneapolis, MN. [4]Northwestern University, Chicago, IL. [5]University of Alabama at Birmingham, Birmingham, AL. [6]University of Iowa, Iowa City, IA. [7]National Heart, Lung, and Blood Institute, Bethesda, MD.*
(No relevant relationships reported)

PURPOSE: Describe the 10-year race/sex specific changes in accelerometer-determined physical activity (PA) and sedentary time in a midlife cohort.
METHODS: Data are from 881 Coronary Artery Risk Development in Young Adults (CARDIA) participants aged 18 to 30 years at baseline (1985-86) who wore the accelerometer and had valid wear ($\geq$4 of 7 days, $\geq$10 hours per day) at the Year 20 (2005-06; ages 38-50) and Year 30 (2015-16; ages 48-60) exams. At Year 20, accelerometer measures were first collected using the ActiGraph 7164; at Year 30 the ActiGraph wGT3X-BT model was used. A calibration factor (counts divided by 1.088, based on a subset who simultaneously wore both devices at Year 30) was applied to Year 30 data to account for differences in models. All 10-year change estimates are expressed as median (25th, 75th percentiles). Wilcoxon Rank Sum tests were used to examine 10-year changes overall and within the four race/sex groups.
RESULTS: Over 10 years, participants experienced significant reductions in average accelerometer counts [-46.7 (-122.7, 31.1 ct·min·d^{-1}; $p<0.001$]. This reduction was shown within each race/sex group, with the greatest decline observed in black men (all $p<0.001$). Sedentary time significantly increased overall (32.9 min·d^{-1}), with the largest increases shown in black women (56.9 min·d^{-1}) followed by black men (50.2 min·d^{-1}), white women (28.9 min·d^{-1}) and men (19.0 min·d^{-1}); all $p<0.001$. Light intensity PA decreased (-29.2 min·d^{-1}), with black men having the greatest reductions (-38.3 min·d^{-1}), followed by white (-35.3 min·d^{-1}) and black (-26.6 min·d^{-1}) women, then white men (-25.6 min·d^{-1}); all $p<0.001$. Moderate to vigorous intensity PA (MVPA) also declined (-5.5 min·d^{-1}) with the largest reductions shown in black men (-7.3 min·d^{-1}), then white men (-6.9 min·d^{-1}), and white (-4.9 min·d^{-1}) and black (-4.3 min·d^{-1}) women; all $p<0.001$. Of note, black women had the lowest accumulated MVPA at Year 20. Finally, median time spent in MVPA bouts lasting $\geq$8 of 10 consecutive minutes slightly increased in white men and women (2.3 and 0.60 min·d^{-1}, respectively; both p<0.01), which was not shown in black participants.
CONCLUSIONS: We found a decline in overall PA during the midlife transition. This reduction was largely attributable to increases in sedentary time and reductions in light intensity PA.

Effects of Replacing Prolonged Sedentary Bouts with Short Sedentary Bouts or Physical Activity On Mortality

Keith M. Diaz[1], Andrea T. Duran[1], Natalie Colabianchi[2], Suzanne E. Judd[3], Virginia J. Howard[3], Steven P. Hooker, FACSM[4]. *[1]Columbia University Medical Center, New York, NY. [2]University of Michigan, Ann Arbor, MI. [3]University of Alabama at Birmingham, Birmingham, AL. [4]Arizona State University, Phoenix, AZ.*
(No relevant relationships reported)

Evidence suggests that prolonged, uninterrupted sedentary bouts (e.g. sitting for hours at a time) may be the most harmful manner in which to accumulate sedentary behavior. Little is known concerning the type of activity that should be substituted for prolonged, uninterrupted sedentary bouts to impart health benefit. For example, does substituting longer sedentary bouts with shorter sedentary bouts reduce mortality risk, or is physical activity needed? **PURPOSE**: Using isotemporal substitution techniques, the purpose of this study was to examine whether replacing prolonged sedentary bouts with (1) shorter sedentary bouts, (2) light-intensity physical activity (LIPA), or (3) moderate-vigorous intensity physical activity (MVPA) is associated with reductions in all-cause mortality risk. **METHODS**: Participants (n=7,999) from the REasons for Geographic and Racial Differences in Stroke (REGARDS) Study, a national cohort study of black and white U.S. adults $\geq$45 years, were studied. Sedentary time was measured using a hip-mounted accelerometer worn for 7 consecutive days. In isotemporal substitution models, short sedentary bout time (bouts <30 min), LIPA, MVPA, and accelerometer wear time (each expressed in 30 minute units per day) were included in a single Cox regression model that included adjustment for covariates. Resultant hazard ratios (HR) estimated associations for replacing 30 min of prolonged sedentary bout time (bouts $\geq$

30 min) with an equal amount of time in a given type of activity (short sedentary bouts, LIPA, or MVPA) on all-cause mortality risk. **RESULTS**: Over a median follow-up of 5.5 years, there were 647 deaths. There was a beneficial association for replacing prolonged, uninterrupted sedentary bout time with both LIPA (per 30-minute HR: 0.85; 95% CI: 0.80-0.90) and MVPA (per 30-minute HR: 0.69; 95% CI: 0.52-0.90) on all-cause mortality risk, but no association for replacement with shorter sedentary bouts (per 30-minute HR: 0.99; 95% CI: 0.96-1.03). **CONCLUSIONS**: In this national cohort study of middle-aged and older adults, replacing prolonged, uninterrupted sedentary bouts with shorter sedentary bouts was not associated with a reduction in all-cause mortality risk. Instead the all-cause mortality risk incurred by prolonged, uninterrupted sedentary bouts was only reduced by LIPA or MVPA.

Mortality Risk Reductions for Replacing Sedentary Time with Physical Activities

Erika Rees-Punia[1], Charles E. Matthews, FACSM[2], Susan Gapstur[1], Alpa V. Patel[1]. [1]*American Cancer Society, Atlanta, GA.* [2]*National Cancer Institute, Bethesda, MD.* (Sponsor: Charles Matthews, FACSM)

(No relevant relationships reported)

BACKGROUND: Insufficient physical activity is a well-established risk factor for chronic disease and early mortality. More recent evidence suggests that excess sitting time may be an additional risk factor, independent of physical inactivity. This may be due, at least in part, to the displacement of physical activities with sedentary behaviors. PURPOSE: To examine the mortality risk reductions associated with replacing thirty minutes of daily sitting time for an equivalent duration of physical activity. METHODS: Participants included 40,866 men and 60,891 women in the Cancer Prevention Study-II Nutrition Cohort. An isotemporal substitution approach to Cox proportional hazards regression models were used to estimate adjusted hazard ratios (HR) and 95% confidence intervals (HR, 95% CI) for all-cause mortality associated with the substitution of thirty minutes of daily sitting time with an equal duration of light or moderate-to-vigorous intensity physical activity (LPA, MVPA). RESULTS: During 14 years (1999-2013) of follow-up, 16,163 men and 15,638 women died. Overall, reallocation of 30 min·day^{-1} of sitting to LPA (HR=0.94, 0.92-0.97) or MVPA (HR=0.91, 0.88-0.93) was associated with significant reductions in mortality risk. Among the least active participants, the replacement of 30 min·day^{-1} of sitting time with 30 min·day^{-1} LPA was associated with a 14% mortality risk reduction (HR=0.86, 0.83-0.89) and replacement with MVPA was associated with a 50% mortality risk reduction (HR=0.50, 0.44-0.58). Similar associations were seen among the moderately active group (HR=0.91, 0.89-0.96 for LPA replacement, HR=0.65, 0.56-0.79 for MVPA replacement). However, among the most active participants, substitution of sitting time with LPA or MVPA was not associated with a significant reduction in mortality risk (HR=1.00, 0.97-1.02, HR=0.97, 0.95-1.01, respectively). CONCLUSIONS: Among the least active and moderately active, the replacement of modest amounts of sitting time with either LPA or MVPA was associated with longevity, although the associations were strongest when sitting time was replaced with MVPA.

Changes in Energy Reserves Contribute to Cognitive Decline with Aging

Jennifer A. Schrack[1], Amal A. Wanigatunga[1], Adam P. Spira[1], Vadim Zipunnikov[1], Eleanor M. Simonsick[2], Susan M. Resnick[2]. [1]*Johns Hopkins University, Baltimore, MD.* [2]*National Institute on Aging, Baltimore, MD.*

(No relevant relationships reported)

PURPOSE: Identification of physiological changes that predict functional decline and reflect the onset of cognitive change may identify mechanisms common to mobility and cognition; potentially leading to earlier diagnoses and intervention efforts. Although greater peak VO$_2$ and walking efficiency have been linked to better preservation of physical functioning with aging, it is unclear how changes in energy reserve affect cognitive performance. The objective of this study was to assess the association between longitudinal changes in energy reserve and cognitive performance in a cohort of well-functioning adults. METHODS: Peak VO$_2$ (ml/kg/min), the energetic cost of a 5-min 1.5 mph treadmill walk (ml/kg/min), and cognitive performance were assessed in over 1000 participants (mean baseline age 67.5, range 24- 96, 49% male) of the Baltimore Longitudinal Study of Aging. The primary outcomes were changes in the domains of attention, memory, and executive function over an average of 4-years (range 1-7 yrs), measured through a neuropsychological battery at each visit. The primary predictor was energy reserves (mean walking VO$_2$/peak VO$_2$). The association between change in energy reserves and change in cognitive performance was modeled using linear regression models with generalized estimating equations for repeated measures, adjusted for age, sex, body mass index (kg/m^2), race, education, number of chronic conditions, and an interaction between energy reserves and age.

RESULTS: In fully adjusted population average models, a significant interaction between energy reserves and age was observed for memory (β = -0.42, p<0.001), executive function (β = 1.63, p<0.001), and attention (β = -0.19, p=0.04), indicating that declining energy reserves contributed to poorer cognitive performance in all domains over time. Z-scores indicate these effects were greatest for memory, followed by executive function and attention.
CONCLUSIONS: Among well-functioning, community-dwelling adults, declining energy reserves are linked to poorer cognitive performance over time. This evidence indicates that combining measures of energy capacity and energy cost to assess physiologic reserve may serve as an early indicator of cognitive decline and convey evidence of those at risk of poorer cognitive outcomes over time.

Strong Evidence from the 2018 Physical Activity Guidelines Advisory Committee

Alison Vaux-Bjerke[1], Eric Hyde[2], Katrina L. Piercy[1], Richard D. Olson[1], Richard P. Troiano[3], Janet E. Fulton, FACSM[2]. [1]*Office of Disease Prevention & Health Promotion, U.S. Dept. of Health & Human Services, Rockville, MD.* [2]*Centers for Disease Control and Prevention, U.S. Dept. of Health & Human Services, Atlanta, GA.* [3]*National Cancer Institute, National Institutes of Health, U.S. Dept. of Health & Human Services, Bethesda, MD.* (Sponsor: Janet Fulton, FACSM)

(No relevant relationships reported)

The U.S. Department of Health and Human Services (HHS) charged an external federal advisory committee to review the scientific literature and provide independent recommendations to the government to inform the development of the second edition of the *Physical Activity Guidelines for Americans*.
Purpose To present a selection of conclusions with evidence graded as 'strong' from the 2018 Physical Activity Guidelines Advisory Committee (Committee) systematic literature review.
Methods The Committee asked 38 questions on relationships between physical activity and health outcomes in systematic literature reviews. A grading rubric was used to evaluate the strength of evidence - Strong, Moderate, Limited, or Grade Not Assignable (insufficient evidence). A grade of 'strong' indicated that evidence from the literature directly applied to the systematic review question; was free from serious doubts about generalizability; limited the risk of bias; showed consistency in the direction and approximate size of the effect across studies; and provided considerable confidence in the accuracy of the findings. The Committee presented its conclusions during five public meetings.
Results The Committee concluded there was strong evidence that physical activity has a beneficial effect on many health outcomes, including improvements in weight and bone health in children under age six, physical function in older adults, and incidence of seven types of cancer. Examples are provided in Table 1.
Conclusion The Committee's systematic reviews will be compiled into a Scientific Report and submitted to the HHS Secretary. The Department will use the Committee's evidence-based recommendations, as well as public and federal agency comments, to develop the second edition of the *Physical Activity Guidelines for Americans*. The Committee's work firmly grounds the second edition of the *Physical Activity Guidelines for Americans* in the current science on physical activity and health.

Table 1. Selected conclusion statements for 'strong' evidence.

Subcommittee / Work Group	Topic	Conclusion Statement
Brain Health	Dementia	Strong evidence demonstrates that greater amounts of physical activity are associated with a reduced risk of developing dementia.
	Anxiety	For the general population, strong evidence demonstrates reduced state anxiety following acute bouts of exercise and reduced trait anxiety following weeks/months of regular exercise.
	Depression	Strong evidence demonstrates that greater amounts of physical activity reduce the risk for depression.
Cardiometabolic Health and Weight Management	Weight Gain	Strong evidence demonstrates a relationship between greater amounts of physical activity and attenuated weight gain in adults, with some evidence to support that this relationship is most pronounced when physical activity exposure is above 150 minutes per week.
Sedentary Behavior	All-cause mortality	Strong evidence demonstrates a significant relationship between greater time spent in sedentary behavior and higher all-cause mortality rates.
Youth	Fitness in youth ages 6-17	Strong evidence demonstrates that increased moderate-to-vigorous physical activity increases cardiorespiratory fitness and increased resistance exercise increases muscular fitness in children and adolescents.
Pregnancy Work Group	Prevention of gestational weight gain	Strong evidence demonstrates a significant, but modest, inverse relationship between physical activity and gestational weight gain.
	Incidence of gestational diabetes mellitus	Strong evidence demonstrates a significant inverse relationship between leisure-time physical activity and risk of gestational diabetes mellitus.

Effects of Increased Preload on Cardiac Function in Younger vs Older Women

David N. Proctor, FACSM[1], Samuel J. Ridout[2], Zhaohui Gao[3], Joaquin U. Gonzales[4], Danielle Jin-Kwang Kim[3], Matthew D. Muller, FACSM[5], Urs A. Leuenberger[3]. *[1]Penn State University, University Park, PA. [2]Kaiser Permanente, San Jose, CA. [3]Milton S. Hershey Medical Center, Hershey, PA. [4]Texas Tech University, Lubbock, TX. [5]Case Western Reserve University School of Medicine, Cleveland, OH.*

(No relevant relationships reported)

PURPOSE: Limitations in cardiac preload and/or compliance could underlie diminished stroke volume and ventricular remodeling adaptations to endurance exercise in older women. The present study tested the hypothesis that attenuated cardiac function in older women persists during acute increases in preload, both at rest and during exercise. **METHODS**: Nine younger (Y, 21-28 y) and ten older (O, 61-73 y) healthy, non-endurance trained women were studied 1) at rest in the supine and seated positions, and 2) during graded upright cycle ergometer exercise (20, 40, 60 and 80% of VO$_2$peak), both before and after acute plasma volume (PV) expansion (via IV infusion of 5% albumin; 10ml/kg). Cardiac responses to postural change, exercise, and PV expansion were measured using echocardiography (rest and low intensity exercise) and open circuit C$_2$H$_2$ (exercise). **RESULTS**: Under resting normovolemic conditions, stroke volume (SV) was augmented in the supine (vs. upright) posture in both Y (61±9 vs. 52±8 ml/beat, P<0.05) and O (55±10 vs. 49±7 ml/beat, P<0.05) women. Hypervolemia augmented supine SV further in Y (68±4 ml/beat, P<0.05 vs. normovolemia), but not in O (55±10 ml/beat, P>0.05 vs. normovolemia) women. These resting postural and hypervolemic effects were mediated by changes in end diastolic volume, and not secondary to age group differences in the extent of PV expansion (averaged +16% and +13% in Y and O, respectively) or estimated filling pressures (E/E'). E/A ratio during peak resting preload conditions (i.e., supine hypervolemia), moreover, was positively associated with VO$_2$peak in Y, but not in O women. During upright exercise, hypervolemia increased SV an average of 15 ml/beat across all 4 work intensities in Y women (p<0.05 vs. normovolemia). This was in contrast to O women, who exhibited very small increases in SV during hypervolemic exercise (i.e., <5 ml/beat). **CONCLUSIONS**: Healthy older women appear to have a reduced ability (relative to younger women) to utilize acute increases in preload to raise left ventricular stroke volume, including during large muscle exercise. These findings likely reflect the combined effects of exceptional lusitropic function in younger women, and a less compliant ventricle in the aged female heart.

Critical Speed in Heart Failure Rats: The Central Determinant of Performance

Jesse C. Craig, Joseph H. Merino, Daniel M. Hirai, Trenton D. Colburn, Ayaka Tabuchi, Jacob T. Caldwell, Carl J. Ade, Timothy I. Musch, FACSM, David C. Poole, FACSM. *Kansas State University, Manhattan, KS.* (Sponsor: David C. Poole, FACSM)

(No relevant relationships reported)

A hallmark symptom of heart failure (HF) is exercise intolerance. The power-duration relationship for high intensity exercise is a powerful phenomenon that integrates multiple physiological systems to define the framework of tolerance within and across species in health and disease. The parameters of this relationship, critical speed (CS) and D′ represent the aerobic and 'anaerobic' capacities of the animal and in combination accurately predict exhaustion. Elucidating the determining mechanisms of CS and D′ in HF will allow for development of more efficacious therapies. **PURPOSE:** To establish the power-duration relationship in a validated model of HF and elucidate the mechanism(s) that determine CS and D′. Specifically, we tested the hypotheses that: 1) CS (but not D′) would be reduced in HF; and 2) measurements of heart function would correlate with CS. **METHODS:** Nine adult female Sprague-Dawley rats were randomized to control (CON; n = 4) or HF (n = 5) groups. HF was induced via surgical myocardial infarction and the rats were given ≥ 21 days to recover. Multiple constant speed treadmill runs to exhaustion were used to determine CS and D′ in both groups. Doppler echocardiography was used to evaluate heart function (i.e., fractional shortening (FS) which approximates ejection fraction) following CS and D′ determination. **RESULTS:** HF reduced FS by 50% (HF: 24 ± 2%, CON: 48 ± 3%; p < 0.001); indicative of moderate severity HF. CS was reduced by ~15% in HF rats compared to CON (38 ± 1 vs 45 ± 1 m/min; p < 0.001). D′ was not different (HF: 79 ± 13 m, CON: 61 ± 13 m; p = 0.34). CS was positively correlated with FS (r 0.9, p = 0.002); D′ was not (r -0.33, p = 0.42). **CONCLUSION:** CS and D′ can be resolved in an animal model of moderate HF where CS is reduced but D′ is not. Crucially, this HF model is free from the prescription therapeutics that confound interpretation of the mechanistic relationship between HF and CS or D′ in humans. That FS was correlated with CS has important mechanistic and clinical implications.

Structural and Functional Determinants of Critical Speed in Heart Failure

Non-invasive Assessment Of Right And Left Ventricular Cardiac Output After Changes In Gravity And Posture

Uwe Hoffmann[1], Jessica Koschate[1], Uwe Drescher[1], Lutz Thieschäfer[1], Daniel Dumitrescu[2], Andreas Werner[3]. *[1]German Sport University, Koeln, Germany. [2]University of Cologne, Koeln, Germany. [3]German Air Force - Centre of Aerospace Medicine, Koenigsbrueck, Germany.*

(No relevant relationships reported)

Gravity changes along the z-axis (posG$_z$) influence right and left ventricular cardiac output (CO$_{RV}$, CO$_{LV}$). This is of importance in many sports after changes in posture or in phases of accelerations. **PURPOSE:** This study aimed to compare estimates of cardiac output by gas exchange and continuous blood pressure (cBP) measurements to assess transient differences in CO$_{RV}$ and CO$_{LV}$. **METHODS:** Nine healthy male subjects (age: 31 ± 3 y, BMI: 24 ± 2 kg·m^{-2}) participated in experiments on a long-arm human centrifuge (laHC; base line: 1.7 g), in parabolic flights (PF) and on a tilt seat (TS; initial position 65°). Three consecutive posGz changes for ~22 s intervals (I_1, I_2, I_3) were performed (laHC: 2.1 g - 1.2 g - 2.1 g; PF 1.8 g - 0 g - 1.8 g; TS: 90° - -6° - 90°). Breath-by-breath V'O$_2$, heart rate and cBP were measured. Left ventricular stroke volume was determined from cBP allowing to estimate CO$_{LV}$. Arterio-venous O$_2$ concentration difference was calculated as average for 30 s before the first posGz change (I_1). This allows calculating CO$_{RV}$ for the following periods (I1, I2, I3) according to Fick's principle. **RESULTS:** Differences between CO$_{RV}$, CO$_{LV}$ are shown in Fig. 1. The highest difference (9.26 L·min^{-1}) was found in TS after the change from the 90° to -6° position. **CONCLUSION:** The combination of V'O$_2$ and cBP measurements allows to assess differences in CO$_{RV}$ and CO$_{LV}$. The differences in I_2, after a reduction in posGz indicate a blood volume shift into the pulmonary veins which has an impact on CO$_{LV}$, which increases during the following posGz increase (I_3). Further influences from breathing must be studied.

Right Ventricular Remodeling In Olympic Athletes During 8 Years Of High-intensity Training

Vincent L. Aengevaeren[1], Stefano Caselli[2], Maria T.E. Hopman, FACSM[1], Thijs M.H. Eijsvogels[1], Antonio Pelliccia[2]. *[1]Radboud University Medical Center, Nijmegen, Netherlands. [2]Institute of Sports Medicine and Science, Rome, Italy.* (Sponsor: Maria Hopman, FACSM)

(No relevant relationships reported)

Previous studies suggested that long-term exposure to repeated bouts of high-intensity exercise may have detrimental effects on the right ventricle (RV), potentially causing an 'exercise-induced' cardiomyopathy. **PURPOSE:** We aimed to evaluate the effects of 8 years of intensive exercise training on cardiac adaptations in Olympic athletes. **METHODS:** We selected Italian athletes who qualified consecutively for the 2008, 2012 and 2016 Summer Olympic Games. Athletes underwent a complete cardiovascular evaluation before every Olympic event including a clinical and echocardiographic examination. Athletes were categorized as either endurance or non-endurance athletes. **RESULTS:** 50 Olympic athletes (64% male; 24 ± 4 y) from different sporting disciplines (n=20 endurance and n=30 non-endurance athletes) met the criteria for inclusion. Mild increases in RV outflow tract diameter (long axis 6 ± 12%; short axis 5 ± 13%), RV basal (7 ± 12%) and mid diameter (18 ± 21%), RV end-diastolic area (7 ± 15%), right atrium area (6 ± 15%), and RV/Left Ventricle (LV) diameter ratio (5 ± 11%) were observed during follow-up. Furthermore, significant increases in aortic root size (8 ± 7%), left atrium area (9 ± 21%) and left ventricle

diameter were found (1 ± 4%). Systolic functional parameters of both ventricles did not change over time, whereas a mild decrease in indices of LV diastolic function (E/A ratio: -12 ± 21%; E': -5 ± 17%) was observed. Most changes occurred between the first and second evaluation, and parameters plateaued between the second and third evaluation. Endurance athletes demonstrated greater increases in RV end-diastolic area compared to non-endurance athletes. **CONCLUSION:** Olympic athletes showed mild but continued cardiac remodeling, including RV and LV cavity, RV and LV atrium, and the aortic root while maintaining intensive exercise training over 8 years follow-up. However, cardiac RV and LV remodeling appears to plateau and no signs of reduced RV or LV cardiac function occurred over time. Therefore, our data does not support the hypothesis that exercise alone may cause detrimental effects on cardiac morphology and function in Olympic athletes. V.L.A is financially supported by a grant from the Radboud Institute for Health Sciences.

Heart Rate Responses in the Diving Reflex among Aerobically Trained and Untrained Men

Kathryn Lewis, Samuel Headley, Jessica Peacock, Christa Winter, Vincent Paolone, FACSM. *Springfield College, Springfield, MA.*

(No relevant relationships reported)

The mechanisms of the diving reflex involve the simultaneous activation of the sympathetic and parasympathetic nervous systems (PNS). The enhanced PNS capabilities as achieved through aerobic training has been investigated in the diving reflex, specifically vagally-mediated bradycardia, and the research remains controversial. **PURPOSE:** The current study was conducted to evaluate heart rate responses associated with the diving reflex in aerobically trained and untrained men. **METHODS:** Using 2 x 3 mixed factorial ANOVA, lowest heart rate achieved, percent heart rate reduction, and time course of heart rate reduction were compared between aerobically untrained ($n = 7$) and trained ($n = 9$) men while breath holding in air, water at 15 °C, and water at 0 °C. **RESULTS:** Results showed that trained men did not differ in percent heart rate reduction or lowest heart rate achieved, although there was a tendency for lowest heart rate achieved in the trained group ($p = .06$). A significant interaction was found for time course ($p = .01$), where trained men took significantly longer to reach a plateau in heart rate in the air compared to untrained men. No differences in training status were found for time course in the two water conditions. However, a linear increase in time course for untrained men in the water conditions indicated a potentially delayed response by the PNS with the diving reflex. **CONCLUSION:** No additional clarification on the impact of training status on the diving reflex has been made except that an effect may lie in the timing of the response of the PNS.

Exercise Training May Attenuate the Cardiac Changes Associated with the Menopause

Amanda Q.X. Nio, Eric J. Stöhr, Samantha Rogers, Rachel Mynors-Wallis, Victoria L. Meah, Jane M. Black, Mike Stembridge, Rob Shave. *Cardiff Metropolitan University, Cardiff, United Kingdom.*

(No relevant relationships reported)

The menopause is generally associated with lower cardiovascular function. Exercise training is known to improve cardiovascular function, but whether it attenuates the effects of the menopause are unclear. PURPOSE: To investigate the effects of exercise training on left ventricular (LV) function and mechanics in post-menopausal women. METHODS: Eleven pre-menopausal and 14 post-menopausal healthy untrained middle-aged women (age 45-58 years) were included in this retrospective study. Peak aerobic capacity was assessed on an upright cycle ergometer. Resting LV function and basal and apical mechanics were assessed using echocardiography. Post-menopausal women were reassessed after 12 weeks of exercise training (3 sessions/week consisting of 4×4 min intervals at 90-95% maximum heart rate; attendance ≥70%). Data on LV mechanics are reported for 11 pre- and 12 post-menopausal women. The Bayes factor [BF_{10}=p(H$_1$)/p(H$_0$)] from the Bayesian independent samples t-test was used to assess the evidence for differences in cardiovascular function between untrained pre-menopausal women and post-menopausal women before and after exercise training (H$_1$). A BF_{10} of 1 indicates equal evidence for both the null (H$_0$) and alternative hypotheses, while smaller values indicate increasing strength of evidence for the null hypothesis and larger values favour H$_1$. RESULTS: We found weak evidence for similar peak aerobic capacity, cardiac output, heart rate, systemic vascular resistance, LV volumes and most measures of LV function and mechanics between untrained pre- and post-menopausal women (BF_{10} range 0.37-0.77). The key exception to this was a lower peak septal wall velocity during early diastole (E') in untrained post-menopausal women, compared with pre-menopausal women (mean±SD: 0.09 ± 0.02 vs. 0.11 ± 0.02 m/s; BF_{10}=3.56). After exercise training, peak aerobic capacity was higher in post-menopausal women (34 ± 5 vs. 29 ± 5 mL/min/kg; BF_{10}=2.58), while strength of evidence for menopause-related differences in E' decreased (BF_{10}=1.80).

CONCLUSION: Short-term high-intensity aerobic interval training improves peak aerobic capacity in middle-aged post-menopausal women, and reduces the extent of menopause-related differences in LV function. Amanda Nio is the beneficiary of a doctoral grant from the AXA Research Fund.

Differential Effects of Three Distinct Training Approaches in a Rat Model of Severe Pulmonary Hypertension

Mary Beth Brown[1], Andrea Frump[2], Gary Long[1], Ashley Troutman[1], Amanda Fisher[1], Robert Presson[2], Tim Lahm[2]. [1]Indiana University School of Health and Rehabilitation Sciences, Indianapolis, IN. [2]Indiana University School of Medicine, Indianapolis, IN.

(No relevant relationships reported)

PURPOSE: Optimizing exercise as therapy for pulmonary arterial hypertension (PAH) requires an understanding of which approaches maximize benefit and minimize detriment, particularly in more advanced disease. Therefore, in rats with severe, angioproliferative PAH we examined cardiopulmonary effects of three distinct training approaches: 1) high-intensity interval training (HIIT), 2) low-intensity continuous exercise training (CET), or 3) voluntary wheel running (VWR).
METHODS: SD rats (~200g, male) with Sugen+Hypoxia- induced PAH (SuHx) underwent 6 wks of training as either HIIT (2 min at ~85% VO_2reserve [VO_2R] + 3 min at 30%VO_2R, for 4-5 cycles, n=12) or CET (45-60 min at 50%VO_2R, n=11) performed 5 days/wk on a treadmill, or were housed with computer-monitored wheels (n=14). Additional SuHx rats were untrained (SED, n=15). Healthy, unexercised animals were controls (CON, n= 14). Echocardiography was performed at pre- and post-training; all other measures were post-training.
RESULTS: Mortality in SuHx was highest for SED (5 deaths at days 65, 66 (2), 77, and 81) and HIIT (4 deaths at days 56, 60, 68, and 71), and lowest for CET (2 deaths at days 60 and 73) and VWR (2 deaths at days 59, 68). While all animals exhibited similar baseline RV function, SuHx rats that died prematurely (n=13) had worse (p<0.05) cardiac output (CO, 148±12mL) and stroke volume (SV, 466±39uL/min) at pre-training compared to surviving SuHx (n=39, 216±19uL, 593±30mL/min). SuHx-induced elevation in RV systolic pressure (RVSP) and RV hypertrophy were not ameliorated by training with any approach (p>0.05 vs.SuHx-SED). However, final RV function in surviving SuHx was higher for all 3 training approaches (p<0.05 vs. SuHx-SED) as indicated by CO (mL/min) = 258±51, 222±44, 191±17, and 126±16; and by SV (uL/min) = 564±60, 529±51, 554±48, and 364±32, for HIIT, CET, VWR, and SED SuHx, respectively.
CONCLUSION: In a rat model of severe, angioproliferative PAH, 3 different training approaches achieved gain in RV function despite no amelioration of RV hypertrophy and elevated RVSP. However, in contrast to previous findings in a model of mild PAH, HIIT resulted in increased mortality for animals with poorer RV function prior to training onset and suggests that it may not be appropriate in the presence of more advanced disease. Prediction Equation For Estimating Total Daily Energy Requirements Of Special Operations Personnel

Lee M. Margolis[1], Nicholas D. Barringer[1], Holly L. McClung[1], Aaron P. Crombie[2], Stefan M. Pasiakos, FACSM[1]. [1]United States Army Research Institute of Environmental Medicine, Natick, MA. [2]US Military-Baylor University Graduate Program in Nutrition, US Army Medical Department Center & School US Army Health Readiness Center of Excellence, San Antonio, TX. (Sponsor: Stefan M Pasiakos, FACSM)

(No relevant relationships reported)

Abstract
Special Operations Forces (SOF) engage in a variety of military tasks with many producing high energy expenditures, resulting in undesired energy deficits and loss of body mass. Therefore, the ability to accurately estimate daily energy requirements would be useful to generate adequate feeding regimens to support maintenance of energy balance during military operations. **Purpose:** Generate a predictive equation estimating energy requirements of SOF. **Methods:** Retrospective analysis of data collected from SOF personnel engaged in 12 different SOF training scenarios. Energy expenditure and total body water were determined using the doubly-labeled water (DLW) technique. Physical activity level was determined as daily energy expenditure divided by resting metabolic rate. Physical activity level was broken into quartiles (0 = mission prep, 1 = common warrior tasks, 2 = battle drills, 3 = specialized intense activity) to generate a physical activity factor (PAF). Regression analysis was used to construct two predictive equations (Model A; body mass and PAF, Model B; fat-free mass and PAF) estimating daily energy expenditures. **Results:** Average measured energy expenditure during SOF training was 4468 (range: 3700 to 6300) Kcal·d[-1]. Regression analysis revealed that physical activity level ($r = 0.91$; $P < 0.05$) and body mass ($r = 0.28$; $P < 0.05$; Model A), or fat-free mass (FFM; $r = 0.32$; $P < 0.05$; Model B) were the factors that most highly predicted energy expenditures. Predictive equations coupling PAF with body mass (Model A) and FFM (Model B), were correlated ($r = 0.74$ and $r = 0.76$, respectively) and did not differ (mean ± SEM: Model A; 4463 ± 65 Kcal·d[-1], Model B; 4462 ± 61 Kcal·d[-1]) from DLW measured energy expenditures. **Conclusion:** By quantifying and grouping SOF training exercises into activity factors, SOF energy requirements can be predicted with reasonable accuracy and these equations can be used by dietetic/logistical personnel to plan appropriate feeding regimens to meet SOF nutritional requirements across their various mission profile.

Comparison of Pandolf Equation and Measured Metabolic Cost of Load Carriage in UK Military Personnel

Christopher A J Vine[1], Sarah L. Coakley[1], Stephen D. Myers[1], Ella F. Walker[1], Carla A. Rue[1], Ben J. Lee[1], Tessa R. Flood[1], Julianne Doherty[1], Beverley Hale[1], Mark Rayson[2], Joeseph J. Knapik, FACSM[3], Deborah Gebhardt, FACSM[4], Bradley C. Nindl, FACSM[5], Piete E H Brown[6], Sarah Jackson[7], Julie P. Greeves[7], Sam D. Blacker[1]. [1]University of Chichester, Chichester, United Kingdom. [2]Mark Rayson Consulting Limited, Bristol, United Kingdom. [3]Fitness, Injury, and Performance Analysis, Abingdon, MD. [4]Human Resources Research Organization, Alexandria, VA. [5]University of Pittsburgh, Pittsburgh, PA. [6]Institute of Naval Medicine, Royal Navy, Gosport, United Kingdom. [7]Army Personnel Research Capability, Army HQ, Andover, United Kingdom.

(No relevant relationships reported)

PURPOSE: The metabolic cost of load carriage (LC) is frequently predicted using the Pandolf et al. (1977) equation. Recent laboratory investigations have identified that the Pandolf equation under-predicts the metabolic cost of LC in untrained personnel during treadmill walking (Drain et al., 2017). However, the relationship between the actual and Pandolf predicted metabolic cost of outdoor LC in UK Armed Forces personnel has not been established.
METHODS: Twenty-two UK Armed Forces personnel (Royal Marine Commandos and Parachute Regiment, mean ± SD: age 23 ± 3 years; stature 180.9 ± 4.9 cm; body mass 83.1 ± 6.6 kg; predicted VO_{2max} 54.0 ± 3.1 ml·kg[-1]·min[-1]) completed 15, 20 minute stages of outdoor LC, with external load masses ranging from 25 to 70 kg. The stages were completed at a patrol, forced, and insertion marching speed (2.5, 4.8, and 5.5 km·h[-1], respectively). During the final 2-4 minutes of each LC stage, oxygen uptake (VO_2) was measured using the Douglas bag technique. Predicted VO_2 for each speed-load mass combination was calculated using the Pandolf equation and compared to the measured VO_2 using paired t-tests and 95 % Limits of Agreement (LoA).
RESULTS: The Pandolf equation systematically under-predicted the metabolic cost of LC for all speeds and load masses combined [mean difference 3.2 ± 2.9 ml·kg[-1]·min[-1] (p<0.001), 95% LoA -2.5-8.9 ml·kg[-1]·min[-1]] resulting in a VO_2 predictive error of 17.5 %. Mean difference and 95% LoA at the different speeds were: (a) 2.5 km·h[-1] [4.8 ± 1.9 ml·kg[-1]·min[-1], (p<0.001), 95% LoA 1.0-8.6 ml·kg[-1]·min[-1]], (b) 4.8 km·h[-1] [1.5 ± 2.7 ml·kg[-1]·min[-1] (p<0.001), 95% LoA -3.9-6.9 ml·kg[-1]·min[-1]], and (c) 5.5 km·h[-1] [4.2 ± 3.3 ml·kg[-1]·min[-1] (p<0.001), 95% LoA -2.1-10.7 ml·kg[-1]·min[-1]], with prediction errors of 30 %, 6 % and 14 %, respectively.
CONCLUSIONS: The current study demonstrates a systematic under-prediction of VO_2 for British Army personnel during outdoor LC when applying the Pandolf equation, supporting the findings of previous laboratory studies. Furthermore, the error appears to be of greater magnitude when LC speeds are lower, i.e. at a representative patrolling pace. This in part could be attributed to the load mass distribution of the modern solider, which differs from the back mounted load carried data used to develop and refine the Pandolf equation.

Pandolf Equation Efficacy In Predicting Gender-Specific Energy Expenditure Differences While Carrying Light To Heavy Loads

Victoria A. Gregory, Charles S. Fulco, Peter N. Frykman, Rebecca E. Fellin, Nathaniel I. Smith, Joseph F. Seay. *U.S. Army Institute of Environmental Medicine, Natick, MA.*

(No relevant relationships reported)

With the recent decision permitting women to enter Combat Arms roles in the military, knowledge of gender-based differences in energy expenditure (EE) during load carriage has become more operationally relevant. However, one of the most common equations for predicting the energy cost of load carriage has not been systematically compared between male and female Soldiers.
PURPOSE: To examine the efficacy of the Pandolf equation [1] to predict EE of male and female Soldiers while carrying light to heavy loads.
METHODS: Seven women were individually matched with 7 men by height and body weight (differences < 2.54 cm and 4.54 kg for each pair). All participants walked at 1.34 m·s⁻¹ for 10-min bouts on a level treadmill while unloaded (BW) and then carrying vest-borne loads of 15, 35 and 55 kg. VO_2 data were collected during the last 3 min of each bout. 2-way RM ANOVA compared VO_2 at each load between the men and women. Measured results were then compared to equation predictions.
RESULTS: Measured EE increased significantly with load and was significantly greater for men (443 ± 92 W) than women (388 ± 97 W). The equation predicted EE more accurately for women at lighter loads and more accurately for men at heavier loads (Figure 1).
CONCLUSION: Using height and weight matched men and women, the Pandolf equation was more accurate for predicting EE at the heavier loads for men and at the lighter loads for women. These results support modification of the Pandolf equation to account for differences in gender and carried load.

Comparison of Training Intensity, Energy Balance, and Sleep Duration in British Army Officer Cadets between Base and Field Exercise

Sarah C. Needham-Beck[1], Andrew G. Siddall[1], Jane E.S. Thompson[1], Steven D. Powell[1], Victoria C. Edwards[1], Sam D. Blacker[1], Sarah Jackson[2], Julie P. Greeves[2], Steve D. Myers[1]. [1]*University of Chichester, Chichester, United Kingdom.* [2]*Army Personnel Research Capability, Army HQ, United Kingdom.*

(No relevant relationships reported)

PURPOSE: Initial military training typically prepares personnel for service through a combination of structured activities such as physical training, foot drill, and classroom and practical lessons conducted on base and during field exercises. This study compared the training intensity, energy balance, and sleep duration between 5 days of training on base and 5 days on a field exercise in Officer Cadets (OCs). METHODS: Twenty-nine (12 Female, 17 Male, mean ± SD: age 24 ± 2 y, 1.76 ± 0.10 m, body mass 79.4 ± 11.0 kg) OCs volunteered. Energy expenditure was assessed using a wrist-mounted research grade accelerometer, worn during weeks 9 (base) and 22 (field exercise) of the 42-week British Army Regular Commissioning Course. Energy intake was quantified from researcher-led dietary weighing and food diaries for a sub-set of OCs (n=16), which was compared to daily energy expenditure to calculate energy balance. On base and field exercise data were compared using paired and independent

sample t-tests, with statistical significance set at p<0.05. RESULTS: Time spent in the sedentary, light, and moderate exercise intensity zones was similar while training on base and on field-exercise (p>0.05). However, more time was spent in the vigorous exercise intensity zone on base compared to the field exercise (mean difference ± SD: 28 ± 22 min, p<0.001). Daily sleep time was higher on base compared to the field exercise (333 ± 91 vs. 126 ± 79 min, p<0.001) and the OCs were in negative energy balance both on base (-3.17 ± 2.00 MJ), and during the field exercise (-7.18 ± 5.35 MJ), with a greater energy deficit experienced on exercise (p<0.05). CONCLUSIONS: Time spent in physical activity zones were similar during training on base and on field exercise, although less time was spent in the vigorous intensity zone during the latter. However, OCs had less sleep and a greater energy deficit during field exercise, which has potential implications for their ability to sustain the level of activity required; therefore, impacting physical performance and potentially increasing fatigue-related injury risk.

Timing of Energy and Macronutrient Intake of British Army Officer Cadets during Military Training

Victoria C. Edwards[1], Steve D. Myers[1], Andrew G. Siddall[1], Jane E.S Thompson[1], Steven D. Powell[1], Sarah Jackson[2], Julie P. Greeves[2], Sophie L. Wardle[2], Sam D. Blacker[1]. [1]*University of Chichester, Chichester, United Kingdom.* [2]*Army HQ, Andover, United Kingdom.*

(No relevant relationships reported)

Purpose: In athletic populations, the amount and timing of macronutrient intake can influence the restoration of muscle glycogen, attenuation of muscle damage and affect training recovery and adaptations. Despite similarities in the physically demanding, long-term nature of training for both athletes and military personnel, the composition and timing of dietary intake by military personnel is often more limited than athletes, particularly in initial military training establishments. This study quantified the total energy intake and timing of energy and macronutrient intake for Officer Cadets (OC) during training. **Methods:** Twenty (10 male and 10 female) OC's (mean ± SD: age 22 ± 1 years, 1.73 ± 0.08 m, body mass 77.0 ± 9.3 kg) undertaking the British Army Officer Commissioning Course at the Royal Military Academy Sandhurst completed food diaries for 10 days, alongside researcher-led dietary weighing of main meals. Daily energy intake and carbohydrate (CHO), protein (PRO) and fat proportions were analysed using nutritional analysis software (Nutritics). Paired and independent samples t-tests were used to compare dietary intake between meals and sex, respectively. **Results:** Total average energy (M; 16 ± 5, F; 13 ± 3 MJ·day⁻¹) and PRO (M; 144 ± 42, F; 114 ± 25 g·day⁻¹) intake over 10 days was greater for men than women (p<0.05). However33w2, no difference (p>0.05) was found between sexes for CHO (M; 453 ± 148, F: 377 ± 80 g·day⁻¹) and fat (M; 149 ± 46, F; 122 ± 34 g·day⁻¹) intake. Energy, PRO and fat intake, but not CHO intake, was in line with UK Military Dietary Reference Values for both sexes. Average PRO and CHO intake was greater (p<0.05) at mealtimes (M) than snacks (S) irrespective of sex (PRO 112 ± 48 (M) vs 28 ± 28 (S); CHO 306 ± 137 (M) vs 167 ± 134(S) g). However, unlike PRO (breakfast (B) 32 ± 14; mid-morning (S1) 10 ± 10; lunch (L) 38 ± 15; mid-afternoon (S2) 11 ± 11; dinner (D) 42 ± 18; evening (S3) 8 ± 7 g), CHO intake was more evenly spread throughout the day (B 91 ± 43; S1 52 ± 43; L 101 ± 42; S2 66 ± 53; D 114 ± 52; S3 43 ± 38 g). **Conclusion:** The present study indicates that OC energy, PRO and fat intake is in line with current UK military guidelines, however CHO intake was suboptimal. Future research should consider whether a more even distribution of macronutrient intakes throughout the day can aid training adaptions and recovery.

2624   Board #6   June 1 3:15 PM - 5:15 PM

Comparison of Research- and Consumer-grade Energy Expenditure Estimation Methods during 10 Days of Military Training

Andrew G. Siddall[1], Jane E. S. Thompson[1], Steven D. Powell[1], Victoria C. Edwards[1], Sarah S. Kefyalew[2], Priya A. Singh[2], Elise R. Orford[2], Michelle C. Venables[2], Sarah Jackson[3], Julie P. Greeves[3], Sam D. Blacker[1], Steve D. Myers[1]. [1]*University of Chichester, Chichester, United Kingdom.* [2]*Medical Research Council, Cambridge, United Kingdom.* [3]*Army HQ, Andover, United Kingdom.*

(No relevant relationships reported)

PURPOSE: Wearable physical activity monitoring devices have improved the ability to estimate free-living total energy expenditure (TEE) but their application during arduous military training alongside more well-established techniques has not been widely documented. This study aimed to assess the validity of two wrist-worn activity monitors to estimate TEE by evaluating performance against doubly labelled water (DLW) during British Army Officer Cadet (OC) training.
METHODS: Twenty (10 male and 10 female) OCs (mean ± SD: age 22 ± 1 years, height 1.73 ± 0.08 m, body mass 77.0 ± 9.3 kg) wore one research-grade accelerometer (GENEActiv, Cambridge, UK; "RES") on the dominant wrist and one commercially

available (FITBIT SURGE, USA; "COM") monitor on the non-dominant wrist for 10 days of training. Immediately prior to this 10-day period, participants consumed a bolus of DLW and provided daily urine samples, which were analysed by mass spectrometry to determine TEE. Bivariate correlations and limits of agreement were calculated to compare the 10-day mean TEE from DLW with both activity monitors to evaluate device performance.

RESULTS: TEE (mean ± SD) from DLW, RES and COM were 17.2 ± 2.7 MJ day^{-1} (4112 ± 652 kcal day^{-1}), 17.3 ± 2.8 MJ day^{-1} (4129 ± 677 kcal day^{-1}) and 15.1 ± 3.7 MJ day^{-1} (3607 ± 888 kcal day^{-1}), respectively. TEE from DLW was linearly correlated with both RES (r=0.786, p<0.001) and COM (r=0.888, p<0.001). Despite a stronger association with DLW however, COM tended to underestimate TEE (mean bias [95% CI]) by -2.1 [-5.6-1.4] MJ day^{-1} (-505 [-1348-339] kcal day^{-1}; p<0.05). In contrast, mean TEE from RES was similar to DLW (-0.05 [-3.6-3.5] MJ day^{-1}; -11 [-867-845] kcal day^{-1}; p>0.05).

CONCLUSION: Wearable physical activity monitors provides a cheaper and more practical method for estimating free-living TEE than DLW, and could be useful for military populations. However, this study suggests a consumer monitor may underperform, by underestimating TEE, during physically demanding training in comparison to a research-grade device.

Comparison Of Daily Energy Expenditure And Weekly Physical Activity Exposure Estimated Using Consumer And Research-grade Physical Activity Monitors During Officer Cadet Initial Military Training

Steven D. Powell[1], Andrew G. Siddall[1], Jane E. S Thompson[1], Victoria C. Edwards[1], Sarah Jackson[2], Julie P. Greeves[2], Sophie Wardle[2], Sam D. Blacker[1], Steve D. Myers[1]. *[1]University of Chichester, Chichester, United Kingdom. [2]Army HQ, Andover, United Kingdom.*

(No relevant relationships reported)

PURPOSE: Wearable physical activity monitors provide the capability to estimate the physical demands of military training and to potentially inform training practices. This study aimed to compare both the daily energy expenditure (EE) and weekly physical activity (PA) measured from two wrist-worn activity monitoring devices in Officer Cadets (OC) during initial military training.

METHODS: Forty (26 male, 14 female) OC's (mean ± SD: age 24 ± 2, height 1.76 ± 0.08 m, body mass 79.21 ± 9.97 kg) wore a consumer ("CN"; Fitbit Surge, San Francisco, USA) and a research-grade ("RG"; GENEActiv Original, Activinsights, Cambridge, UK) activity monitor during the second 14-week term of British Army OC training. A filtering process was implemented to exclude training days that did not fulfil wear-time criteria. Bivariate Pearsons correlations and limits of agreement (LoA) were used to compare EE measurement and duration of sedentary, light, moderate and vigorous PA between devices.

RESULTS: Mean daily estimated EE from the CN and RG were 13.9 ± 2.5 and 15.7 ± 1.8 MJ day^{-1}, respectively. Estimated daily EE ranged from 8.6 ± 2.8 (day 35) to 22.4 ± 6.7 MJ day^{-1} (day 49) in CN and from 10.7 ± 4.5 (day 55) to 21.3 ± 8.1 MJ day^{-1} (day 49) in RG. There was a strong correlation between EE in CN and RG over 14 weeks (r = 0.761, p<0.001). However, the LoA indicated that CN underestimated EE (mean bias [95% CI] by -1.4 [-16 - 3.2] MJ day^{-1}, p<0.001) compared to the RG. Mean daily estimates from CN were 1069 ± 86 sedentary minutes, 221 ± 44 light minutes, 40 ± 14 moderate minutes and 56 ± 16 vigorous minutes. RG estimated 543 ± 53 sedentary minutes, 90 ± 16 light minutes, 249 ± 52 moderate minutes and 33 ± 14 vigorous minutes. All intensities were significantly different between CN and RG (p<0.05). The CN overestimated on sedentary minutes (526 mins day^{-1} [319 - 734] mins day^{-1}), light minutes (131 [39 - 224] mins day^{-1}) and vigorous minutes (24 [-15 - 62] mins day^{-1}), but underestimated moderate minutes -208 [-295 - -122] mins day^{-1}).

CONCLUSION: Consumer grade physical activity monitors provide an easily accessible tool for monitoring military training but more research is required to improve their accuracy before they can be used to inform training practices.

2626   Board #8   June 1 3:15 PM - 5:15 PM

The Use of Modern Technology to Evaluate Shipboard Metabolic Rate Aboard a U.S. Navy Ship While Deployed in the Persian Gulf

Jay H. Heaney[1], Douglas M. Jones[2], Katherine M. Wilson[2], Eric S. Duckworth[2], Melissa D. Laird[1], Magnus Perkins[3]. *[1]Naval Health Research Center, San Diego, CA. [2]Leidos Inc, San Diego, CA. [3]USS NIMITZ, Bremerton, WA.*

(No relevant relationships reported)

Physiological data are often used to develop work/rest cycles and thermal exposure guidance. A large component of the U.S. Navy's shipboard heat exposure guidance, known as Physiological Heat Exposure Limit (PHEL) curves, relies on metabolic rate. Shipboard work spaces present an extremely challenging work environment

with respect to the impact of high heat and humidity on the integrity of obtaining digital data. Data collections conducted on an aircraft carrier have an increased potential for signal disruption due to the potential for electromagnetic interference and previous attempts have been unsuccessful. With the availability and technological advancement of more robust commercial, wireless physiological data devices, it is now possible to evaluate if existing exposure guidance accurately reflects the work rate performed within the shipboard environment. **PURPOSE:** To obtain actual shipboard metabolic rates of various personnel aboard an aircraft carrier deployed in the Persian Gulf. **METHODS:** Twenty-nine personnel (age: 23 ± 3 yrs, height: 169 ± 10 cm, weight: 79.4 ± 14.3 kg) had their VO_2, HR, and T_{core} measured while performing actual shipboard duties for approximately three hours on two separate days (T1 and T2). Personnel were from the following work spaces: Flight Deck, Hangar Bay, Scullery, Galley, Waste Management, Catapult, and Reactor Room. **RESULTS:** From a possible total collection time of 12,771 min, there were 9,248 min (72%) of usable data for VO_2, 12,120 min (95%) for HR, and 10,711 min (84%) for T_{core}. Mean results were consistent across all personnel for both trials (mean trial duration = 194 ± 33 min). VO_2 was 0.67 ± 0.14 L/min and 0.67 ± 0.11 L/min, p=.22; HR was 102 ± 11 bpm and 96 ± 11 bpm, p=.06; and T_{core} was 37.6 ± 0.2°C and 37.4 ± 0.2°C, p=.04 for T1 and T2, respectively. **CONCLUSION:** Findings from this pilot study indicate that physiological data, including actual work setting VO_2, HR, and T_{core} data, can be obtained using current technology in extreme work place (i.e., field) environments. This sophisticated technology can have a significant impact on developing new work/rest guidance, in addition to heat exposure guidance, in military and civilian work place environments. Results from this pilot evaluation will lead to an effort to revise the U.S. Navy's shipboard PHEL curve guidance.

F-33 Thematic Poster - **Movement Biomechanics in People with Obesity**

Friday, June 1, 2018, 3:15 PM - 5:15 PM

Differences in Jump Landing Mechanics, Strength, and Vertical Jump Height Between Obese and Non-Obese Children

Bradley Bowser, Claire Sylvestre, Christopher Kaddatz. *South Dakota State University, Brookings, SD.* (Sponsor: Matt Vukovich, FACSM)

(No relevant relationships reported)

It has been reported that overweight and obese children display increased joint loading, higher impact loading and decreased joint ROM during walking and running. There is limited research examining the movement mechanics of other high impact activities in children. **PURPOSE:** To compare jumping mechanics, strength, and max vertical jump between healthy weight children and children classified as overweight or obese. **METHODS:** 42 children (22 males, ages 11.1±1.6 yrs; 20 females, ages 10.9±1.3 yrs) were divided into 2 groups based on the CDCP's BMI percentile for children. 24 children were classified as healthy weight (HW) (n=13 males, 11 females; BMI percentile 44.8±25.8) and 18 children were classified as overweight/obese (OW/OB) (n=9 males, 9 females; BMI percentile 95.6±3.9). Participants completed 2 testing session approximately 1 week apart. During the first session age, height, mass, and leg strength were collected. Max torque created during isokinetic knee extensions at 90 degrees/s was used to determine leg strength. For the second visit participants completed a max vertical jump test and 5-10 drop jump trials. For jump trials, participants jumped off a 20 cm platform onto 2 force plates and immediately jumped up to a target set at 60% of their max jump height. Ground reaction forces (1000Hz) and joint kinematics (200Hz) were captured for each trial. One way ANOVAs (α=0.05) were used to determine group differences for each of the variables of interest listed in Table 1. **RESULTS:** Results can be found in Table 1. **CONCLUSION:** There appear to be no group differences in leg strength, max vertical jump height, or max landing force. However, similar to other studies, HW children displayed greater ROM during landings than children classified as OW/OB. Increased joint ROM while landing from a jump has typically been thought to decrease vertical loading, however our data suggests significantly greater ROM does not always result in increased vertical loading.

Variable	HW Mean(SD)	OW/OB Mean(SD)	ANOVA
Leg Strength (Nm/BW)	223.8(41.0)	221.3(57.7)	0.87(0.05)
Max vertical jump (cm)	33.6(7.34)	30.8(7.44)	0.22(0.38)
Max landing force (BW)	2.02(0.38)	1.96(0.47)	0.64(0.14)
Average load rate (BW/s)	34.1(12.6)	26.5(10.0)	0.041(0.67)*
Instantaneous Load rate (BW/s)	110.4(24.1)	82.9(20.3)	0.0003(1.23)*
Dorsiflexion excursion (degrees)	48.6(5.07)	42.6(7.92)	0.008(0.90)*
Knee flexion excursion (degrees)	43.4(9.32)	35.3(8.20)	0.007(0.92)*
Hip flexion excursion (degrees)	21.3(9.83)	14.8(6.10)	0.026(0.79)*

Table 1. Summary of means, p-values and effect sizes for variables of interest

Gait Characteristics In Persons With COPD Who Have Obesity

Micah J. Munoz, Ann Marie N. Wilson, Christian P. Manhard, Stephen Bailey, FACSM, Gytis Balilionis, Srikant Vallabhajosula. *Elon University, Elon, NC.* (Sponsor: Dr. Stephen Bailey, FACSM)
(No relevant relationships reported)

Persons with Chronic Obstructive Pulmonary Disease (COPD) experience a greater fall risk than healthy individuals of the same age. Obesity has been associated to an even greater fall risk in persons with COPD. Gait abnormalities such as an increasing step width has also been associated with severity of COPD. Recent research has shown that a high intensity intervention decreases step width in persons with COPD. However, no research has been done to investigate possible difference in gait pattern between persons with COPD who have obesity and those who have a healthy body mass index (BMI). **PURPOSE**: To investigate differences in gait pattern between people with COPD who have obesity and those who have a healthy BMI. **METHODS:** 9 persons with COPD who have a BMI in the Obese category (OBMI) and 5 persons with COPD who have a BMI in the healthy category (HBMI) participated. Participants completed 5 trials of walking forward at a comfortable pace on pressure-sensor walkway. Velocity, cadence, step width, stride length, and stance % were measured as average of 5 trials and compared between groups using a 2-tailed independent samples t-tests or a Mann-Whitney U test depending on normality. Hedges' effect size was also calculated. **RESULTS**: OBMI group walked with wider steps showing a trend towards statistical significance (OBMI: 15.7±4.9cm; HBMI: 9.9±2.5cm; p=0.053). No other variables were significantly different between the groups. Effect sizes ranged from trivial (0.05 for cadence) to large (1.08 for step width). **CONCLUSION:** A wider step gait in OBMI may be related to increased fear of falling. Research with greater sample size must be done to further investigate the how obesity affects gait patterns in persons with COPD.

Kinetic Features and Recent History of Lower Extremity Injury in Overweight and Obese Runners

Heather K. Vincent, FACSM, Cong Chen, Michelle L. Bruner, Daniel C. Herman, FACSM, Joseph G. Wasser, Kevin R. Vincent, FACSM. *University of Florida, Gainesville, FL.*
(No relevant relationships reported)

Kinetics of running mechanics have been implicated in the development of bony and soft tissue injuries. Progressively heavier runners may be at increased risk for lower extremity injuries due to kinetic factors, but this has yet to be examined. The relationships between running kinetics and recent lower extremity injury among runners of different body sizes are not clear. **PURPOSE:** To determine the key kinetic characteristics of running gait among runners across the spectrum of body mass index (BMI in kg/m^2) values with and without recent history of lower extremity injuries. **METHODS:** Recreational competitive runners (N=278; 46.6% women; 34.8 ± 14.9 yr) were stratified into three BMI groups in kg/m^2: healthy weight BMI<24.9, overweight BMI 25-30, obese BMI≥30. A 3D motion tracking system and instrumented treadmill captured ground reaction forces (GRF) and loading rates at preferred running speed. BMI group comparisons were made using univariate analyses of variance covaried for running speed. Recent history of lower extremity bony and soft tissue injuries related to running was self-reported. Key variables included peak GRF and vertical instantaneous loading rate (VILR). Linear regressions were used to determine the relationship between BMI and VILR after accounting for running speed; models included age, sex, running speed, GRF and VILR. **RESULTS:** Injury prevalence (stress fractures, tendonitis, plantar fasciitis, patellofemoral pain) was not different among the three BMI strata (28%-38%). Peak GRFs were highest in the overweight group compared to the healthy weight and obese runners, respectively (1919 ± 282 N vs 1566 ± 318 and 1794 ± 419 N; p<0.0001). VILR was also highest in

the overweight group compared to the healthy weight and obese runners, respectively (47.9 ± 11.9 kN/s vs 40.7 ± 14.1 kN/s and 39.9 ± 13.3 kN/s; p<0.001). Regression results indicated that after accounting for running speed (R2=.123), BMI accounted for an additional 6% of the variance to the model for VILR (B coefficient 0.251). **CONCLUSIONS:** The effect of BMI on loading rates during running at a preferred speed is relatively small. Our findings indicate that progressively heavier runners were not at a higher risk for lower extremity injury, and this may be due to internal motion adjustments that are made to control VILR and peak GRF at preferred speeds.

Relative Muscle Strength Is Associated With Obesity-induced Biomechanical Adaptations Of The Trunk During Sit-to-stand

Lance M. Bollinger, Amanda L. Ransom, Rebekah F. Seay. *University of Kentucky, Lexington, KY.*
(No relevant relationships reported)

Obesity decreases relative skeletal muscle strength and alters biomechanics during daily activities such as rising from a chair. To date, the role of this decreased muscle strength in obesity-induced biomechanical alterations is unknown. **Purpose:** To determine the relationship between lower extremity skeletal muscle strength and biomechanics during sit-to-stand. **Methods:** Nine obese (BMI 32.5 ± 2.5 kg/m^2) young adults (age: 28.4 ± 5.7 y) completed sit-to-stand task three times from a chair (seat height: 52 cm). Ten high speed cameras were used to track retroreflective coordinate data through 3D motion analysis at a rate of 200Hz. Specific outcomes of interest included: peak trunk flexion velocity (deg/s), peak trunk flexion angle (deg), and task duration (s). Maximal voluntary isometric contractions (MVICs) of the knee extensors and flexors were measured via a previously validated handheld dynamometer (Hoggan MicroFET2) and normalized to body mass. Linear regression was used to determine relationships between body mass and relative muscle strength with independent variables. **Results:** Body mass index was positively associated with peak trunk flexion velocity (y = 4.458x - 57.208, r^2 = 0.506, p = 0.032), but not peak trunk flexion angle (p = 0.127) or task duration (p = 0.924). Conversely, relative knee extensor and knee flexor strength were inversely related to peak trunk flexion velocity and angle (r^2 = 0.541 - 0.780, p < 0.05). The ratio of relative knee extensor to knee flexor strength was inversely related to task duration (y = -0.773x + 4.784 r^2 = 0.553, p = 0.022). **Conclusions:** Excess body mass induces greater trunk flexion velocity, likely to generate sufficient momentum to stand. High levels of knee extensor and flexor strength may decrease peak trunk flexion angle and velocity reduce sit-to-stand time in obesity.

Fatigability of the Dorsiflexor Muscles in People with Type 2 Diabetes and Controls

Kevin Ryan, Jonathon Senefeld, Sarah D'Astice, Bonnie Schlinder-Delap, Sandra Hunter, FACSM. *Marquette University, Milwaukee, WI.* (Sponsor: Dr. Sandra Hunter, FACSM)
(No relevant relationships reported)

People with type 2 diabetes (T2D) and diabetic polyneuropathy are more fatigable for the dorsiflexor muscles during isometric fatiguing contractions; however, it is unknown if the greater fatigability is observed in people with T2D and no signs of neuropathy. **PURPOSE**: To determine the neural and muscular mechanisms of dorsiflexor muscle fatigability for an intermittent isometric contraction task in people with T2D and healthy controls. **METHODS**: 8 people with T2D (65±6 yrs; 29±5 kg·m^{-2}; 8,378±2,712 daily steps; 2 women) with no signs of diabetic polyneuropathy were matched based on age, BMI, and physical activity with 5 healthy controls (64±6 yrs; 26±2 kg·m^{-2}; 9,400±828 daily steps; 2 women). Fatigability was assessed with an intermittent isometric protocol using 6-s contractions at 50% of maximal voluntary contraction (MVC), followed by a 4-s rest until task failure. MVCs were performed every 60s. Task failure was defined as MVC ≤ 50% baseline MVC. Electrically-evoked twitch contractions were elicited during and after each MVC to estimate voluntary activation and contractile properties of the dorsiflexor muscles. **RESULTS**: Time to task failure of the fatiguing task was 42% briefer in people with T2D compared with controls (6.62±4.17 vs. 11.40±6.58 min, respectively; P=0.065). Voluntary activation was similar between T2D and control group at baseline (96.8±3.7 vs. 98.2±1.4%, P=0.43) and declined similarly during the fatiguing task (task end; 94.9±6.4 vs. 92.6±4.0%, P=0.39). The electrically-evoked twitch amplitude was similar for people with T2D and controls before the fatiguing task (5.3±3.8 vs. 5.4±2.3 Nm, P=0.96) and declined similarly during the fatiguing task (51.1±28.0 vs. 55.0±43.3% reduction, P=0.13). **CONCLUSIONS**: Both muscular and neural mechanisms contributed to fatigability of the dorsiflexor muscles for an intermittent isometric fatiguing task in people with T2D and age- and BMI matched-controls, although mechanisms in the muscle played a greater role than the reduction in neural drive. These findings that suggest people with T2D whom have no signs of diabetic polyneuropathy are more

fatigable than controls independent of physical activity levels, although, statistical power analysis indicates 11 people in each group are needed to clarify the findings of this preliminary data set.

2633   Board #6   June 1 3:15 PM - 5:15 PM

Quadriceps Impairment Is Associated With Knee Mechanics During Gait In Obese Young Adults

Michael N. Vakula[1], Koren L. Fisher[2], Pablo B. Costa[2], Derek N. Pamukoff[2]. *[1]Utah State University, Logan, UT. [2]California State University, Fullerton, Fullerton, CA.* (Sponsor: Daniela Rubin, PhD, FACSM)
(No relevant relationships reported)

Obesity is a preventable risk factor for osteoarthritis (OA), a leading cause of pain and physical disability. Prior studies have linked altered gait biomechanics and quadriceps strength deficits to OA development in clinical populations, but data are lacking in young obese individuals without OA.
PURPOSE: To compare quadriceps strength and gait biomechanics between obese (OB) and normal weight (NW) young adults. A secondary purpose was to examine the relationship between quadriceps function and gait biomechanics.
METHODS: 47 participants were recruited and classified by body mass index (BMI), 24 NW (BMI = 21.9±1.7; 54% female) and 23 OB (BMI = 33.7±2.4; 48% female). Fat and fat-free mass (FFM) were obtained via air displacement plethysmography. Quadriceps strength was assessed using a maximal voluntary isometric knee extension at 60° of knee flexion. Gait biomechanics were collected at a standardized (ST) (1 m/s) and self-selected (SS) gait speed. A 2 group by 2 condition ANOVA was used to evaluate peak knee flexion angle (PKF), knee flexion excursion (PKE), peak internal knee extension moment (KEM), peak vertical ground reaction force (vGRF), vertical loading rate (vLR), isometric peak torque (PT), and rate of torque development (RTD). Pearson correlations were calculated between quadriceps strength and gait biomechanics at ST and SS speed.
RESULTS: OB had lower PT (3.52 [95%CI: 3.11, 3.93] vs. 4.11 [95% CI: 3.67, 4.55] Nm/FFM, p=.03), and late RTD (7.6 [95%CI: 6.1, 9.1] vs. 10.0 [95%CI: 8.8, 11.2] Nm/FFM/sec, p=.02) compared to NW. NW had a faster SS gait speed compared to the OB (1.30 [95%CI: 1.29, 1.31] vs. 1.19 [95%CI: 1.11, 1.21] m.s^{-1}, p=.02). *Post hoc* analyses reveal that at SS gait speed, NW had greater vGRF (p =.002), vLR (p=.009), and KEM (p=.01). No differences between groups were found at ST gait speeds. Partial correlation adjusted for SS walking speed revealed a moderate relationship between early RTD and KEM (r=0.42, p<.01).
CONCLUSIONS: OB have deficits in quadriceps strength relative to FFM, and walk slower compared to NW. RTD was moderately associated with KEM, and KEM was lesser in OB compared to NW. Smaller KEM suggests that OB walk with a quadriceps avoidance gait, which may contribute to knee OA development. Exercise interventions targeting RTD may be useful for improving walking mechanics in OB.

F-34   Thematic Poster - Muscle Physiology in Muscular Dystrophy and Cancer

Structural Mechanism For Small-molecule Activation Of The Serca Calcium Pump In Muscular Dystrophy

Samuel F. Carlson, J. Michael Autry, Ji Li, Hideki Aihara, Razvan L. Cornea, David D. Thomas. *University of Minnesota - Twin Cities, Minneapolis, MN.* (Sponsor: Dawn Lowe, FACSM)
(No relevant relationships reported)

Purpose: We have characterized a small-molecule activator of SERCA, the sarcoplasmic reticulum calcium transporting ATPase in muscle. A hallmark of muscular dystrophy (MD) is decreased sarcolemma stability and increased calcium influx, leading to myocyte damage and death. Increasing SERCA activity by gene therapy reverses MD in cell culture and animal models. We continue the characterization of recently-discovered small-molecule activators (SMA) of SERCA by the Thomas lab, since their binding site on SERCA was unknown. **Methods:** Small-molecule activation of SERCA was characterized by three techniques: enzyme assays, fluorescence spectroscopy, and x-ray crystallography, with particular focus on the potent SMA1163. **Results:** ATPase assays indicate that SMA1163 stimulates SERCA activity by 36 ± 11%, with an EC$_{50}$ of 3 ± 1 µM (n=6). SMA1163 activated

both ATPase activity and calcium transport by SERCA. Tryptophan (TRP) residues of SERCA exhibit a potent, dose-dependent fluorescence quenching by SMA1163, with an EC$_{50}$ = 2 ± 1 µM, indicating a transmembrane binding site of SMA1163. Fluorescence of a site-directed fluorescein probe (FITC) identifies kinetic transitions resulting from SMA activation, including enhancement of calcium binding and phosphate release. Conformation-specific proteolytic cleavage and intramolecular glutaraldehyde cross-linking were used to determine the effect on SERCA headpiece structure, indicating that SMA1163 retains normal ligand-binding effects. An atomic structure of SERCA+SMA1163, determined by x-ray crystallography, indicates a transmembrane domain binding site for SMA1163 on SERCA, consistent with TRP fluorescence. Furthermore, the binding site of SMA1163 is located on the energy transduction segment of SERCA, consistent with the kinetic mechanisms of activation detected by FITC fluorescence. **Conclusions**: We propose that SMA1163 may be a useful activator of SERCA calcium transport to help alleviate MD, as an alternative approach to SERCA gene therapy.

Isometric Training Increases Strength and Improves Pathophysiology of Dystrophic Skeletal Muscle

Angus Lindsay, James M. Ervasti, Dawn A. Lowe, FACSM. *University of Minnesota, Minneapolis, MN.* (Sponsor: Dawn A. Lowe, FACSM)
(No relevant relationships reported)

Mice lacking dystrophin (*mdx*) exhibit skeletal muscle weakness and susceptibility to contraction-induced injury. Because dystrophin mediates radial force transmission and skeletal muscle membrane integrity, the debate continues regarding the practicality and ethical implications of prescribing exercise training for patients with Duchenne muscular dystrophy (DMD). **PURPOSE:** To determine if isometric contractions improve skeletal muscle strength and morphology of *mdx* mice. **METHODS:** Anterior crural muscles of male wildtype and *mdx* mice were subjected to either no training or training sessions composed of 5 isometric tetanic contractions and a torque-frequency protocol *in vivo*. In Study 1, mice (n = 8) completed 3 training sessions over 7 days followed by an i*n vivo* eccentric contraction injury protocol. In Study 2, mice (*mdx* only, n = 8) completed 6 training sessions over 28 days. Centrally-nucleated fibers, myosin/actin content, fiber cross-sectional area and embryonic MHC (eMHC) positive fibers from *tibialis anterior* (TA) muscles were quantified. **RESULTS:** In Study 1, peak isometric torque increased in both wildtype (2.6 to 2.9 N·mm, p = 0.03) and *mdx* (3.0 to 3.6 N·mm, p < 0.01) mice after 7 days; however this did not affect *in vivo* susceptibility to eccentric contraction-induced injury of *mdx* mice (p = 0.69). In Study 2, peak isometric torque of *mdx* mice increased after 28 days (2.6 to 3.4 N·mm, p = 0.04). Training resulted in lower TA mass of the trained compared to the contralateral leg (67 ± 4 vs 81 ± 3 mg, p = 0.02) without altering the content of myosin-actin (p = 0.82). Trained TAs also had reduced fibrosis (5.1 ± 0.5 vs 2.9 ± 0.4%, p = 0.02), fewer eMHC positive fibers (3.6 ± 0.8 vs 0.9 ± 0.2%, p = 0.03) and more uniformly-sized fibers compared to untrained TAs. **CONCLUSION:** These results show that exercise training in the form of isometric tetanic contractions can improve dystrophic muscle strength and morphology indicating a potential alternative therapy for enhancing muscle strength and ambulation in patients with DMD.

2637   Board #3   June 1 3:15 PM - 5:15 PM

Recovery of Membrane Excitability in Dystrophic Skeletal Muscle Following Eccentric Contractions

Cory W. Baumann[1], Gordon L. Warren, FACSM[2], Dawn A. Lowe, FACSM[1]. *[1]University of Minnesota, Minneapolis, MN. [2]Georgia State University, Atlanta, GA.*
(No relevant relationships reported)

PURPOSE: Dystrophin, a subsarcolemmal protein, plays a role in maintaining membrane integrity of muscle fibers. A key feature of skeletal muscle that lacks dystrophin, as in the *mdx* mouse model for Duchenne muscular dystrophy (DMD), is a heightened sensitivity to contraction-induced strength loss. We have previously reported that this exaggerated loss of strength is attributed to impaired membrane excitability, which is evident during and immediately following eccentric (ECC) contractions. However, a detailed electromyographic (EMG) analysis of the time course of recovery from this type of injury is currently lacking. The purpose of this study was to assess recovery of strength and membrane excitability of injured, dystrophic muscle. **METHODS:** Male *mdx* mice were chronically implanted with stimulating electrodes on the left common peroneal nerve and EMG electrodes on the left tibialis anterior muscle. The left anterior crural muscles of anesthetized mice performed 50 maximal ECC contractions. Peak isometric torque and M-wave root mean square (RMS) were measured up to 14 days post-injury. **RESULTS:** Torque and M-wave RMS were reduced 66% (p < 0.001) from the first to last ECC contraction, with 99% (p < 0.001) of the variance in torque being explained by the variance in M-wave RMS. Immediately after the ECC protocol, isometric torque and M-wave RMS were reduced 61% (2.87 to 1.10 mN m) and 52% (1.37 to 0.65 mV), respectively,

---

compared to pre-injury (p < 0.001). By day 2, the low M-wave RMS recovered to pre-injury (1.37 vs. 1.18 mV, p = 0.34) and coincided with a large improvement in isometric torque (1.10 to 1.85 mN·m, p < 0.001), which fully recovered by day 9 (2.87 vs. 2.90 mN·m, p = 0.82). **CONCLUSIONS:** These data substantiate that a main contributor to ECC contraction-induced strength loss in dystrophic muscle is impaired membrane excitability. Moreover, acute recovery of strength in the days after the ECC protocol occurred in conjunction with the restoration of membrane excitability. Our results provide a mechanistic explanation for why dystrophic muscle is more prone to ECC contractions and gives insight into how the muscle recovers post-injury. Importantly, these findings may aid in the development of therapeutic treatments for patients with DMD, particularly in regards to establishing safe and effective exercise programs.

The Effect of Exercise Interventions on Muscle Fiber Type in mdx Mice

Matthew C. Kostek, FACSM, Kailey Omstead. *Duquesne University, Pittsburgh, PA.*
(No relevant relationships reported)

Duchenne Muscular Dystrophy (DMD) is the most common lethal genetic disease in boys. There is no cure and few treatments. A gene mutation (dystrophin) causes the disease and the pathology is exacerbated by chronic inflammation. Our previous studies have shown exercise interventions affect the pathology of dystrophic muscle. In the current study we sought to examine the effect of two different exercise protocols and contraction types on muscle fiber type. **Purpose:** The goal of our study is to determine the effect of exercise and contraction type on muscle fiber type changes in dystrophic mouse muscle. **Methods:** 36 male mdx mice and 7 control (healthy) mice, approximately 5 weeks of age were randomized to four groups: voluntary wheel running exercise, concentric-only, or eccentric-only exercise for 4 or 8 weeks. At study conclusion, skeletal muscle tissue was extracted and preserved for analysis. Fiber typing was conducted with standard immunohistochemistry techniques. All dependent variables were analyzed with a one-way ANOVA to examine differences between treatment groups. A p-value of < 0.05 was considered significant. **Results:** All mice completed the study. Fiber type of gastrocnemius muscle demonstrated an increase in the percentage of type I fibers (5.2 + 3.6%, p = 0.04). No differences were noted between concentric and eccentric-only exercise muscle contractions. A standard histologic analysis of the gastrocnemius revealed a decrease in fiber necrosis due to exercise interventions (p = 0.03). Exercise was able to modify muscle fiber type in mdx mice. **Conclusion:** Exercise may have a role in improving the oxidative capacity and muscle fiber characteristics in muscular dystrophy and is dependent on the type of exercise.

2639   Board #5   June 1 3:15 PM - 5:15 PM

The Effect of Creatine and Creatinine on Myocellular Injury in Doxorubicin-Treated Skeletal Muscle Myoblasts

Eric Bredahl[1], Wisam Najdawi[1], Sarah Hook[1], Joan Eckerson, FACSM[1], Jake Siedlik[1], Kristen Drescher[2]. *[1]Creighton University, Omaha, NE. [2]Creighton University School of Medicine, Omaha, NE.* (Sponsor: Dr. Joan M. Eckerson, FACSM)
(No relevant relationships reported)

Doxorubicin (DOX) is a powerful chemotherapy agent that is associated with a number of deleterious side effects including skeletal muscle dysfunction and atrophy. Although the exact mechanisms behind the observed myotoxicity are not fully understood, DOX treatment has been shown to result in the generation of reactive oxygen species and changes in short-term energy metabolism. Conversely, creatine (Cr) supplementation has been shown to have a therapeutic role in several disease states characterized by muscle atrophy, which is a hallmark of DOX treatment. **PURPOSE:** To examine the ability of Cr and CrN to attenuate the decline in Cr metabolism and minimize DOX-induced apoptosis and necrosis in skeletal muscle myoblasts. **METHODS:** Rat skeletal muscle myoblasts were cultured until they reached 85-90% confluency using rat skeletal muscle growth media (GM). Cells were subcultured and treated with one of the following for 12 hours: normal GM (control); Cr (10mM Cr+GM); CrN (10mM CrN+GM); DOX (25µM DOX+GM); DOX+Cr+GM; and DOX+CrN+GM. After incubation, protein analysis was performed using western blotting and rates of apoptosis and necrosis were assessed using an Annexin V apoptosis detection kit and high contrast staining. A one-way ANOVA with Tukey's *post-hoc* testing was used to detect significance. **RESULTS:** There was a significant change relative to GAPDH in creatine kinase (CK) expression between the control and DOX-treated cells (15±18.2% vs. 90±8.7%, p=0.03). In addition,13.2±7.5% of DOX-treated cells were undergoing apoptosis, which was significantly higher than the 3.26±5.5% in the control cells (p=0.04). No significant differences in rates of apoptosis were found between control samples and cells treated with DOX+Cr or DOX+CrN. **Conclusion:** These findings suggest that CK expression is significantly altered in skeletal muscle myoblasts treated

with DOX relative to control cells and that DOX treatment results in higher rates of necrosis and apoptosis. Treatment with Cr or CrN minimized the DOX-induced change in CK expression, as well as the rate of apoptosis and necrosis. These findings suggest that Cr and CrN may attenuate the degree of skeletal muscle dysfunction and atrophy during chemotherapy with DOX.

Effect of Resistance Training on Contractile Force Production during Doxorubicin-Treatment

Mikayla Kaufenberg[1], Allison Tigner[1], Sarah Hook[1], MacKenzie Twaddell[1], Meghan Wagner[1], Eric Bredahl[1], Jake Siedlik[1], Joan Eckerson, FACSM[1], Kristen Drescher[2]. *[1]Creighton University, Omaha, NE. [2]Creighton University School of Medicine, Omaha, NE.* (Sponsor: Dr. Joan Eckerson, FACSM)
(No relevant relationships reported)

Doxorubicin (DOX) is a powerful chemotherapy agent associated with several harmful side effects including cardiovascular and skeletal muscle dysfunction. The observed muscle dysfunction can have a significant impact on the capacity of the DOX-treated patient to perform activities of daily living. Although it has been shown that aerobic and anaerobic exercise before treatment can minimize the degree of DOX-induced muscle dysfunction, few studies have examined the effect of resistance training (RT) on muscle dysfunction during chemotherapy treatment with DOX. **PURPOSE:** To examine the ability of RT on skeletal muscle dysfunction during DOX treatment using a rat model. **METHODS:** Male Sprague-Dawley rats (N=39) were randomly assigned to one of four groups: Sedentary + Saline (SS, n=8), Sedentary + DOX (SDOX, n=10), RT + Saline (RTS, n=12), and RT + DOX (RTDOX, n=9). Animals in the RT groups were housed in specialized cages where the food and water height was progressively elevated so that they achieved an erect bipedal stance to access their food and water for a total of 15 wk. Animals in the sedentary groups remained in standard animal housing for the duration of the study. Starting week 10, animals received weekly intraperitoneal injections of DOX (3 mg/kg) for 4 wk. One week after their last injection, animals underwent *ex vivo* muscle analysis of the soleus (SOL) and extensor digitorum longus (EDL) muscles. A one-way ANOVA with Tukey's post-hoc testing was used to detect significance. **RESULTS:** Maximal twitch forces for the EDL were significantly lower in the SDOX (6.01 ± 1.85 g/s vs. 11.39 ± 3.48 g/s, p=≤0.05) group compared to SS. Rats in the RTDOX had a significantly higher maximal twitch force compared to SDOX (9.37 ± 3.01 vs. 6.01 + 1.85 g/s, p=≤0.05) and a significantly lower twitch force compared to RTS (9.37± 3.01 vs. 15.42 ± 4.83, p=≤0.05) for the EDL. No significant differences were found among the groups for maximal twitch forces in the SOL. **CONCLUSION:** These findings suggest that DOX-induced muscle dysfunction is more pronounced in the EDL than the SOL. However, it appears that RT during treatment is effective in mitigating some of the effects of DOX-induced muscle dysfunction in the EDL.

Cancer Environments Effect on Skeletal Muscle mTORC1 Regulation by Physical Activity and Feeding in Mice

Brittany Counts, Brandon VanderVeen, Justin Hardee, Dennis Fix, Ryan Montalvo, James Carson, FACSM. *University of South Carolina, Columbia, SC.* (Sponsor: Dr. James Carson, FACSM)
(No relevant relationships reported)

Physical activity and feeding behaviors exert continuous regulation on daily skeletal muscle anabolic signaling. Mice exhibit diurnal variation in physical activity levels and food intake, which are significantly elevated during the dark cycle and negligible during the light cycle. The mechanistic target of rapamycin complex 1 (mTORC1) signaling axis serves to integrate feeding and activity behaviors to regulate muscle anabolism. The Apc[Min/+] (MIN) mouse is an established preclinical model of cancer cachexia. While cachexia suppresses basal mTORC1 signaling, there are significant gaps in our understanding of how the cancer environment effects diurnal mTORC1 fluctuations to feeding and activity. **Purpose**: We examined the cancer environment's effect on diurnal mTORC1 flux in skeletal muscle. **Methods**: Body weight, food consumption, physical activity, and plasma glucose were monitored for 4 consecutive days at the end of the light (SEDINTARY [SED]) and dark (ACTIVE [ACT]) cycles in male C57BL/6 (B6; N=16) and MIN (N=14) mice. Mice had free access to food and water, and were sacrificed at the end of either the SED or ACT state. Gastrocnemius muscle was used for analysis. Statistical significance was set at p≤0.05. **Results**: B6 exhibited significant differences in physical activity, food consumption and plasma glucose between SED and ACT states; the cancer environment disrupted this response. MIN activity was reduced 50% (p=0.002) during the ACT state compared to B6. MIN did not have a diurnal variation in circulating glucose (p=0.186), and food intake was increased 2.3 (p<0.001) fold during the SED state. B6 muscle 4EBP1 phosphorylation, a marker of mTORC1 signaling, was induced by the ACT state compared to SED state (p=0.003). Muscle 4EBP1 phosphorylation flux (ACT / SED ratio) was suppressed (p=0.002) in the MIN compared to B6. **CONCLUSION**: Daily muscle anabolic flux

FRIDAY, JUNE 1, 2018

is disrupted in MIN mice. Moreover, this suppressed anabolism, which may be driven by decreased feeding and reduced physical activity behaviors. Future studies should examine if targeting these behaviors can improve skeletal muscle anabolic flux in the presence of the cancer environment. Supported by NCI R01-CA121249

Effect Of Aerobic Physical Training On The Expression Of Muscular Myomirs In Experimental Models Of Cancer.

João LP Gomes, Gabriel C. Tobias, Tiago Fernandes, Andre C. Silveira, Patricia C. Brum, Roger Chammas, Edilamar M. Oliveira. *University of Sao Paulo, Sao Paulo, Brazil.*

(No relevant relationships reported)

PURPOSE: There are several comorbidities associated with cancer as muscle cachexia. MicroRNAs (miR) in skeletal muscle (myomiRs) has been highly investigated for being related to several physiological and pathological factors. Aerobic physical exercise plays an important role in the regulation of the expression of several microRNAs.**METHODS**: We analyzed the expression of myomiRs using two mice models MMTV-PyMT (breast cancer, non-cachectic) and CT26 (colon cancer, cachectic). Animals were running trained and divided into 4 groups: SH-sedentary Health; ST-Sedentary Trained; CS-Cancer Sedentary; CT-Cancer Trained. Body and skeletal muscles were weights. Skeletal muscle function was analyzed by grip strength. We analyzed microRNAs expression by RT-PCR and proteins levels by Western blot. The tumor volume was determined by macroscopic caliper measures.**RESULTS**: Exercise training prevented the tumor progression. MMTV non-cachectic animals showed no loss of muscle mass and function. MiR-206 expression increased CS and miR-486 was decreased and it was not prevented in CT group. We also evaluated the same parameters in the CT26 model. The body mass, gastrocnemius and anterior tibial weight were decreased in CS and it was not prevented in CT group. Cancer increased the expression of miR-206 in skeletal muscle and aerobic training does not prevent these effects. The expression of miR-486 was decreased in CS group and PTEN levels was increased (p<0.05), decreasing PI3K-AKT-mTOR pathway and decreased muscle mass and function. However aerobic trained does not prevented theses effects. **CONCLUSIONS**: MiR-486 expression was decreased in skeletal muscle and circulation due to cancer and can be regulating cachexia by decreasing protein synthesis pathway. While miR-206, that is a skeletal muscle specific, was increased and the target genes tested were not modified. Thus, these two microRNAs can be markers of the skeletal muscle damage in cancer cachexia, regulating the of protein synthesis pathways.

Evaluation Of Lean Body Mass As A Predictor Of Dietary Protein Intake

Joseph R. Stanzione, Joseph I. Boullata, Michael Bruneau, Jr., Stella L. Volpe, FACSM. *Drexel University, Philadelphia, PA.* (Sponsor: Stella L. Volpe, FACSM)

(No relevant relationships reported)

Protein is of increasing concern with respect to intake recommendations. Presently, most predictive calculations for protein recommendations are based on either actual body weight (ABW) or a calculated ideal body weight (IBW). It has been proposed that, when calculating protein needs, dosing may be better predicted using lean body mass (LBM) rather than ABW or IBW. **PURPOSE:** To explore whether a relationship exists between average protein intake and LBM in Masters athletes**. METHODS:** This was a cross-sectional study, where 132 Masters athletes (70 women; 62 men) (39±10 years of age) were measured for LBM with dual-energy X-ray absorptiometry (DXA). Athletes also completed a food frequency questionnaire (FFQ) to determine average daily protein intake. Bivariate and multivariate regression models were used to correlate and predict LBM with protein intake, after controlling for percent body fat (PBF), sex, age, and body mass index (BMI) as potential confounders. Alpha levels were set *a priori* at p<0.05. **RESULTS:** Significant correlations were reported between LBM and protein intake (r=0.297, p<0.001), PBF and protein intake (r=-0.343, p<001), and sex and protein intake (r=-0.272, p<0.01), and were included in our multivariate regression. LBM predicted protein intake bivariately (R^2=0.088,p<0.001), but was lost in the multivariate model when PBF and sex were controlled (p>0.05). PBF alone predicted protein intake in this model (sr=0.112, sr =-0.215, p<0.01). **CONCLUSION:** Our results support a significant relationship between protein intake and LBM in Masters athletes using a bivariate model; however, it is unclear whether a definitive relationship exists due to lack of significant results in the multivariate model. An additional finding revealed that PBF demonstrated a significant negative relationship with protein intake. Longitudinal research should be conducted to better elucidate these relationships.

Blood Flow Restriction Combined With Low-load Resistance-type Exercise Increases Myofibrillar Protein Synthesis Rates

Jean Nyakayiru, Cas J. Fuchs, Joey S.J. Smeets, Annemie P. Gijsen, Joy P.B. Goessens, Luc J.C. van Loon, Lex B. Verdijk. *Maastricht University, Maastricht, Netherlands.* (Sponsor: Professor Janice L Thompson, PhD, FACSM)

(No relevant relationships reported)

Blood flow restriction (BFR) with or without resistance type exercise training has been suggested to increase muscle mass and strength. However, there is limited data on the acute effects of blood flow restriction in combination with or without low-load resistance-type exercise on muscle protein synthesis rates.
PURPOSE: To determine the impact of blood flow restriction with and without concomitant low-load resistance-type exercise on *in vivo* myofibrillar protein synthesis rates in healthy young males.
METHODS: Twenty young healthy men (age: 24±1 y, BMI: 22.9±0.6 kg/m²) were randomly subjected to two 5-min cycles of single leg blood flow restriction combined with (LLRE-BFR; n=10) or without (REST-BFR; n=10) low-load resistance-type exercise (20%-1RM). Myofibrillar protein synthesis rates were assessed by combining a primed continuous L-[ring-$^{13}C_6$]phenylalanine infusion with the collection of blood samples and muscle biopsies from both the blood flow restricted and control leg in each participant.
RESULTS: In resting conditions, blood flow restriction (REST-BFR) did not increase myofibrillar protein synthesis rates when compared to the control leg (0.0445±0.0037 vs 0.0432±0.0038 %/h, respectively; P=0.683). In contrast, when combined with low-load resistance-type exercise, blood flow restriction (LLRE-BFR) increased post-exercise myofibrillar protein synthesis by 10±5% when compared to the control leg (0.0475±0.0047 vs 0.0433±0.0042 %/h, respectively; P=0.042).
CONCLUSIONS: Blood flow restriction does not increase myofibrillar protein synthesis rates in healthy young men. When combined with low-load resistance-type exercise, blood flow restriction increases post-exercise myofibrillar protein synthesis rates.

Myofibrillar Protein Synthesis to Traditional and Cluster Sets in Trained Young Men and Women

Amadeo F. Salvador[1], Sarah K. Skinner[1], Joseph W. Beals[1], Justin Parel[1], Alexander Ulanov[1], Lucas Li[1], Scott A. Paluska, FACSM[1], Jonathan M. Oliver[2], Nicholas A. Burd[1]. *[1]University of Illinois at Urbana-Champaign, Urbana, IL. [2]Texas Christian University, Fort Worth, TX.* (Sponsor: Scott A. Paluska, FACSM)

(No relevant relationships reported)

During traditional (TRD) resistance exercise, there is a decrease in the velocity and power output achieved over the course of a set consisting of multiple repetitions. Reconfiguration of an exercise set into a cluster set (CLU), which includes a brief intra-set rest period, has been shown to counteract this performance decline. However, the effect of intra-set rest manipulations during resistance exercise on changes in postexercise myofibrillar protein synthesis rates (MPS) is not clear. **PURPOSE:** We determined if any differences exist in the stimulation of postexercise MPS to acute bouts of CLU and TRD paradigms of barbell back squats. **METHODS:** In crossover trials, 5 resistance trained men and women (23±2 y; LBM: 60±5 kg; 1RM back squat: 143±13 kg) performed CLU or TRD configurations of barbell back squats and ingested 20 g whey protein before and immediately after exercise. Blood and muscle biopsy samples were collected at rest and after exercise during primed continuous L-[ring-$^{13}C_6$]phenylalanine infusions. The TRD condition consisted of 4 sets × 10 repetitions with 120 seconds inter-set rest. CLU condition consisted of 4 sets × (2 × 5) repetitions with 90 seconds inter-set rest and 30 seconds intra-set rest at ~70% of 1RM. Mean and peak velocity were measured for all repetitions. **RESULTS:** Volume load (repetitions × load) was matched between the TRD (8400±39 kg) and CLU conditions (8400±39 kg; P=XX)). CLU condition tended to allow for greater mean velocities versus TRD condition over the 4 sets (0.52±0.02 m/s and 0.47±0.02 m/s, respectively). The cumulative (0-5 h) MPS were increased (P<0.05) above basal in both TRD (237%) and CLU conditions (215%) with no difference between conditions (P=0.72).

Abstracts were prepared by the authors and printed as submitted.

However, the temporal pattern of change in MPS tended to be greater in the TRD conditions versus CLU condition (P=0.10). **CONCLUSION:** These data showed that both TRD and CLU configurations of barbell back squat augment postexercise MPS throughout 0-5 h of recovery in trained young men and women. These data indicate that the intra-set rest manipulations present in CLU do not induce differences in muscle anabolism from TRD-style of resistance exercise in trained young men and women.

Dose Effect of Whey Protein on Gut Hormone Responses in Pre-Diabetics and Type 2 Diabetics

Chris Irvine[1], Todd Castleberry[1], Michael Oldham[1], Matthew Brisebois[1], Sarah Deemer[2], Ryan Gordon[1], Aubrien Henderson[1], Vic Ben-Ezra[1]. [1]*Texas Woman's University, Denton, TX.* [2]*The University of Alabama Brimingham, Brimingham, AL.* (Sponsor: Dr. David Nichols, FACSM)

(No relevant relationships reported)

BACKGROUND: GLP-1 and GIP have been shown to increase following a 50 g dose of whey protein prior to a high glycemic load in type 2 diabetics. However, this increase is reduced in diabetics compared to healthy individuals. Pancreatic polypeptide (PP) and peptide tyrosine tyrosine (PYY) also increase, while ghrelin decreases after the consumption of whey protein; however, it is not known if a similar hormone response occurs with a lower dose of whey protein consumption prior to a glycemic load or if there is a dose effect. Our hypothesis was that 20 g and 30 g of whey protein would elicit an increase in GLP-1, GIP, PP, and PYY and decrease ghrelin in a dose dependent manner.
PURPOSE: The purpose of this study was to examine the effect of two different doses of whey protein ingested 30 min prior to a 50 g OGTT on gut hormone and incretin response.
METHODS: Nine diabetic and pre-diabetic participants (n=9, mean ± SD; age: 64.3 ± 8.1 yrs; BMI: 29.4 ± 6.0 kg/m²; HbA1c: 6.4 ± 0.6%) completed three trials. The randomly assigned trials consisted of: ingestion of 250ml of water (CON); 250 ml of water + 20 g whey (20g); 250ml of water + 30 g whey (30g), prior to completing a 50 g OGTT. Blood was collected at -30, 0, 15, 30, 60, 90, 120, and 150 min for the measurement of GIP, GLP-1, ghrelin, PP, and PYY. The whey protein mixture was administered immediately following the -30 min and the 50 g OGTT began immediately after the 0 min blood draw. Metabolites were measured using multiplex fluorescent detection. One-way repeated measure ANOVA was used for statistical analysis for each dependent variable ($P < 0.05$).
RESULTS: 20g and 30g of whey protein significantly increased integrated area under the curve (AUC) of GIP 32% and 38% compared to CON. 30g significantly decreased ghrelin AUC -13.9% and -20% compared to 20g and CON. 30g significantly increased PP AUC 28% compared to CON only. There were no differences in ghrelin and PP AUC between 20g and CON. There were no significant differences for GLP-1 and PYY between all trials.
CONCLUSION: 30 g of whey protein prior to a glucose challenge increased the secretion of GIP and PP and decreased ghrelin in type 2 and pre-diabetics. There seems to be a dose affect relationship between whey, ghrelin, and PP. 30 g of whey preload may induce insulinotropic and satiety effects stemming from GIP, PP, and ghrelin responses in type 2 and pre-diabetics.

Aerobic Exercise Training Improves Myofibrillar Protein Synthesis, Capillarization, and Quadriceps Strength in Older Adults

Camille R. Brightwell[1], Tatiana Moro[1], Christopher S. Fry[1], Melissa M. Markofski[2], Elena Volpi[1], Blake B. Rasmussen[1]. [1]*University of Texas Medical Branch, Galveston, TX.* [2]*University of Houston, Houston, TX.*

(No relevant relationships reported)

Skeletal muscle atrophy and subsequent strength loss occur in aging via a myriad of biological mechanisms. This involuntary loss of muscle and strength, termed sarcopenia, can progress to a clinically relevant decline in physical function. Resistance exercise training (RET) effectively attenuates sarcopenia, but RET may not be feasible for many older adults. Aerobic exercise training (AET) is well-established to improve cardiopulmonary health; however, its effects on protein turnover, skeletal muscle mass and strength are less clear. **PURPOSE:** The aim of this study was to determine if AET improves basal myofibrillar protein synthesis (MPS) and capillarization, thereby promoting skeletal muscle hypertrophy and increased strength. We hypothesized that basal MPS would increase in response to AET and that this would be accompanied by enhanced capillarization, skeletal muscle mass, and strength. **METHODS:** Subjects included healthy older adults who were randomized to non-exercise (NON; n=11, 71.4 ± 1.3 y) or exercise (EX; n=12, 73.7 ± 1.2 y). EX group completed 24 weeks of walking 3x/week for 1 hr at 70% heart rate reserve, while the NON group did not participate in structured exercise. For both groups, a stable isotope tracer was infused after an overnight fast before and after 24 weeks.

Muscle biopsies were taken from the *vastus lateralis* to assess MPS and capillarization. Subjects performed maximal strength testing via isokinetic dynamometry, and lean mass was determined with dual-energy X-ray absorptiometry (DXA). **RESULTS:** Basal MPS increased in the EX group (+50.7%, p=0.0094) along with capillary density (+66.4%, p=0.0333), peak oxygen consumption (+15.8%, p=0.0104), and isokinetic quadriceps strength (+15.1%, p=0.0149). Lean mass did not change in either group (p>0.05). **CONCLUSION:** These results indicate the effectiveness of AET to increase muscle protein turnover and capillarization in healthy older adults, possibly ridding muscle of damaged proteins and improving overall muscle quality. We conclude that AET improves muscular strength which may mitigate the functional decline associated with sarcopenia.

Blunted Muscle Protein Synthetic Response To Feeding And Resistance Exercise In Obese Young Adults

Joseph W. Beals, Sarah K. Skinner, Stephan van Vliet, Isabel G. Martinez, Elizabeth G. Poozhikunnel, Alexander V. Ulanov, Li Lucas, Scott A. Paluska, Nicholas A. Burd. *University of Illinois, Urbana, IL.* (Sponsor: Scott A Paluska, FACSM)

(No relevant relationships reported)

Abstract

Obesity induces anabolic resistance of myofibrillar protein synthesis rates (MPS) to the ingestion of a protein-dense food in young adults. However, the effectiveness of acute resistance exercise before food ingestion to enhance the amino acid sensitivity of MPS with obesity has not been examined. **PURPOSE:** To compare the impact of resistance exercise on MPS responses to protein-dense food ingestion in normal-weight (NW) and obese (OB) young adults. **METHODS:** 7 NW (21±1y, BMI 21.9±0.5 kg/m²) and 7 OB (22±1y, BMI 35.7±2.3 kg/m²) men and women underwent primed continuous L-[*ring*-¹³C$_6$]phenylalanine infusions coupled with blood and muscle biopsy collections to measure MPS at basal and fed-state of the exercise (EX) and non-exercise (CON) legs. Participants performed unilateral resistance exercise (4 sets × 10-12 repetitions) followed by the ingestion of 6 oz of lean pork loin (36 g protein; 4 g fat; 180 kcal). **RESULTS:** Total work performed during exercise was similar among groups (NW: 1610±164 kg; OB: 1888±154 kg, P=0.24). Plasma essential amino acid concentrations increased similarly after pork ingestion in both groups (time effect: P<0.05) with peak values at 2 h of the postprandial period. Basal MPS was similar between NW and OB groups (P>0.05). MPS was stimulated in the EX and CON legs after pork ingestion in both the NW (absolute change from basal: CON 0.027±0.008 %/h; EX 0.058±0.011 %/h) and OB groups (CON 0.027±0.006 %/h; EX 0.033±0.011 %/h; P<0.05). MPS was stimulated to a greater extent in the EX vs. CON legs in NW (P=0.02) but not OB group (P=0.26). **CONCLUSION:** Our results suggest that increased adiposity may attenuate the effectiveness of resistance exercise to augment the postprandial MPS response.

The Effect of Pre Sleep Casein Protein Consumption on Next Morning Resting Metabolic Rate in Resistance Trained Women

Brittany R. Allman, Margaret C. Morrissey, Michael J. Ormsbee, FACSM. *Florida State University, Tallahassee, FL.*

(No relevant relationships reported)

The Effect of Pre-Sleep Casein Protein Consumption on Next-Morning Resting Metabolic Rate in Resistance-Trained Women
Brittany R. Allman, Margaret C. Morrissey, Michael J. Ormsbee FACSM
Institute of Sports Sciences & Medicine, Florida State University
Nighttime eating has been discouraged by the media due to its purported negative implications on metabolism. However, recent studies have shown that nighttime casein protein (PRO) either increases or has no effect on next morning resting metabolic rate (RMR). However, the effects of eating PRO at night on RMR in resistance-trained women is unclear. **PURPOSE**: To examine the effect of consuming nighttime PRO on next-morning RMR in resistance-trained women. **METHODS**: Thirteen healthy, resistance-trained (squat 100% body weight, bench press 70% body weight), normal weight and fatness (BMI, 19.9±2.3 kg/m²; body fat 28.7±4.9%), eumenorrheic females (age, 22±3 years) volunteered for this study. Participants reported to the lab on four different occasions: pre-testing and maximal testing familiarization (1a), maximal testing (1b), and two experimental trials (2 and 3). Thirty minutes before bed participants consumed micellar casein protein (PRO; 30g protein, 120kcals) or a non-caloric, sensory-matched placebo (PLA; 0g protein, 0kcals) in random order. RMR and respiratory exchange ratio (RER) were measured using open-circuit indirect calorimetry at baseline (BL) and immediately upon waking (AM) the following morning. **RESULTS**: There was no significant change in next-morning RMR when

consuming PLA (BL: 1554±193; NM: 1537±204 kcal/d; Δ= -17kcal/day; p=0.41), or PRO before bed (BL: 1551±156; NM: 1525±171 kcal/d; Δ=-26 kcal/day; p=0.36). There was no significant change in next-morning RER when consuming PLA (BL: 0.74±0.05 CO_2/O_2; NM: 0.76±0.04 CO_2/O_2, Δ=0.02 CO_2/O_2; p=0.13) or PRO before bed (BL: 0.77±0.05; NM: 0.77±0.02; Δ=0.0; p=0.29). **CONCLUSIONS**: In resistance-trained women, 30g of casein PRO pre-sleep does not significantly change next morning RMR or RER. Therefore, it is metabolically feasible for women to consume protein at night without negative metabolic implications. This study was supported by Dymatize® Nutrition and FrieslandCampina®.

Higher Protein Intakes Enhance Whole Body Protein Metabolism and Exercise Performance in Endurance-Trained Males

Eric Williamson, Hiroyuki Kato, Kimberly A. Volterman, Daniel R. Moore. *University of Toronto, Toronto, ON, Canada.*
(No relevant relationships reported)

Dietary amino acids are important for both the repair and rebuilding of body proteins and the replenishment of exercise-induced oxidative losses. Current athlete recommendations are based primarily on the protein intake required to maintain nitrogen (i.e. protein) balance rather than one that optimizes whole body protein metabolism and maintains exercise performance. **PURPOSE**: To determine how a range of protein intakes, including a new tracer-derived safe intake, altered protein metabolism and exercise performance during a period of controlled training. **METHODS:** Using a double blind randomized crossover design, 10 male endurance-trained runners (~32y; ~65 ml O2/kg/min; ~62 km/wk) completed 3 trials, each consisting of 4 days of controlled training (20, 5, 10, 20km days 1-4, respectively). Controlled diets provided 6-9 g/kg/d of carbohydrate and 0.80 g protein/kg/d from whole foods that was supplemented with 0.12 (LOW), 0.40 (MOD), and 1.03 (HIGH) g of crystalline amino acids/kg/d modelled after egg protein. Oral [^{15}N] glycine was ingested on the 1st and 4th day to determine whole body protein synthesis (S), breakdown (B), and net balance (NB). Maximum voluntary isometric contraction (MVC), 5-km Time Trial (5kmTT) and peak force (Jump) were tested 2 days before and immediately after the controlled diet and training. **RESULTS:** S and B were not altered by training or protein intake. NB was negative in LOW and positive in HIGH with a dose-response between conditions (HIGH > MOD > LOW, p<0.05). Inferential statistics revealed that for MVC, HIGH likely (probability 87%) had a moderate benefit over LOW (ES=0.57) and likely (probability 77%) a small benefit over MOD (ES=0.42). For the 5kmTT, HIGH likely (probability 79%) had a moderate benefit over LOW (ES=0.57) and a possible (probability 69%) small benefit over MOD (ES=0.26). No differences were found for Jump performance. **CONCLUSION:** Endurance trained males consuming adequate carbohydrate maintained exercise performance and enhanced whole body protein metabolism when consuming >1.2g/kg/d of dietary protein. Our data suggest that training quality and post-exercise recovery would be optimized in endurance-trained runners who consume dietary protein towards at the higher end of current ACSM recommendations (i.e. 1.2-2g/kg).

F-36   Free Communication/Slide - Physical Activity Promotion and Intervention Strategies

Physical Activity Maintenance Among African American Women: Factors Associated with Lapses and Recovery

Amber W. Kinsey[1], Melicia C. Whitt-Glover, FACSM[2], Michelle Segar[3], Olivia Affuso, FACSM[1]. *[1]University of Alabama at Birmingham, Birmingham, AL. [2]Gramercy Research Group, Winston-Salem, NC. [3]University of Michigan, Ann Arbor, MI.* (Sponsor: Olivia Affuso, FACSM)
(No relevant relationships reported)

PURPOSE: Studies have demonstrated that lapse-recovery cycles, or the brief periods of little to no physical activity (PA) that may persist for days or weeks (lapses) followed by a return to normal PA levels (recovery), are integral to long-term PA maintenance in African American (AA) women. Given the low PA levels and high

rates of chronic disease among AA women, understanding factors associated with lapse-recovery cycles in AA women who successfully maintain PA may improve interventions for promoting and sustaining PA in high-risk populations. **METHODS**: AA women (≥ 18 years) who self-reported PA maintenance (≥ 6 months) were recruited via email, word-of-mouth, and social media to complete an online survey. Questions included whether respondents experienced a lapse in the previous year, and if so, the number and causes of lapses, the longest lapse experienced, and factors that helped to resume PA. Trained reviewers coded open-ended responses separately, using a priori codes; discrepancies were discussed to reach consensus. **RESULTS**: Of the 206 respondents, 139 (67.5%; age 38.4 ± 11.6 years) experienced a lapse in PA in the past year. Most women (58.3%, n=81) experienced 1-2 lapses, with most lasting <1 month (43.9%). The top five predictors of lapses included work demands (33.1%), an injury or surgery (24.5%), travel/vacations (22.3%), lack of time (19.4%; e.g. scheduling conflicts) and family factors (16.5%; e.g. caretaking, relationship issues). The factors associated with resuming PA included becoming motivated again (18.0%; e.g. goal-setting, self-talk), social support (15.1%; e.g. encouragement from friends/family, joining PA groups), weight (14.4%; e.g. gaining weight as motivation), feeling better (14.4%; e.g. physically and mentally, body craving PA), and recovering from an injury or surgery (14.4%). **CONCLUSIONS**: Understanding correlates of PA lapse-recovery cycles in AA women who maintain PA can aid in developing strategic interventions to foster long-term PA behaviors among this important population. Our findings suggest that motivation, social support, weight and positive affect might be ideal intervention targets. Future studies should explore the impact of targeted strategies to address lapse-recovery cycles.

2654   June 1 3:30 PM - 3:45 PM

African American Women and Outdoor Physical Activity: Understanding Patterns and Group Engagement

Olivia Affuso, FACSM[1], Amber W. Kinsey[1], Melicia C. Whitt-Glover, FACSM[2], Michelle Segar[3]. *[1]University of Alabama at Birmingham, BIRMINGHAM, AL. [2]Gramercy Research Group, Winston-Salem, NC. [3]University of Michigan, Ann Arbor, MI.*
(No relevant relationships reported)

PURPOSE: New strategies are needed to improve leisure-time physical activity (PA) levels among African American (AA) women. Outdoor PA provides immediate benefits such as stress reduction and social cohesion and shows promise for PA promotion. However, little is known about the prevalence of outdoor PA among AA women as well as if engaging in PA with others is associated with outdoor PA participation. The purpose of this study was to: 1) describe outdoor PA among AA women and 2) examine differences in outdoor PA participation between those who engage in PA in a group compared to those who engage in PA alone. **METHODS:** Using an assets-based approach, we conducted an online survey of 206 AA women who had maintained PA for at least 6 months. Those who completed both of the following questions were included in this preliminary analysis (N=195): 1) In the last 6 months, what type(s) of outdoor physical activities did you engage in most often? and 2) In the past 6 months, have you engaged in PA with others? Chi-square tests were used to examine differences in outdoor physical activities by group engagement. Significance was set at alpha < .05 and SAS 9.3 was used to perform these analyses. **RESULTS:** Of the 195 respondents completing both questions (age in years: 40.3±11.8), 107 (54.9%) reported participating in at least 1 outdoor PA. Hiking (35.5%) was the most frequently reported outdoor PA followed by walking (19.6%) and running (14.0%). The majority of respondents (50.8%) participated in PA with others as a part of an organized group (30.8%), with family (6.2%) or with friends (13.9%). However, there was no significant difference in frequency of outdoor PA by category of group PA engagement (chisq: 8.93, p=0.0630). **CONCLUSIONS:** Our findings suggest that a significant proportion of AA women participate in outdoor PA. However, more research is needed to explore the potential of outdoor PA to motivate AA women.

Incentivizing Physical Activity in American Indian Adolescents At Risk For Metabolic Disorders

Kevin R. Short[1], Jennifer Q. Chadwick[1], Mary A. Tullier[2], Lisa Wolbert[3], Charlotte Coleman[2], David F. Wharton[4], Dannielle E. Branam[4], Tamela K. Cannadt[2], Kenneth C. Copeland[1]. *[1]University of Oklahoma Health Sciences Center, Oklahoma City, OK. [2]Choctaw Nation of Oklahoma, Talihina, OK. [3]Choctaw Nation of Oklahoma, Hugo, OK. [4]Choctaw Nation of Oklahoma, Durant, OK.*
(No relevant relationships reported)

PURPOSE: American Indians (AI) have high prevalence of diabetes in youth and may benefit from programs designed to promote increased exercise behavior as a strategy to improve metabolic health. In this study, we tested whether financial incentives would elicit greater frequency and/or duration of exercise in AI youth at high risk to

Abstracts were prepared by the authors and printed as submitted.

FRIDAY, JUNE 1, 2018

develop diabetes. **METHODS**: We enrolled overweight or obese, non-diabetic AI boys and girls, 11-20 years old with low physical activity. Participants were instructed to exercise 3 days/week for 48 weeks at a Choctaw Wellness Center, earning payments for 20-60 minute sessions of moderate-to-vigorous physical activity. The program was subdivided into three, 16-week-long phases to test different incentive strategies. **RESULTS**: Mean ± sem age of the 43 girls and 34 boys who completed baseline tests and started exercise was $14.0 ± 2.2$ y. Several risk factors for future diabetes were present, including high body fat ($43 ± 8\%$), low physical activity ($6,400 ± 2,899$ steps per day) and low aerobic fitness (VO_2max: $19.4 ± 5.7$ ml/kg/min). In Phase 1, the financial incentive to exercise more frequently was not effective; the incentivized subgroup had a similar number of exercise sessions ($28 ± 2$) as the control payment group ($26 ± 3$, $p > 0.05$). However, in Phase 2, the financial incentive to increase exercise duration was successful; exercise duration for the incentivized and control subgroups were $38 ± 2$ versus $29 ± 1$ minutes per session ($p= 0.002$, Effect size $=0.9$), respectively. In Phase 3, the effect of reducing the incentives was inconclusive due to high participant withdrawal. **CONCLUSIONS**: Our goal to get habitually sedentary, obese adolescents to increase their exercise behavior was at least partly successful, since the participants collectively completed 3,229 exercise sessions. The use of incentives was also helpful to promote the program and to extend the duration of exercise sessions in Phase 2. However, a remaining challenge is to help adolescents overcome barriers that prevent them from exercising more frequently and sustaining a daily exercise program. (No relevant relationships reported)

Prostate cancer (PC) treatments can result in long-term side effects that impact physical function and quality of life. Exercise has been shown to be a safe and effective strategy to reduce and manage treatment side effects; however, very few PC survivors are sufficiently active and providing supervised exercise programming is not feasible in many clinical settings. To address this need, the Prostate Cancer Supportive Care (PCSC) Program implemented an exercise counselling clinic led by a certified exercise physiologist that focused on facilitating exercise behaviour change. **Purpose:** To evaluate if an exercise counselling clinic can improve the aerobic and resistance exercise levels in men with PC, to align with the exercise oncology guidelines. **Methods:** Participants of the PCSC Program were invited to attend an exercise counselling clinic as part of their regular PC clinical care, namely 4 x 45-minute one-on-one sessions over 12-months (baseline, 3-, 6- and 12-months). At each session, the total amount of aerobic and resistance exercise, current PC treatments, physical symptoms and readiness for change were recorded using self-report questionnaires and a guided interview. A retrospective chart review was performed from data collected between July 2015 (clinic inception) and September 2017. **Results:** 128 men (age = $67.6±7.0$) attended the clinic at baseline. 93 of these men attended 2 or more visits and were analyzed further. 55% were currently receiving treatment or had received it in the past 6-months. Attendance was 73% at the 6-month follow-up and dropped to 36% at 12-months. Compared to baseline, there was an 18% increase in men meeting aerobic exercise guidelines (62%, $p<0.01$), 26% increase for resistance training guidelines (47%, $p<0.01$) and 22% increase for both aerobic and resistance training guidelines (39%, $p<0.01$). At baseline, the vast majority of men were in the preparation, action or maintenance stage of change (41%, 13% and 40% respectively). **Conclusion:** An exercise counselling clinic can significantly improve aerobic and resistance exercise levels in men with PC and improve adoption of the exercise oncology guidelines. Future work will focus on duration and intensity of support required to increase long-term behaviour change and target men with PC who are not meeting exercise oncology guidelines.

Exercise Prescription in Cancer Survivors: What Explains Poor Retention?

Nicole J. Richards[1], Cynthia Villalobos[1], Justin C. Brown[2], Paul D. Vosti[3], Courtney D. Jensen[1]. [1]*University of the Pacific, Stockton, CA.* [2]*Harvard University, Cambridge, MA.* [3]*St. Joseph's Medical Center, Stockton, CA.* (Sponsor: Kathryn H. Schmitz, FACSM)

(No relevant relationships reported)

There are approximately 13 million cancer survivors in the U.S.; fewer than 10% meet the exercise recommendations outlined by the American College of Sports Medicine. Poor adherence is likely explained by a variety of factors. If we can identify these

factors, we may be able to tailor the prescription, monitoring, and encouragement of exercise more effectively. **PURPOSE:** To determine variables that influence retention in an exercise trial on cancer survivors. **METHODS:** We enrolled 157 cancer survivors in an exercise program lasting 10 weeks and consisting of biweekly cardiovascular, strengthening, and flexibility components. At baseline and following the intervention, we assessed anthropometric and cardiovascular profiles, health and cancer history, and physical functioning. Chi-square and logistic regression analyses tested variables associated with program completion. **RESULTS:** We retained 37.7% of patients through follow-up. Women were more likely to complete the trial (43.2%) than men (19.4%; $p=0.010$). Differences between cancer type were minimal. Adherence was better among breast cancer patients ($p=0.016$) but this was attributable to sex; there was no difference among patients with multiple cancers ($p=0.583$) or patients who had a previous heart attack ($p=0.681$) or stroke ($p=0.528$), had diagnosed hypertension ($p=0.513$) or pulmonary disease ($p=0.199$), were obese ($p=0.893$), or smoked ($p=0.333$). Fatigue ($p=0.696$) and mode of treatment (surgery, chemotherapy, radiation; $p>0.225$) did not affect completion. There was a difference among patients with hyperlipidemia (50.0% retained) compared to patients without hyperlipidemia (32.4%; $p=0.040$). Patients with poor sit-and-reach scores were also more likely to drop out: 53.3% of patients who could reach their toes completed the program compared to 26.5% who could not reach their toes ($p=0.016$). **CONCLUSION:** Exercise adherence is low among cancer survivors; in our sample, fewer than 40% of patients were retained through follow-up. Several factors predicted retention, but sex had the strongest association. Further efforts must be made to identify risk factors for attrition in this population. The differences observed in retention by sex suggest other cohorts may need to be stratified by sex to verify our findings.

2658 June 1 4:30 PM - 4:45 PM

Effects Of Three-stage Training Program On Functional Fitness And Physical Activity For Community-dwelling Old-old Japanese

Hiroshi Kohno[1], Hidenori Asai[2]. [1]*TOYO University Faculty of HUman Life Desige, Asaka-shi, Saitama, Japan.* [2]*Ehime University, Matsuyama-shi, Ehime, Japan.*

(No relevant relationships reported)

PURPOSE: To examine the effectiveness of a three-stages physical training program on ADL-related functional fitness and daily physical activity for community-dwelling old-old Japanese women.
METHODS: After giving written informed consent, the subjects, unable to stand on one leg for more than 20 seconds with eyes open, were divided into a 3 times/week group (HFG; 13 females, $81.5±2.7$ yrs, BMI $22.8±1.6$) and a 1time/week group (LFG; 10 females, $81.7±3.2$ yrs, BMI $21.9±1.3$). The program was composed of three stages for 16 weeks. First, participants learned about management skill for their physical soreness and asked to stand on one-leg with eyes open for one minute, 3 times a day for each leg at class and at home. Second, they learned to strengthen their core and lower leg muscle using an elastic band. The last stage was to learn a three-minute arm and leg combined exercise program with music. ADL-related functional fitness(sitting & standing time, zigzag walking time), one-leg standing time with eyes open, and knee extension strength were obtained. Balance ability was measured by the area covering and total length of the center of gravity sway(COP). Each measurement item was assessed before and after the intervention period. Daily physical activity was measured by pedometer in the first and last 7days during the intervention period. Student's T-test and two-way repeated measures ANOVA were used to test the effectiveness.
RESULTS: The class participation were $82±4\%$ and $81±8\%$ respectively. Sitting & standing time (HFG: 18.4±5.6 to 16.3±5.1 sec., LFG: 17.4±3.9 to 17.7± 3.6sec. F=3.573, P=0.073), zigzag walking time(HFG: 19.2±2.9 to 17.2±4.2sec., LFG: 16.6±3.1 to 16.8±2.9sec, F=11.88,P=0.002), one-leg standing time with eyes open(HFG: 6.1±3.1 to 13.7±4.2 sec., LFG: 5.9±2.3 to 6.1±1.8sec, F=30.69,P=0.000), knee extension strength(P=0.040), and balance ability(area covering of COP; F=13,58, P=0.001, total length of COP; F=21.00, P=0.022) ,daily steps(HFG: 3864±747 to 4454±632steps, LFG: 3831±832 to 4001±860steps, F=5.28,P=0.032) also improved significantly in HFG.
CONCLUSIONS: Three-stage physical training program was effective for functional fitness and daily physical activity by old-old Japanese females.

2659   June 1 4:45 PM - 5:00 PM

Lifestyle Strategies to Support Sustained Physical Activity after Intentional Weight Loss: Results from MAINTAIN-pc Trial

Molly B. Conroy, FACSM[1], Bethany B. Gibbs[2], Margaret P. Lott[3], Rachel Hess[1], Cindy Bryce[2], Gary S. Fischer[2], Dana Tudorascu[2], Diane Comer[2], Laurey Simkin-Silverman[2], Kimberly Huber[2], Kathleen M. McTigue[2]. *University of Utah, Salt Lake City, UT. [2]University of Pittsburgh, Pittsburgh, PA. [3]University of Miami, Miami, FL.*
(No relevant relationships reported)

PURPOSE: Weight maintenance after intentional loss is challenging, and sustained physical activity (PA) levels can help. Less is known about lifestyle strategies that may promote sustained PA levels after intentional weight loss.
METHODS: We analyzed baseline and 24-month data from the Maintaining Activity and Nutrition through Technology-Assisted Innovation in Primary Care (MAINTAIN-pc) trial. MAINTAIN-pc recruited adults who had intentionally lost >= 5% body weight in past 2 years and were randomized to tracking tools with tailored coaching (CC) or tracking tools alone (TO). At assessments, participants reported lifestyle strategies used in the past six months, including self-monitoring, group support, behavioral skills, and professional support. PA levels were assessed with Omron pedometer HJ-720ITC with blinded feedback screen. Wilcoxon rank sum or t tests compared PA levels between strategy use vs. no use.
RESULTS: At baseline, the 194 participants were 53.4 (SD 12.2) years old, 74% female, and 88% White. Median baseline PA level was 5998 steps/day. At baseline, 69% used self-monitoring, 73% group support, 100% behavioral skills, and 68% professional support in past 6 months; at 24 months these rates were 75%, 60%, 98%, and 61%, respectively. Recording PA (53% baseline; 57% 24 months) and calories (52% baseline; 43% 24 months) were the most common self-monitoring strategies. There were no differences in strategies between CC and TO groups at either baseline or 24 months. Participants who used self-monitoring strategies at 24 months had higher PA levels at baseline (6473 vs. 4730 steps; p =0.045) and 24 months (6103 vs. 5251 steps; p=0.02) than those who did not. Within self-monitoring strategies, participants recording steps had greater PA levels than those who did not at 24 months (6103 vs. 5251; p=0.04, respectively). Participants with group support at 24 months also had higher baseline PA compared to those who did not (6779 vs. 5752; p=0.03). No differences were found in PA levels at baseline or 24 months based on behavioral skills or professional support.
CONCLUSIONS: Participants reported frequent use of a variety of lifestyle strategies at baseline and 24 months. Self-monitoring, especially recording daily steps, may be particularly important in sustaining PA levels after intentional weight loss.

2660   June 1 5:00 PM - 5:15 PM

Perceived Physical Fatigability Improves after a Weight Management Intervention in Obese Older Adults

Nancy W. Glynn, Theresa A. Gmelin, Adam J. Santanasto, John M. Jakicic, FACSM, Robert M. Boudreau, Steven M. Albert, Anne B. Newman, Elizabeth M. Venditti. *University of Pittsburgh, Pittsburgh, PA.* (Sponsor: John Jakicic, FACSM)
(No relevant relationships reported)

Obesity and lower physical activity (PA) are related to higher perceived global fatigue in older adults. Fatigue is also associated with disability and higher mortality. However, the effects of weight loss and PA interventions on improving physical fatigability are unknown. **PURPOSE:** We examined the impact of a community health care worker delivered healthy aging and behavioral weight management intervention on perceived physical fatigability among community-dwelling elders with obesity enrolled in the 13-month Mobility and Vitality Lifestyle Program (MOVE UP). **METHODS:** This analysis examined the effects of the first 5 months of intervention, which included the 10 Keys™ to Healthy Aging (month 1) and Diet, Weight, Activity Behavioral Induction (months 2-5) phases. We measured physical fatigability (perceived whole-body fatigue anchored to activities of fixed intensity and duration) using the validated 10-item Pittsburgh Fatigability Scale (PFS, range 0-50 with lower score= less fatigability); self-reported PA using the Community Healthy Activities Model Program for Seniors Survey (CHAMPS) questionnaire; and weight. **RESULTS:** At baseline, participants (N=115) were age 68.8±4.0 years, 83.5% female, 37.8% African American, with Body Mass Index of 34.4±4.5 kg/m^2. Baseline PFS score was 18.6±8.3 with 70.4% (N=81) having higher fatigability (PFS score = ≥15). After 5 months, participants lost 10.7 lbs (5.2% of body weight) and increased total physical activity by 0.8 hours/week. Concurrently, PFS scores significantly decreased by 2.5 points (13.4%) to 16.1±9.0 (p=0.001); the number of participants classified with higher fatigability after the 5 month intervention also declined to 53% (N=61). Preliminary 13-month data (N=93) indicate that mean PFS scores continue to decline to 15.6±8.2 (p=0.0003 for difference between baseline and 13-months). **CONCLUSION:** Moderate weight loss and modest gains in PA were accompanied by notable

improvement in perceived physical fatigability. Thus, lifestyle interventions may be effective at reducing fatigability, which is an important component in the age-related disablement pathway. Supported by CDC Cooperative Agreement #5U48DP0050001.

Comparison of the Firefighter Candidate Physical Ability Test to Weight Lifting Exercises in Firefighters.

Charity Lane, Dustin Hardwick, Thomas Janus, O'Dane Brady, John Mayer, FACSM. *University of South Florida, Tampa, FL.* (Sponsor: John Mayer, FACSM)
(No relevant relationships reported)

Firefighting is an extremely demanding occupation requiring high levels of muscular strength and endurance to attend to a multitude of emergency situations. Matching resistance exercise programs to firefighter job demands has not been well-studied. PURPOSE: The purpose of this study was to compare the EMG activity of relevant muscles during the Candidate Physical Ability Test (CPAT) and weightlifting exercises in firefighters.
METHODS: A repeated measures study was conducted in 13 full-duty career firefighters (1 F, 12 M; aged 18-44 years) from 3 Florida fire departments. Participants reported to a university laboratory to complete 7 low load weightlifting exercises: Romanian deadlift, back squat, overhead press, bent-over row, banded Romanian deadlift, kneeling rotational throw, and glute hyperextension. On a separate day, participants reported to firefighter training grounds to complete the CPAT. The CPAT is a pre-employment functional capacity evaluation that reflects usual tasks performed during emergency responses, which consists of 8 events - stair climb, hose drag, equipment carry, ladder raise and extension, forcible entry, search, rescue, and ceiling breach and pull. During exercises and CPAT events, surface EMG activity was recorded from the oblique abdominal, deltoid, trapezius, latissimus dorsi, lumbar multifidus, gluteus maximus and medius, and hamstring muscles. For each muscle group, surface EMG activity (% maximum voluntary isometric contraction - MVC) was compared between the exercises and CPAT.
RESULTS: No difference (p > 0.05) in EMG activity was observed between weightlifting exercises and CPAT for the deltoid, trapezius, lumbar multifidus, gluteus maximus and medius, and hamstring muscles. EMG activity was significantly greater (p = 0.002) during the CPAT compared to the exercises for the abdominal obliques (39.9% +/- 27.8% vs. 12.0% +/- 6.4%, respectively). EMG activity was significantly greater (p = 0.049) during the exercises compared to CPAT for the latissimus dorsi (21.8% +/- 16.7% vs. 11.4% +/- 4.6%, respectively).
CONCLUSION: Standardized weightlifting exercises, along with additional exercises to activate and strengthen the abdominal obliques, should be considered when designing resistance exercise programs to match firefighter job demands.

2663   June 1 3:30 PM - 3:45 PM

High IntensityFunctional Training Improves Multiple Domains of Fitness in Females and Males

Katie M. Heinrich, Sarah J. Cosgrove, Jacob Frye. *Kansas State University, Manhattan, KS.* (Sponsor: Yuri Feito, FACSM)
(No relevant relationships reported)

It is unclear if high intensity functional training (HIFT), that temporally combines aerobic, gymnastics, and weightlifting exercises for general physical preparedness (GPP), improves multiple fitness domains. **PURPOSE**: To examine effects of 6-months of HIFT on nine fitness domains.
METHODS: Program evaluation participants (N = 48, 50% female, age = 31.8 ± 13.3 years, range = 18-66 years, 87.5% white) were new/existing members of a university HIFT gym at enrollment (HIFT experience = 9.8 ± 8.4 months, range = 0-27 months), and reported usually doing HIFT workouts 4.0 ± 1.1 days/week. At baseline and 6-months, field fitness tests measured coordination and balance (agility hop), agility (pro-agility), flexibility (sit-and-reach), power (standing long jump and seated medicine ball put), and muscular endurance/stamina (60-seconds of push-ups/ knee push-ups, sit-ups, air squats, and max repetitions of strict/banded pull-ups) on day 1; strength (1RM back squat, press, and deadlift) on day 2; and speed (400m run), and

cardiorespiratory endurance (1.5 mile run) on day 3. Participants completed the same standardized warm-up before each measurement day. Paired/independent samples t-tests were conducted using SPSS 24.
RESULTS: Females significantly improved flexibility (31.1 ± 9.2 cm to 34.1 ± 8.1 cm, t = 3.8, p = .001), power (long jump = 1.75 ± 0.33 m to 1.81 ± 0.31 m, t = 3.0, p = .006), muscular endurance (push-ups [n=13] = 25.2 ± 7.0 to 29.8 ± 7.8 reps, t = 2.4, p = .035), and strength (back squat = 58.2 ± 12.4 kg to 64.3 ± 13.9 kg, t = 4.6, p < .001; press = 32.3 ± 5.9 kg to 34.7 ± 7.4 kg, t = 3.7, p = .002; and deadlift = 80.0 ± 18.9 kg to 87.7 ± 22.0 kg, t = 3.2, p = .005). Males significantly improved flexibility (29.5 ± 8.6 cm to 31.6 ± 7.4 cm, t = 2.1, p = .043), muscular endurance (pull-ups [n=16] = 3.6 ± 0.9 to 4.2 ± 1.0 reps, t = 2.7, p = .018) and strength (back squat = 101.8 ± 27.0 kg to 110.6 ± 30.0 kg, t = 5.0, p < .001; deadlift = 130.4 ± 31.6 kg to 139.5 ± 31.2 kg, t = 4.2, p < .001). Females improved significantly more than males only for power (long jump, t = 3.1, p = .004).
CONCLUSIONS: The GPP-focused HIFT training significantly improved multiple fitness domains for females and males after 6 months of training, with no significant fitness decreases. Improvements were found even among experienced HIFT participants, which may help facilitate continued participation.

2664   June 1 3:45 PM - 4:00 PM

Effect of Heavy Resistance and Plyometric Training on Running Economy and 5km Performance in Well-trained Male Athletes

Li Fei, Ding Haiyong, Zhang Xiaohui, Han Guangqiang, Chen LinShan, Huang Chunyan. *SHANGHAI UNIVERSITY OF SPORT, SHANGHAI, China.*
(No relevant relationships reported)

Purpose The present study was to investigate the effect of 8-week heavy strength training plus plyometric training on well-trained male athletes' running economy and 5km performance.
Methods Twenty-three male long-distance runners (25.2 ± 3.8years; BMI:21.0 ± 1.1kg·m^{-2}; VO$_2$max: 66.4 ± 7.0 mlO2·kg^{-1}·min^{-1}) were allocated into experimental group (EG, N=12) or control group (CG=11).EG performed 8-weeks heavy resistance plus plyometric training, include 5sets of 5RM squats, RDL, Bulgaria squats plus 3sets of 10-15reps on low hurdle jumping and single leg jumping. CG performed endurance-strength, include 5sets of 20RM squats, RDL, Bulgaria squats plus 3sets of 20reps on trunk stability exercises. EG and CG did the similar endurance training program, which include 60-80km LSD per week, the intensity was a little bit below the anaerobic threshold. Before and after 8 weeks intervention, performed the following tests:(a) incremental test, (b) 12km·h^{-1},14km·h^{-1},16km·h^{-1}running economy test(c) 5-km running time trial, (e) counter movement jump test, (f) maximum dynamic strength test (1RM),(g) ground contact time at 16km/h.
Results: The EG showed significant improvement(p≤0.05)on 1RM strength($27.8\% \pm 5.4$), RFD($18.1\% \pm 3.3$),CMJ($13\% \pm 7.8$)12km·h^{-1}RE($3.3\% \pm 2.1$),14km·h^{-1}RE($4.6\% \pm 3.7$)16km·h^{-1}RE($6.2\% \pm 5.4$) ,5km($4.7\% \pm 3.2$). CG did not show any change in 1RM,RFD,CMJ and 5km trial, but a improvement on 12km·h^{-1}RE($2.3\% \pm 2.7$). Both EG and CG did not have any change in 16km·h^{-1} ground contact time.
Conclusions: The 8-week heavy strength training plus plyometric training have a good effect on running economy and 5km performance, and was more effective in improving neuromuscular performance and running economy compare with endurance-strength training.

2665   June 1 4:00 PM - 4:15 PM

Exercise Time and Intensity: The Ideal Ratio to Prevent Overtraining and Maximize Fitness

Heather J. Porter[1], Joshua J. Davis[2], Jinger S. Gottschall[1]. [1]*The Pennsylvania State University, University Park, PA.* [2]*Penn State Hershey Medical Center, Hershey, PA.* (Sponsor: W. Larry Kenney, FACSM)
(No relevant relationships reported)

The American College of Sports Medicine recommends that adults achieve at least 30-50 minutes of moderate-intensity cardiorespiratory exercise 5 days per week or 20-60 minutes of vigorous-intensity exercise 3 days per week. While these minimum guidelines are clearly described, there are currently no maximum guidelines, particularly with respect to high-intensity time and frequency, for the prevention of overtraining. **PURPOSE**: To evaluate the correlation between salivary hormones, time in varying heart rate zones, and psychosocial stress variables in order to prevent overtraining and improve fitness. Our hypothesis is that chronic exercise durations greater than 1 hour per week in the high intensity (greater than 90% maximum heart rate) zone will lead to decreased variation in the production of stress hormones, decreased ability to reach heart rate max and increased self-reporting of tension as well as fatigue. **METHODS**: Twelve healthy adults between 25-50 years who regularly exercised more than 8 hours per week recorded their heart rate during every training session and answered daily surveys regarding their mood for 3 weeks. Next, they

completed an experimental day composed of 2, 30-minute high-intensity interval sessions separated by 4-hours of non-active recovery. We collected saliva samples prior to each exercise session, immediately following, and 30-minutes post to assess changes in cortisol and testosterone concentrations. Heart rate was monitored throughout the experimental day to determine exercise and recovery values. **RESULTS**: There was a correlation between weekly time training at an intensity greater than 90% maximum heart rate and the variables associated with overtraining. Cortisol and testosterone saliva concentration fluctuated less in the participants who exercised in this extreme zone for more than 50 minutes per week. To add, these participants were not able to reach the same intensity during the second-high intensity session on the experimental day and reported greater tension as well as fatigue on the surveys in the weeks prior to testing. **CONCLUSIONS:** Our data demonstrate that 50 minutes of high-intensity training per week is a suggested maximum, cumulative time in order to prevent symptoms related to overtraining.

2666   June 1 4:15 PM - 4:30 PM

The Effect of Pre-Workout on Resistance Training Repetitions to Failure

Jacob Prete, Elaina Biechler, Adam Brogley, Matthew Greene, Emma Corkill, Hunter Dunlap. *Loras College, Dubuque, IA.* (Sponsor: Vincent Paolone, FACSM)
(No relevant relationships reported)

The usage of pre-workout supplementation has increased substantially in recent years, as research has shown pre-workout supplements can significantly enhance resistance performance in all populations.
PURPOSE: To compare and determine the effectiveness of a caffeine-free pre-workout and a caffeinated pre-workout on repetitions to failure in bench press and squat.
METHODS: Subjects completed a total of four trials. The first trial was done to find the subject's one-repetition maximum (1RM) for squat and bench press. A cross over design was used to determine the order of the final three trials in which the subject would drink eight ounces of a caffeinated pre-workout out (CA), a caffeine-free pre-workout (NC), or water (C). 20 minutes post consumption of fluid, the subjects did a standard warmup, then completed four sets of back squat for five repetitions at 70% of 1RM, and on the fifth set the subject would complete repetitions until fatigue. Bench press was done for four sets for five repetitions at 70% of 1RM, on the fifth set the subject would complete repetitions until fatigue. The number of repetitions completed on the last set of both squat and bench press were recorded.
RESULTS: An ANOVA was utilized to determine if significant differences occurred in repetitions to failure in the control trial, with caffeinated pre-workout, and with non-caffeinated pre workout. There was a statistically significant difference in squat ($F(1.304, 7.823)= 5.543$, p =.041) and bench press ($F(1.857, 11.141)= 5.484$, p=.024) repetitions to failure. Post hoc analysis revealed that squat repetitions to failure were significantly greater in CA and NC when compared to C (p=.028; p=.044). There was no significant difference between repetitions to failure when comparing CA and NC (p=.99). Post hoc analysis also revealed that bench press repetitions to failure were significantly greater in CA when compared to C and NC (p=.05; p=.234).
CONCLUSIONS: The use of CA significantly increased repetitions to failure for both squat and bench press when compared to a control trial. The use of NC resulted in a significant increase in repetitions to failure for squats, but no significant improvement in repetitions to failure in the bench press. The use of CA and NC have an ergogenic effect on resistance training performance.

2667   June 1 4:30 PM - 4:45 PM

Developing And Validating The Sit-to-stand As A Muscular Power Measure In Older Adults

Jennifer J. Sherwood, Cathy Inouye, Shannon L. Webb, Pavel V. Romanovski, Trenton Ashizawa, Tori Coleman, John W. Adams, Michel Mintsa Ossene. *California State University, East Bay, Hayward, CA.*
(No relevant relationships reported)

Purpose: Here, we tested the validity and reliability of velocity and power measurements performed with a Gymaware linear position transducer (LPT) during a sit-to-stand (STS).
Methods: Fifty-one asymptomatic men (n = 14) and women (n = 37) (ages 60-95 yrs.; 79.5 ± 9.9, mean $\pm$ SD) were recruited from California State University, East Bay (CSUEB) campus, and local independent-living senior populations. Sit-to-stand performance velocity and power was assessed with an LPT connected to a waist belt and base, and video recorded simultaneously and analyzed with Dartfish. Maximum hand-grip strength was assessed with a Jamar dynamometer. **Results:** The Pearson correlation coefficients of STS velocity and power were r = 0.9702 and r = 0.9651, providing evidence that the LTP and cinematography measurements were similar. The trial-to-trial reliability of the STS measured by the LPT gave an intraclass correlation

coefficient of 0.0.916-0.966 for velocity and 0.860-0.940 for power. The Pearson correlation between STS performance measured with the LPT and maximum hand-grip strength was r = 0.651.
Conclusion: Our findings show that the calculations derived from the LPT were very similar to those of cinematography and provide evidence for the validity of this method. The data from the LPT were shown to be reliable. Sit-to-stand performance power showed a good association with maximal hand-grip strength in older adults. These results suggest that power measures during the STS may be a safe and cost-effective method of assessing muscular fitness in older adults.

2668   June 1 4:45 PM - 5:00 PM

Bilateral Training Results in Superior Strength Improvements to Unilateral Despite Similar Changes in Fat-Free Mass

Courtenay Dunn-Lewis, Shawn D. Flanagan. *University of Pittsburgh, Pittsburgh, PA.*
(No relevant relationships reported)

PURPOSE: To determine if strength increases differ between bilateral and unilateral training; to determine whether differences, if any, were mediated by muscle hypertrophy. **METHODS**: College-aged men and women (n=67; age=19.7 ± 0.9 yr; height=168.7 ± 9.8 cm; body fat = 22.14 ± 10.23%) provided written informed consent to participate. Subjects were randomized to a unilateral or a bilateral training group for eight weeks. Strength testing (chest press and leg press) was performed at pre, mid, and post, with body composition (air displacement plethysmography) at pre and post. Statistics included a repeated measures ANOVA with LSD post-hocs and planned contrasts. **RESULTS**: As shown in Figure 1 (leg press), strength increased (significant linear trend for chest press and leg press: p=0.000) across all three time points. While there were no significant differences in strength at any time point, within-subjects contrasts displayed a significant linear trend interaction between time and training group for both leg press (0.049) and chest press (p=0.029) strength; the slopes of the two lines were therefore significantly different in favor of the bilateral trend. Although both groups increased FFM, the increase was comparable (mean kilogram change from pre to post: 1.6 ± 0.5, p=0.001 bilateral, 1.4 ± 0.4, p=0.001 unilateral). **CONCLUSION**: Bilateral training results in superior strength improvements over eight weeks as compared to unilateral despite similar changes in fat-free mass.

Table 1. Change in Leg Press Strength (lbs)

	Bilateral	Unilateral
Pre	0 ± 0	0 ± 0
Mid	19.3 ± 32.1	7.0 ± 11.3
Post	32.6 ± 42.0	15.2 ± 16.4

Early Pubertal Children Perceive High Intensity Interval Exercise as Less Strenuous than Young Adults

Ronen Bar-Yoseph, Pearl Law, Dan M. Cooper, Shlomit Radom-Aizik. *UCIrvine, Irvine, CA.*
(No relevant relationships reported)

High-intensity interval training (HIIT), which consists of repeated sessions of brief, intense bouts of exercise, has been shown to be an effective and time-efficient approach to improve aerobic training. Early pubertal children rely more heavily on aerobic metabolism and recover faster from exercise bouts. Borg's Rating of Perceived Exertion (RPE), a subjective measure of exercise intensity used to evaluate responses to specific training loads, has yet to be systematically explored in relation to HIIT among children of different maturation stages and sex groups. **PURPOSE:** To evaluate RPE during HIIT in children, adolescence, and young adults and to investigate the relationship between RPE, sex, and puberty. **METHODS:** One hundred healthy children and young adults (7-34 y/o, 47 males) participated in two exercise sessions on a cycle ergometer: 1) ramp-type progressive cycle ergometry to determine peak VO_2; 2) HIIT - ten times, 2-min bout at 80% peak work rate interspersed with 1-min rest. Borg's RPE (scale of 6-20) was recorded at the end of each 2-min exercise bout. **RESULTS:** Fifty two participants completed HIIT at 80% peak work rate. Completion rates were higher in early pubertal children (70%, 26/37) and young adults (68%, 13/19) compared to adolescents (30%, 13/44) with no sex difference. Among completers, mean RPE was significantly lower in the early pubertal children (14.9±1.7%, "hard") compared to adults (16.8±1.7%, "very hard") with no sex-effect. In all 3 groups RPE was increased with the progression of the test. Heart rate recovery was fastest in early pubertal children with no group difference in oxygen uptake. **CONCLUSION:** Early pubertal children perceive high-intensity exercise as less strenuous than young adults. Differences in RPE reported by the 3 groups may be partially explained through faster HR recovery and relying more on aerobic metabolism in early pubertal children compared to older children and young adults. Researchers and coaches should take into consideration the age of the participant

when using RPE in research or as a training tool. Underlying mechanisms involved in RPE-maturational related differences should be further explored (including cognitive responses).

F-38   Clinical Case Slide - **Hip and Pelvis III**

Friday, June 1, 2018, 3:15 PM - 5:15 PM

Epidemiology and Clinical Presentation of Anterior Hip Pain among Elite Classical Dancers

Marijeanne Liederbach. *NYU Langone Orthopedic Hospital, New York, NY.* (Sponsor: Malachy P. McHugh, FACSM)
(No relevant relationships reported)

Hip injuries in dance can be commonplace and distressing in terms of human and financial impact. Approximately 11% of all time-loss injuries to dancers are because of hip pain and up to 50% of dancer visits to physicians are because of hip pain. PURPOSE: To assess the clinical presentation of dancers without dysplasia, labral tear or bony deformity in order to understand the movement factors associated with onset and cessation of anterior hip pain. METHODS: 250 student and elite classical dancers (24.1 ± 7.5 years; 72 men, 178 women) were assessed in our physical therapy clinic for strength, flexibility, balance, motor control and joint mobility. RESULTS: 82% of dancers had lower extremity strength asymmetry; 71% had talocrural or subtalar joint hypomobility on the ipsilateral side and 32% on the contralateral side relative to the side of hip pain. On the hip pain side, 100% had a positive Romberg test, 82% had a positive Airplane test and 70% a positive FADIR test. CONCLUSION: Because of the repetitive and movement biased fashion of dance training over many years, it is important for clinicians to understand the presentation of classical dancer hip pain as that of a multi-factorial, postural-behavioral movement impairment syndrome which entails skilled regional interdependent examination and defies a single common diagnostic label.

2674   June 1 3:35 PM - 3:55 PM

Hip Pain - Equestrian

Amanda M. Honsvall Hoefler. *University of Minnesota Methodist Family Medicine Residency, Saint Louis Park, MN.* (Sponsor: William O. Roberts, MD, FACSM)
(No relevant relationships reported)

HISTORY
A 61 year old horseback rider with severe OA and labral tear of the left hip underwent her 3rd fluoroscopically-guided triamcinolone injection for pain relief during competition season. She immediately experienced gradual worsening of left groin pain but was able to continue training.
Ten days post-injection, she returned with severe groin pain limiting weight bearing. She planned to leave the following day for a trip. She had no fever, chills, swelling, bruising or rash. She had mild pain with hip ROM testing. CRP was elevated without leukocytosis. MRI showed a small effusion with mild synovial inflammation. In the absence of systemic signs of infection, findings were consistent with reactive synovitis with low suspicion for infection. Upon discussion, the patient elected to proceed with her trip, monitor her symptoms closely, and present to a local ED if symptoms worsened.
She returned 2 weeks later unable to bear weight.
PHYSICAL EXAMINATION
Left hip exam demonstrated full passive internal and external rotation. Focal groin pain was reproduced by both active and passive ROM. No neurological deficits.
DIFFERENTIAL DIAGNOSIS
1. Septic arthritis
2. Avascular necrosis

Abstracts were prepared by the authors and printed as submitted.

FRIDAY, JUNE 1, 2018

3. Hemarthrosis
4. Reactive or crystalline synovitis
TESTS AND RESULTS
XR pelvis w/L lateral hip: Collapse of superior joint space with subchondral cystic change.
L Hip Aspiration: 4 mL bloody effusion (4.9 million RBCs, 2668 WBC, 69% PMNs). Synovasure positive.
Open I&D w/resection of the femoral head and placement of antibiotic spacer
- Synovitis with small amount of clear joint effusion. No gross purulence. Subchondral collapse and area of necrotic bone in the femoral head.
- 1/5 periarticular tissue cultures and 1/1 bone culture positive for Strep mitis/oralis.
- Bone path revealed acute osteomyelitis and osteonecrosis.
FINAL WORKING DIAGNOSIS
Septic arthritis and osteomyelitis of the left native hip
TREATMENT AND OUTCOMES
1. Six week course of IV ceftriaxone
2. Re-admitted 3 weeks post-op for fever, chills, headache and severe L hip pain following return to riding. Two extra-articular hematomas were identified on MRI and aspirated.
3. Re-admitted 6 weeks post-op for iliofemoral DVT. Underwent catheter-directed thrombolysis and stent placement for May Thurner's defect. Started on 6 months of Xarelto.
4. Left THA completed 6 weeks post-DVT.

2675   June 1 3:55 PM - 4:15 PM

Groin Injury- Swimming

Jennifer Soo Hoo, MD[1], Kristen Abbott, MD[2], Monica Rho, MD[1]. *[1]Shirley Ryan Abilitylab, Chicago, IL. [2]Northwestern University Health Service, Chicago, IL.* (Sponsor: Joseph Ihm, FACSM)

(No relevant relationships reported)

History:
A 20 year old Division 1 varsity swimmer who specializes in breast stroke presented for evaluation of worsening right groin pain over the past several months. Her pain was worse with breast stroke kick and increased intensity of training. The pain was located in right proximal adductor area. Her pain had continued despite working with a physical therapist and relative rest for at least 3 months. X-ray and MRI of pelvis including athletic pubalgia protocol was negative for any pathology. She denied any weakness or numbness/tingling.
Physical Examination:
Examination of her right leg revealed focal tenderness to palpation of proximal adductor tendon attachment on pubic symphysis without any swelling or deformity. She had pain with resisted adduction in all planes and resisted abdominal crunch. Active straight leg raise, pubic symphysis spring test were positive. Negative FADIR and log roll.
Differential Diagnosis:
1. Adductor strain
2. Adductor tendinopathy not seen on MRI
3. Athletic pubalgia
4. Osteitis pubis
5. Pelvic Floor dysfunction
6. Pubic rami stress fracture
Test and Results:
MRI pelvis:
- rectus abdominis insertion and right adductor tendon origin is normal in signal intensity and morphology.
- No evidence of osteitis pubis.
Ultrasound:
- thickening of right adductor tendon with evidence of enthesopathy and calcifications worse on the right.
- No evidence of osteitis pubis.
Final/Working Diagnosis:
Right adductor tendinopathy
Treatment and Outcomes:
1. Underwent PRP injection of right adductor tendon
2. Was non weight-bearing for 1 week post-injection
3. Progressed to full weight bearing and light exercise (swimming with just arms), 1-6 weeks post-injection
4. Began eccentric exercises, 7 weeks post injection
5. Ultrasound showed full tendon healing, cleared to return to full swimming and lifting, 12 weeks post injection

2676   June 1 4:15 PM - 4:35 PM

Hip Injury - Soccer

James Alex, Heather Gillespie, FACSM. *Maine Medical Center, Portland, ME.* (Sponsor: Heather Gillespie, MD, FACSM)

(No relevant relationships reported)

ACSM 2018 National Conference
Clinical Case Abstract Submission
Title: Hip Injury - Soccer
Author: James Alex, Heather Gillespie, Maine Medical Center, Portland, ME. Email: jalex@mmc.org.
(Sponsor: Heather Gillespie, FACSM)
History: A 13 year old male soccer player without significant past medical history sustained an acute onset of anterior right hip pain while sprinting during a soccer game. He was immediately unable to walk and was carried off the field by teammates. He developed occasional transient episodes of pain radiating down his right leg without numbness or tingling noted. He was evaluated in the emergency department that evening, given oxycodone for analgesia, crutches to maintain non-weight-bearing status, and was referred to sports medicine for follow-up.
Physical Exam: Examination in the office 2 days after injury revealed no hip, leg, or abdominal abnormalities on inspection. He was able to bear about 50% of his weight on the right leg without crutches. Mild tenderness to palpation was noted anterior to the right lesser trochanter. Right hip active range of motion was limited to 10 degrees of flexion in the supine position with normal passive range of motion throughout and intolerance of resisted hip flexion. Normal resisted adduction strength was noted. Neurovascular testing of the right lower extremity was normal.
Differential Diagnosis:
1. Iliopsoas strain
2. Apophyseal avulsion fracture: AIIS, ASIS, or lesser trochanter.
3. Adductor strain
4. Femoral neck stress fracture
5. Slipped capital femoral epiphysis
Tests and Results: 2-view xray of the right hip reveals apophyseal avulsion fracture of the lesser trochanter of the right femur with 20mm of proximal displacement.
Final Diagnosis: Closed, proximally-displaced apophyseal avulsion fracture of the lesser trochanter of the right femur.
Treatment and Outcome:
1. Case reviewed with multiple surgeons (sports, trauma, pediatric orthopedics) regarding potential screw fixation.
2. Non-operative management pursued.
3. Stable proximal displacement visualized on repeat xray post-injury day 6.
4. Non-weight-bearing on crutches for 3 weeks.
5. OTC analgesia after post-injury day 3.
6. Gradual weight bearing by week 4.
7. Final return to sport pending at the time of submission.

2677   June 1 4:35 PM - 4:55 PM

Pelvic Pain In A Soccer Player- Soccer

John T. Nelson[1], Delmas Bolin[2]. *[1]Carilion Clinic VTC Family Medicine Residency, Roanoke, VA. [2]Edward Via College of Osteopathic Medicine, Virginia Campus, Roanoke, VA.* (Sponsor: Delmas Bolin, FACSM)

(No relevant relationships reported)

HISTORY: A 23 year old men's soccer player presented with left sided pubic bone pain for seventeen months. The injury occurred after collision with another player and falling onto his left side during a soccer game. He developed left sided pubic symphysis pain later that evening. He finished the season followed by complete inactivity for 2 months. At the start of the next season, the same left sided pain returned that was worse with initial steps, change of direction, and lateral movements. He was seen in a sports medicine clinic and had an MRI which showed edema in the rectus abdominis, left abductor, and pubic symphysis. He completed physical therapy with no improvement. He then developed intermittent sharp pain radiating to the left testicle with running, preventing return to play. Steroid and Platelet Rich Plasma injections did not alter symptoms. He was referred to General Surgery, Orthopedics, given NSAIDs, repeated PT, repeat MRI, and finally referred for a biomechanical evaluation and treatment.
PHYSICAL EXAMINATION: Pelvic compression test is + left. Palpation: left superior pubic rami pain; mild pain in left ischial tuberosity. ASIS to umbilicus measures 12 cm left, 13 cm right. ASIS is inferior on right. PSIS is superior on left. Left leg 1.5 cm shorter. Palpation of left lower abdominal quadrant lateral to the border of pubic symphysis reproduces left sided scrotal pain. Genitourinary/Hip exam: Unremarkable. Sensation intact bilateral L4-S1 distribution. Reflexes: 2+/4 bilateral knee and ankle. Pulses: 2+/4 bilateral post tibial
DIFFERENTIAL DIAGNOSIS: Stress Fracture of Pubic Ramus, Athletic pubalgia, Inguinal Hernia, Abdominal muscles strain/tear, Nerve Entrapment
TEST AND RESULTS: MRI (2nd): small area of edema in the left side of the pubic symphysis and inferior pubic ramus, consistent with stress reaction/athletic pubalgia.

FINAL WORKING DIAGNOSIS: Stress Fracture of the Pubic Ramus (resolving), left hemipelvis in-flare, causing pubic symphysitis and genital branch of Genitofemoral Nerve entrapment
TREATMENT AND OUTCOMES: Osteopathic manipulation- one course resolved pubic symphysis pain. US-guided hydrodissection of the left genitofemoral nerve-immediate alleviation of symptoms with return to play without pain or discomfort.

2678   June 1 4:55 PM - 5:15 PM
Hip Tumor Discovered in High School Basketball Player Referred to Physical Therapy with Knee Pain
Nicholas B. Washmuth. *Samford University, Homewood, AL.* (Sponsor: C Scott Bickel, FACSM)
(No relevant relationships reported)

HISTORY: A 15-year-old high school basketball player reported insidious onset of left knee pain. Knee pain was only present when running and pivoting. He denied ankle or hip dysfunction.
PHYSICAL EXAMINATION: Knee range of motion (ROM) and strength were unremarkable. Moderate weakness noted in bilateral hip extensors and abductors, as well as abdominals. Knee pain was reproduced during squatting movements. Significant lumbar spine, hip, and knee movement compensations were observed while squatting due to hip mobility restrictions. Lower extremity (LE) musculature demonstrated decreased extensibility. Hip internal rotation (IR) ROM limited to 10° left and 20° right, while hip external rotation (ER) limited to 30° bilaterally. Hip flexion limited to 70° left and 100° right. He described "pinching" in left groin during hip impingement special test. All other special tests for hip and knee were negative. Manual assessment of left hip joint accessory mobility revealed hypomobility in all directions.
DIFFERENTIAL DIAGNOSIS:
1. Knee pain compensatory in nature, related to decreased hip joint ROM and LE muscle extensibility
2. Femoral acetabular impingement, due to significant hip mobility deficits
3. Patellar tendinopathy
4. Patellofemoral pain syndrome
Treatment was initiated; however, no improvements in hip ROM were documented after 4 visits of physical therapy that included aggressive joint mobilization and ROM exercises, which led to the suspicion of femoral acetabular impingement. This warranted referral to orthopedic physician for imaging studies.
TESTS AND RESULTS:
Radiographs and MRI of left hip revealed hip tumor, leading to surgery on left hip
FINAL/WORKING DIAGNOSIS:
1. Knee pain compensatory in nature, related to decreased hip joint ROM and LE muscle extensibility2. Surgery, status post tumor excision, left hip
TREATMENT AND OUTCOMES:
Patient followed hip surgical dislocation post-operative rehabilitation protocol and returned to basketball without restrictions at 6 months post-operatively. This clinical case exemplifies the concept of regional interdependence and importance of inter-professional collaboration when patients are not progressing as expected with rehabilitation.

F-39   Clinical Case Slide - **Knee IV**
Friday, June 1, 2018, 3:15 PM - 5:15 PM
Room: CC-200F

A Rare Cause of Knee Pain in a Healthy Male Ultra-marathon Runner
Pierre L. Viviers, FACSM, Riaan Dreyer, Jeandré Viljoen, Wayne Derman. *Stellenbosch University, Stellenbosch, South Africa.*
(No relevant relationships reported)

HISTORY: A 58-year-old healthy male ultra-marathon runner presented with a 3-month history of atraumatic, gradually worsening right-sided anterior knee pain, aggravated by activity and associated with prominent morning stiffness and pain. Night pain was absent. Oral and parenteral NSAIDs provided no relief, nor did massaging. No history of smoking, alcohol or prior corticosteroid use was reported.
PHYSICAL EXAMINATION: The R-knee was slightly swollen with no obvious deformities. No clinical intra-articular effusion was noted. Palpation revealed tenderness over the quadriceps tendon insertion and superomedial knee. In addition, the patient showed significant weakness of the right gluteus medius and quadriceps muscles. Tests for mechanical disruption and intra-articular injury were negative. Further examination of the hip and ankle joints as well as the general systemic examination were unremarkable.
DIFFERENTIAL DIAGNOSIS:
Quadriceps tendinopathy
Patellar tendinopathy
Patello-femoral pain syndrome
Chondromalacia patellae
Patellofemoral osteoarthritis
Iliotibial band syndrome
Other sources of knee pain (such as arthritis and gout)
TEST AND RESULTS: Ultrasound: No soft tissue abnormalities. Suggestive area of a bony infarct in the distal femur. Plain radiographs (R-knee): Hypo-lucent area-distal femur (proximal to the condyles) MRI Knees: Bilateral areas of increased signal in the distal femoral shaft, suggestive of bilateral bony infarcts, were identified. Blood tests: within normal limits.
FINAL WORKING DIAGNOSIS: Spontaneous osteonecrosis of the knee (SPONK)/Ahlback`s Disease.
TREATMENT AND OUTCOMES: 1. Initial management: Conservative - physical therapy and eccentric strengthening exercises. 2. Final outcome: Returned to physical activity, but it is still debated whether this athlete should return to full participation in ultra-marathon running.

2683   June 1 3:35 PM - 3:55 PM
Unusual Knee Pain in a Volleyball Player
Adam Lewno, Daniel R. Lueders. *University of Michigan, Ann Arbor, MI.* (Sponsor: Robert Kiningham, FACSM)
(No relevant relationships reported)

HISTORY:
A 20 year old collegiate volleyball libera presents mid-season with 2 year history of self-resolving right inferolateral burning dysethesitic knee pain with a lasting dull ache that is primarily aggravated with hard contact to her lateral knee as when diving for balls. Over the last 3 weeks her pain has progressed despite multiple forms of knee padding, guards, braces, as well as dive form adjustments causing her to be more hesitant when diving for balls; ultimately negatively affecting her ability to be a defensive specialist on the court. She was previously evaluated for similar complaints in the 2016 season with planned sonographic guided infrapatellar branch of the saphenous nerve (IBSN) corticosteroid injection with hydrodissection but ultimately

did not proceed with treatment due improvement during the off season. She denies any catching, locking, instability, or swelling with no history of prior injury to her right lower extremity.

PHYSICAL EXAM:

SKIN: No rash or lesion

NEUROMUSCULAR: Tenderness at Gerdy's tubercle and distal lateral insertion of the patellar tendon. Normal strength, deep tendon reflexes, and sensation in lower extremities. No ligamentous laxity on special testing.

GAIT: No abnormality

DIFFERENTIAL DIAGNOSIS:

1. Tibial Contusion
2. Fibular Contusion
3. Avulsion fracture
4. Common fibular nerve neuropraxia or neuroma
5. IBSN neuropraxia or neuroma
6. Lateral Meniscus extrusion
7. LCL Strain
8. Distal Iliotibial Band (ITB) Syndrome
9. Distal ITB tendinosis
10. Symptomatic lateral plica

TESTs and RESULTS:

Right knee radiographs indicated bipartite patella with a small joint effusion but no fractures or degenerative changes

Diagnostic ultrasound of the right knee identified asymmetric thickening of the right ITB in its distal-most 5cm to its Gerdy's Tubercle insertion and correlating tenderness with sonopalpation. The adjacent joint line, bursae, nerves, and ligamentous anatomy were normal.

FINFAL DIAGNOSIS:

Distal Iliotibial Band Tendinosis

TREATMENT AND OUTCOMES:

1. Focused exercises on dynamic balance and quadriceps strengthening
2. Progressive ITB stretching
3. Graston instrument assisted soft tissue mobilization
4. Class IV laser treatment

Two weeks of in season treatment achieved complete resolution of her complaints with no disruption of her competitive play.

2684 June 1 3:55 PM - 4:15 PM

Knee Pain in a High School Soccer Player

Brian J. Schutzbach[1], Robert Gillis[2]. *[1]Wellspan Health, York, PA. [2]Wellspan Health, Gettysburg, PA.* (Sponsor: Mark Lavallee M.D., FACSM)

(No relevant relationships reported)

HISTORY: A 17 year old male soccer player presented with left knee pain after feeling an acute "snap" while running across field. He described pain as being sharp, stabbing, worse with movement and associated swelling immediately after the injury. He was unable to continue the game or bear weight. He was sent to Emergency Department for further evaluation.

PHYSICAL EXAMINATION: Examination in emergency department revealed athlete in no acute distress with a left knee appearing to have significant swelling, patella was superiorly displaced, and inability to flex or extend knee. Dorsal Pedis pulse was 2+. Skin was warm, dry, pink, with normal capillary refill. No neurological deficits. Vitals stable.

DIFFERENTIAL DIAGNOSIS: 1. Patella tendon rupture 2. Tibial tuberosity avulsion fracture3. Osgood Schlatter Disease 4. Patellar dislocation 5. Patella sleeve fracture

TEST AND RESULTS:Left Knee anterior-posterior, lateral, and oblique radiographs: Distracted and anteriorly displaced large avulsion fracture involving anterior proximal tibia and anterior tibial tuberosity. Maximum distraction of 18.7 mm. Growth plates not completely fused consistent with continued growth.

FINAL WORKING DIAGNOSIS: Type III tibial tuberosity avulsion fracture

TREATMENT AND OUTCOMES: 1. Initial immobilization, non-weight bearing, pain control.

2. Evaluation by Orthopedic Surgeon in office following day. 3. Open reduction and internal fixation with 2 screws perpendicular to fracture line performed on day 4 after injury. 4. Discharged home the same day with weight bearing as tolerated with knee immobilizer locked in extension with crutches. 5. 10 days post-operation: Transition to hinge brace and leg remained locked straight to prevent hyperextension. 6. 3 weeks: Physical therapy with unlocking brace for range of motion exercises 7. 7 weeks: Full range of motion. Cleared to play limited minutes in senior night game.8. 10 weeks: Return to all activities without restriction.

2685 June 1 4:15 PM - 4:35 PM

Knee Injury - Soccer

Matthew C. Hess, Garry W. K. Ho, FACSM. *VCU-Fairfax Family Practice Sports Medicine Fellowship, Fairfax, VA.* (Sponsor: Garry W. K. Ho, MD, FACSM, RMSK, FACSM)

(No relevant relationships reported)

History:

21 year-old male soccer player presented with a 2-day history of diffuse right knee pain which began suddenly after slipping over a soccer ball and landing awkwardly on his leg. Patient reportedly heard a 'loud pop,' was unable to ambulate off the soccer pitch, and has had difficulty walking since. He noticed immediate swelling, and complained of decreased range of motion. He denied numbness, tingling, weakness or prior injury to the knee.

Physical Examination:

Examination in the clinic was notable for antalgic gait, and a large right knee effusion. The patient's active and passive range of motion was restricted from +5 to 100 degrees on the right secondary to pain with normal tracking of the patella. He had tenderness over the medial joint line. The patient had 5/5 strength with flexion and extension. There was normal patellar glide without apprehension. He had a negative Lachman and anterior drawer, but this examination was limited by guarding, making accurate assessment difficult. Valgus stress testing revealed mild laxity. End point was firm with varus stress. Posterior drawer was negative, and he had no appreciable sag sign. The patient was unable to tolerate a McMurray test secondary to pain. He had a normal distal neurovascular exam.

Differential Diagnosis:

1. Tear of the anterior cruciate ligament
2. Medial meniscus tear
3. Strain of the medial collateral ligament
4. Osteochondral defect
5. Tibial plateau fracture

Tests and Results:

Plain film radiography not immediately available due to technical difficulties.

Targeted point-of-care musculoskeletal ultrasound of the knee:

--Large joint effusion with moderate sized hematoma posteriorly along lateral wall of intercondylar notch suspicious for anterior cruciate ligament injury

Final/Working Diagnosis:

Acute Anterior Cruciate Ligament Tear

Treatment and Outcomes:

1. Rest, ice, compression, elevation
2. Ibuprofen 600-800mg by mouth every 8 hours as needed for pain and inflammation
3. Right knee anterior-posterior, lateral and sunrise radiographs (once completed, showed soft tissue swelling and avulsion (Segond) fracture of the lateral tibial plateau
4. Weight bearing as tolerated
5. Referral to Orthopedic Sports Medicine for consideration of ACL reconstruction

---

2686 June 1 4:35 PM - 4:55 PM

Knee Snapping After Arthroscopy Diagnosed With Ultrasound In A Runner And Weightlifter: A Case Report

Charonn D. Woods, Jonathan T. Finnoff, FACSM, Brennan J. Boettcher. *Mayo Clinic, Rochester, MN.* (Sponsor: Jonathan T. Finnoff, FACSM)

(No relevant relationships reported)

HISTORY: A 38 year old male presented for a diagnostic ultrasound to evaluate right knee snapping and pain with squats. He had a right knee arthroscopy 11 months prior for an osteochondral lesion of the patellofemoral joint with removal of loose bodies and chondroplasty of the defect. Post-operatively, he complained of 3/10 pain in the knee that became sharp with deep squats and a popping sensation within the terminal 10 degrees of extension.

PHYSICAL EXAMINATION:

Gait: Gait was nonantalgic. Heel and toe walking were normal. Squatting reproduced lateral right knee pain.

Knee exam: Active terminal knee extension reproduced superolateral knee snapping. Patellofemoral crepitus was noted. Ligamentous testing and meniscal provocation maneuvers were negative with no joint line tenderness.

DIFFERENTIAL DIAGNOSIS:

Intraarticular loose bodies

Lateral meniscus tear

Osteoarthritis with crepitus

Extra-articular snapping (biceps femoris, IT band, popliteus)

TESTS AND RESULTS:

Right knee plain radiographs demonstrated mild tricompartmental degenerative arthritis.

Diagnostic ultrasound of the superolateral right knee revealed hypertrophic synovial tissue snapping over a lateral femoral condyle osteophyte. There was no associated synovial hyperemia or joint effusion.

FINAL WORKING DIAGNOSIS:

Right superolateral knee snapping secondary to hypertrophic synovial tissue snapping over a lateral femoral condyle osteophyte.

TREATMENT AND OUTCOME:

An ultrasound-guided diagnostic injection of lidocaine was performed around the osteophyte which provided immediate relief. He was able to squat 135 lbs during the anesthetic phase, and had been unable to body weight squat without significant pain pre-injection. Given the positive response to the diagnostic injection, a repeat injection was performed with Depo-Medrol.

At the two month follow-up, patient reported 60-80% symptom reduction during problematic activity (lunging and squatting) and improvement in function.

Snapping in the knee can be a difficult diagnosis to obtain in an individual who has a known history of loose bodies in the knee. While several case reports exist describing snapping biceps femoris and popliteus tendons in the lateral knee, this is the first to our knowledge to describe a lateral femoral condyle osteophyte as the culprit of snapping.

2687   June 1 4:55 PM - 5:15 PM

Snapping Knee After Knee Arthroplasty In Recreational Athlete

Angela N. Cortez, Tracy Hoeg, Brian A. Davis, FACSM. *University of California at Davis, Sacramento, CA.* (Sponsor: Brian Adam Davis, FACSM)

(No relevant relationships reported)

HISTORY: A 63 year-old recreational athlete presented with right knee snapping 3 months after medial unicompartmental knee arthroplasty. Snapping sensation localized to posterior medial knee and aggravated with active knee flexion and extension. She experiences associated pain in the same area, and occasionally at rest. No instability. Surgical incision of anterior knee healing well without pain.

PHYSICAL EXAMINATION: Examination revealed knee extension to 10°, knee flexion to 120°, focal tenderness of distal semimembranosus tendon. Palpable snapping over medial hamstrings with knee extension and flexion between 20° to 90°. No varus or valgus instability. Mild knee effusion. Surgical scar to anterior knee healing well.

DIFFERENTIAL DIAGNOSIS:

1. Snapping Popliteal Recess
2. Hardware Loosening
3. Snapping Hamstring Tendon over Hardware
4. Snapping Pes Anserinus Syndrome
5. Snapping Fabella

TEST AND RESULTS:

- Right Knee AP and lateral radiographs showed slight posterior positioning of hardware, no periprosthetic lucency to suggest loosening or fracture.
- Right Knee MRI Maverick protocol without contrast showed the imaged portions of the biceps, semimembranosus, and semiteninosus are unremarkable. The distal aspect of the semimembranosus and semitendinosus is obscurred by susceptibility artifact as it passes posterior to the unicompartmental arthroplasty.
- Right Knee Dynamic Ultrasound Evaluation showed dynamic snapping of the semimembranosus tendon over the gastrocnemius tendon while patient actively flexed and extended her knee.

FINAL WORKING DIAGNOSIS: Snapping semimembranosus and gastrocnemius tendons due to medial unicompartmental arthroplasty hardware impingement in the right knee

TREATMENT AND OUTCOMES:

1. Completion of post-surgical rehabilitative physical therapy, including achieving full knee extension, for a total of 6 weeks.
2. Trial of ultrasound guided steroid injection to tendon site for persistent symptoms.
3. Consideration for semimembranosus tenotomy if symptoms persist despite steroid injection.
4. Consideration of unicompartmental knee revision vs total knee replacement as a last resort only.
5. Snapping and pain improved though not resolved with rehabilitative exercises 6 months post-op, pending steroid injection to semimembranosus and gastroc tendon.

Recurrent Chest Pain in an 18 Year Old Male with a History of Viral Perimyocarditis

Paul C. Goleb, Jr, Kyle Yost, Andrew Tucker. *University of Maryland Medical Center, Baltimore, MD.*

(No relevant relationships reported)

HISTORY: An 18 year old male athlete detailed a recent hospitalization for viral perimyocarditis during his pre-participation examination (PPE). His medical and surgical histories were otherwise not significant. He took no medications and had no known allergies. He denied alcohol use, smoking, or illicit drug use. His family history was non contributory. During his PPE he was symptom free and was cleared for all activity. Over the next weeks he reported multiple, brief, self-resolved episodes of substernal chest pain and shortness of breath. He denied syncope or palpitations. His symptoms did not worsen with exercise. One episode of chest pain prompted evaluation in a local ER, where he had a normal chest x ray, negative troponins, and normal vital signs. Following this episode, the patient was withheld from activity and referred to cardiology.

PHYSICAL EXAMINATION:

General: Well appearing male.

HEENT: No jugular venous distention.

Cardiovascular: Regular rate and rhythm, normal S1 and S2, no murmurs, rubs, or gallops. Brisk capillary refill. No tenderness to chest wall palpation. No pulsus paradoxus.

Respiratory: Clear to auscultation bilaterally.

Extremities: No clubbing, no cyanosis, no edema.

DIFFERENTIAL DIAGNOSIS:

1. Coronary artery disease
2. Arrhythmia
3. Pericardial effusion
4. Recurrent perimyocarditis
5. Pulmonary embolism

TEST AND RESULTS:

Initial Hospitalization:

EKG: Sinus rhythm with anterolateral ST elevation.

Troponin 11.48.

CRP 2.28.

Transthoracic echocardiogram: LVEF 56%.

Cardiac Catheterization: No coronary artery disease.

CT chest: No pulmonary emboli. No aortic dissection.

Cardiac MRI: Heterogeneous focal enhancement consistent with myocarditis. Normal LV size with low normal LV function (LVEF 51%).

Follow-Up:

TSH 0.6, ANA negative, P-ANCA negative, C-ANCA negative, CRP <0.1, ESR 1, CK 183, BNP 32, Troponin <0.04.

Holter Monitor: Normal sinus rhythm, no arrhythmias.

Exercise stress test: No ischemia.

FINAL/WORKING DIAGNOSIS:

Viral Perimyocarditis (Resolved).

TREATMENT AND OUTCOMES:

1. Withheld from activity following ER visit
2. Referred to Cardiology
3. Exercise Stress Test
4. Holter Monitor
5. Lab work-up
6. Repeat Cardiac MRI to be performed 3 months after initial study to re-assess inflammation
7. Return to play decision to be made following results of repeat cardiac MRI

2692   June 1 3:35 PM - 3:55 PM

Abdominal Trauma - Football

Jonathan Goike, Michael Baria. *Ohio State University, Columbus, OH.*

(No relevant relationships reported)

HISTORY: A 15 year old male football player was tackled during practice and sustained blunt force trauma to his abdomen from his opponent's helmet. He felt immediate right sided abdomen and shoulder pain. He was promptly assessed by the athletic trainer and removed from practice. The athletic trainer examined him and found both right upper quadrant tenderness and pain with rib cage / thorax compression. Though the athlete reportedly felt improved, the athletic trainer recommended further evaluation by a sports medicine physician.

PHYSICAL EXAM: Orthostatic vitals revealed a heart rate increase from 66 to 114 on sit to stand. He was alert, oriented and in no distress. He had significant right upper quadrant tenderness with rebound and positive Murphy's sign with moderate generalized abdominal tenderness. He had minimal right sided tenderness to palpation over the ribs without flail chest. No respiratory distress. Lung fields were clear to auscultation. Heart rate and rhythm were regular.

TESTS AND RESULTS:
Abdominal Radiograph – Non-obstructive bowel gas pattern, no pneumoperitoneum
Ultrasound FAST exam – Free peritoneal and retro-vesicular fluid
CT Abdominal/Pelvis – Grade 3 Liver laceration (7.9 cm) and Grade 1 Splenic laceration

DIFFERENTIAL DIAGNOSIS:
1. Liver laceration
2. Rib fracture
3. Pneumothorax/hemopneumothorax
4. Diaphragm spasm

FINAL/WORKING DIAGNOSIS:
Grade III Liver and grade I splenic laceration

TREATMENT AND OUTCOMES:
1. Immediate transfer to emergency department for trauma evaluation followed by observation in the ICU and surgical floors for 3 days.
2. Limited to walking for exercise and 10 pound lifting restriction for 6 weeks.
3. Returned to low impact, non-contact exercise and machine based strength training after 6 weeks.
4. Anticipate full return to sport following 6 months no contact and after repeat testing including CT, LFTs

2693   June 1 3:55 PM - 4:15 PM

Improved Pulmonary Function in a Patient with Lymphangioleiomyomatosis Following Exercise Training

Thomas W. Lowder. *University of Central Arkansas, Conway, AR.*

(No relevant relationships reported)

HISTORY: Lymphangioleiomyomatosis (LAM) is an interstitial lung disease the results in cystic destruction of the lung parenchyma, resulting in a decline (often rapid) in pulmonary function. There is no cure for this disease and lung transplantation is often required. Even with transplantation, the disease will still present, as the cells originate in the body (origin is at present unknown) and migrate to the lungs. This disease affects women almost exclusively.

PHYSICAL EXAMINATION: A 29 year-old female, diagnosed with Tuberous Sclerosis Complex (TSC) at after 5 and LAM at age 21, underwent 12mo of high-intensity exercise 2d/wk. Prior to training and every 3mo pulmonary function, oxygen uptake (VO$_2$), and bone mineral density were assessed.

DIFFERENTIAL DIAGNOSIS: LAM is similar to TSC in that TSC is a predisposing condition for LAM and several shared clinical features exist in both diseases (angiomyliipomas, TSC2 gene mutations). LAM shares similarities with both Birt-Hogg-Dube syndrome and Sjogren syndrome.

TEST AND RESULTS: After one year of training the patient improved forced expiratory volume in one second (FEV$_1$) by 9%, FEV$_1$/FVC (forced vital capacity) by 10%, peak flow by 47%, and a 20% increase in oxygen consumption.

FINAL WORKING DIAGNOSIS: Exercise can be used to improve pulmonary function and work capacity in a patient with TSC/LAM.

TREATMENT AND OUTCOMES: Treating LAM with high-intensity exercise resulted in marked improvement in this patient. Improvements were not seen until after 6mo, indicating that short-duration interventions may be insufficient in improving lung function.

2694   June 1 4:15 PM - 4:35 PM

Evaluating The Effectiveness Of The Girls On The Run Program With Respects To Self-esteem, Self-perceived Body Image, And Aerobic Capacity.

Amanda J. Cunningham. *Grand Valley State University / Central Michigan University, Allendale, MI.*

(No relevant relationships reported)

The aim of this study was to evaluate the effectiveness of the Girls on the Run program. Twenty seven girls who participated in the Girls on the Run for eleven weeks were evaluated pre and post the program on self-esteem, self-perception of body image and aerobic capacity. The girls were evaluated by a written survey and the PACER test. There was a significant positive increase in self-esteem (p=.014) and body o,age (p=.705). following the program the girls learned to be more accepting of themselves ad their body image. There was a non-significant increase in mean aerobic capacity starting at 39.8 ml/kg/min and ending at 41.87 ml/kg/min. This could be due to part to low intensity training versus highly structured high intensity training. The Girls on the Run program was shown in this study to have a positive outcome on girls' overall mental, emotional, and physical health through varying activities and positive leadership in the role models who coach. Future studies should evaluate the effects of high intensity training over a long period of times. As well as showing the effects of self esteem and positive body image in the young girls as they age.

2695   June 1 4:35 PM - 4:55 PM

Hematuria - Cross Country

Peter Obourn. *University of Connecticut Health Center, Hartford, CT.*

(No relevant relationships reported)

HISTORY: 21 year-old female cross country runner with 1 week of gross hematuria. History of microscopic hematuria on several occasions since age 3 with no history of gross hematuria. She was having hematuria on and off for a week. She had one painful void with 3 out of 10 burning pain at the urethra during hematuric void. Her urine color is consistent with fruit punch. Just prior to the episode of gross hematuria she had completed a 4 mile run consistent with her normal daily activity, not significantly more vigorous than her normal training routine. This had occurred about 3 days prior. She denied any increased urinary frequency or feelings of urinary retention. She denied fevers, chills, nausea, vomiting, muscle cramps, or flank pain. She denied unprotected sexual intercourse or vaginal discharge. She denied any recent illnesses, specifically sore throat.

PHYSICAL EXAMINATION: Vital signs were normal. Healthy, well appearing, in no apparent distress. Head normocephalic and atraumatic. Sclera and conjunctivae normal with EOM intact. No gross deformities of the ears bilaterally and no obvious hearing deficits. Oropharynx clear without erythema or exudates. No cervical lymphadenopathy. Normal respiratory effort. Bowel sounds were normoactive with no tenderness to palpation, no masses, and no organomegaly. There was no costovertebral angle tenderness and no pelvic tenderness. Normal mood and affect. No visible skin lesions.

DIFFERENTIAL DIAGNOSIS:
1. Pyelonephritis
2. Post streptococcal glomerulonephritis
3. Rhabdomyolysis
4. Nephrolithiasis
5. Cancer
6. IgA nephropathy
7. Idiopathic exercise induced hematuria

TESTS & RESULTS:
CMP: unremarkable
ANA screen: negative
C3/C4: normal
Antistreptolysin: normal
ANCA screen: negative
24 hour urine total protein: normal
Renal/bladder ultrasound: unremarkable

FINAL WORKING DIAGNOSIS:
Thin basement membrane disease

TREATMENT AND OUTCOMES:
-Patient is believed to have thin basement membrane disease at this time. Her hematuria workup has been negative to this point. It was determined that she has a brother with thin basement membrane disease.
-Referred to nephrology for further recommendations
-Cleared to continue normal activities for cross country
-Though likely benign, we may need to obtain further testing including possible biopsy to prove benign diagnosis

Energetic Profile of a Wheelchair Racing 1500 m Simulation Test

Lingling Zhang[1], Xueping Wu[2], Yongming Li[2]. *[1]Shanghai University of Finance and Economics, Shanghai, China. [2]Shanghai University of sport, Shanghai, China.*

(No relevant relationships reported)

Wheelchair racing has been one of the official events in Paralympic Games since 1964. Understanding the energetic profiles in wheelchair racing may provide information in developing training strategies. However, there is lack of concrete quantitative research on energetic profile of Wheelchair Racing 1500m.
PURPOSE: To quantify the energy contribution of wheelchair racing 1500 m in high level athletes.
METHODS: Eight males (24±5 years, 174.4±5.9 cm, 67.3±9.1 kg, training experience of 15±10 years) from the Chinese national team participated in the research for a graded exercise test and a 1500 m all-out test. A portable gas analyzer(K4b[2], Cosmed,Italy) was used to measure VO_2 at every breath.A GPSports (GPSports HPU, Canberra, Australia) and heart rate belt (Polar Accurex Plus,Ploar Electro Oy,Finland) were used to monitor speed and HR changes. Capillary blood was taken from the earlobe before and after the warm-up, immediately before the time trials and the during the $1^{st},3^{rd},5^{th},$and 7th minute of the recovery. Then it was assessed with a lactate analyzer (Biosen C_line, EKF, Gemany). The energetic contribution was measured with the maximal accumulated oxygen deficit (MAOD).
RESULTS: Results showed that the accumulate oxygen deficit, the maximal heart rate and the peak blood lactate values were 2667.3±894.5 ml, 188.9±9.0 bpm, and 11.1 ± 2.3 mM, respectively. The total energy contribution of the 1500 m test was 205.5±29.2 kJ. The aerobic and anaerobic energy contributions were 146.6±21.6 kJ (71.7%) and 58.9±18.9 kJ (28.3%), respectively. Significant (P<0.05) negative correlations were noted between race performance,the peak blood lactate and accumulated blood lactate for the 1500 m test(r=−0.638 and −0.735, respectively).
CONCLUSION: Wheelchair racing 1500 m is an aerobic-dominated event. The knowledge of energy supply in this event underestimates the importance of aerobic contribution. Anaerobic glycolysis exerts a significant influence on the performance of this event.
Supported by Shanghai Key Lab of Human Performance(Shanghai University of sport) (NO. 11DZ2261100).

Leucocyte Telomere Length of Master Endurance Athletes is Associated to Resting Nitric Oxide: Possible Role of Redox Balance.

CAIO V. SOUSA, SAMUEL S. AGUIAR, PATRICK A. SANTOS, LUCAS P. BARBOSA, LYSLEINE A. DEUS, THIAGO S. ROSA, ROSÂNGELA V. ANDRADE, HERBERT G. SIMÕES. *UNIVERSIDADE CATÓLICA DE BRASÍLIA, BRASÍLIA, Brazil.*

(No relevant relationships reported)

PURPOSE: Leukocyte telomere length (LTL), a biological marker of aging, is longer in elderly endurance runners than age-matched controls, but the underlying mechanisms are poorly investigated. The LTL, nitric oxide (NO) and redox balance of master endurance runners (ER) were analyzed and compared to untrained middle-aged (MC) and young controls (YC). We hypothesized that NO and redox balance at baseline would be related to longer LTL in ER. **METHODS**: Participants (n = 38) from both ER (n = 10; 51.6 ± 5.2yrs; 28.4 ± 9.4yrs of experience), MC (n = 17; 46.6 ± 7.1yrs) and YC (n = 11; 21.8 ± 4.0yrs) attended to the laboratory for anamnesis, anthropometrics and blood collection for biochemical and molecular analyzes. Pro and antioxidant measures as well as DNA extraction were performed using commercial kits following the fabricant protocols. Relative LTL was measured using qPCR analysis. **RESULTS**: The LTL of YC group (T/S = 1.85 ± 1.59) was longer than MC (T/S = 0.47 ± 0.51; *p* < 0.05) but did not differ from ER (T/S = 0.89 ± 0.50; *p* > 0.05). A large *effect-size* between TL of ER and MC (*d* = 0.85) was also observed. The comparison of antioxidant/pro-oxidant ratios indicated a better redox balance for the ER and young adults in comparison to middle aged untrained participants, which showed lower values for TEAC/TBARS, SOD/TBARS and CAT/TBARS (*p* < 0.05). Furthermore, the NO levels for the ER (175.2 ± 31.9μM) were higher (*p* < 0.05) than MC (67.2 ± 23.3μM) and YC (129.2 ± 17.3.μM), with a positive and strong correlation with LTL (*r* = 0.766; *p* = 0.02). **CONCLUSIONS**: In conclusion, master endurance runners have longer LTL than age-matched controls, what in turn may be related to their better NO bioavailability and redox balance status.

The Energy Expenditure and Relative Exercise Intensity During Pound

Abigail L. Ryskey, John P. Porcari, 54601, FACSM, Kimberly Radtke, Susan Bramwell, Carl Foster, FACSM. *University of Wisconsin - La Crosse, La Crosse, WI.* (Sponsor: John Porcari, FACSM)

(No relevant relationships reported)

A new fitness program that has become popular is Pound®. Pound® incorporates both Pilates and drumming movements into a full-body workout. During a session of Pound® participants use Ripstix. Ripstix are drumsticks that weigh a quarter of a pound (0.11 kg) each and are used to "pound" to the beat of the music together with choreographed body movements. **Purpose:** This study was designed to determine the energy expenditure and relative exercise intensity of a Pound® cardio-jam session. Twenty-two volunteers (6 males; 16 females) between the ages of 18-25 years performed a maximal exercise test on a treadmill. Each subject then completed 2-3 practice session of Pound®, following a DVD. Once proficient, they completed a 38-minute Pound® cardio-jam session. Heart rate and VO_2 were monitored every minute throughout the workout and perceived exertion was recorded approximately every 4 minutes throughout the session using the Borg 6-20 RPE scale. **Results:** It was found that both % HRmax (males: 68 ± 5.2; females: 73 ± 6.8) and % VO_2max (males: 39 ± 4.5; females: 42 ± 6.6) were within ACSM guidelines for improving cardiorespiratory endurance. Throughout the workout subjects considered the workout to be of "somewhat hard" intensity (average RPE = 12.7 ± 1.91). Energy expenditure for both males (280.8 ± 41.38 kcal/session) and females (221.8 ± 34.35 kcal/session) was within ACSM guidelines. Males had a significantly higher energy expenditure than females due to higher body mass (75.1 ± 8.9 kg vs. 67.9 ± 7.3 kg). **Conclusion:** The Pound® cardio-jam session meets standards set forth by ACSM for improving cardiorespiratory fitness and body composition. Collectively, the findings of this study suggest that Pound® may be an enjoyable option for individuals seeking an alternative to traditional aerobic exercise programs.

2721   Board #4   June 1 2:00 PM - 3:30 PM

Validation of Overall Energy Expenditure Measurements in the Fitbit Charge HR 2 and Apple Watch

Kaigang Li, Kayla Nuss, Elizabeth A. Thomson, Ashley Comstock, Sophie Blake, Steven Reinwald, Richard E. Pimentel, Brian Tracy, FACSM. *Colorado State University, Fort Collins, CO.*

(No relevant relationships reported)

PURPOSE: To determine the validity of the energy expenditure (EE) estimation for the Fitbit Charge HR 2 and the Apple Watch devices. **METHODS**: Thirty young adults (15 females, 15 males, aged 23.5±3.0 years) completed the Bruce Protocol. Gross EE of participants was measured by PARVO metabolic cart and estimated by Fitbit Charge HR 2 and Apple Watch devices. A concordance correlation coefficient (CCC, r_c) was conducted to examine the strength of the relationship of PARVO measured EE with EE estimated by each device. Relative error rates (RER) were calculated to indicate the difference between each device and PARVO. **RESULTS**: For the Apple Watch, the relative error was 24.25% for overall, 18.58% for males, and 29.93% for females. For the Fitbit, the relative error was 20.07% for overall, 24.17% for males, and 16.72% for females. Moderate Concordance correlations between estimated EEs and PARVO measured EEs were found for both Apple Watch (r_c = 0.65, 0.43, and 0.39 for overall, males and female) and Fitbit Charge HR 2 (r_c = 0.53, 0.39, and 0.21 for overall, males and females). In addition, stronger relationships were found between PARVO EE and Apple Watch EE than those between PARVO EE and Fitbit Chare HR 2 EE for overall, males and females. **CONCLUSIONS**: This was one of the first studies to examine the accuracy of overall energy expenditure estimated by Apple Watch and Fitbit Charge HR 2. Neither of the two devices showed accurate results compared to the measured EE by the standard approach. The Apple Watch revealed overestimated EE for females but underestimated EE for males. The Fitbit underestimated EE for both males and females. Researchers, practitioners and personal users should consider these results when designing programs or personal training plans targeting physical activity related EE with a wearable device.

2722   Board #5   June 1 2:00 PM - 3:30 PM

Comparison of Reported Energy Expenditure from Polar M430 vs. Polar V800 vs. Actual Energy Expenditure

Olivia Hanzel, Grace Shryack, Joshua Patterson, Courtney Willoughby, Bryan Smith. *Southern Illinois University Edwardsville, Edwardsville, IL.*
(No relevant relationships reported)

INTRODUCTION: The Polar M430 (M430) uses optical technology to measure heart rate (HR) from a sensor that is built into the back of the watch. The Polar V800 (V800) uses a wireless chest transmitter that is held in place by a chest strap. Both of these watches estimate exercise energy expenditure (ExEE) for numerous types of exercise. Although there is evidence that suggests that the wireless transmitters provide accurate estimates of ExEE, there is little information that shows that watches equipped with optical sensors provide accurate measurements of ExEE. **PURPOSE**: The purpose of this study was to compare the ExEE values obtained from the M430 and the V800 to ExEE values measured using indirect calorimetry during different bouts of exercise. **METHODS**: Two females (age = 20 ± 1 y, BMI = 24.2 ± 2.0 kg/m²) and ten males (age = 22.8 ± 1.0 y, BMI = 26.1 ± 1.3 kg/m²) reporting to the lab and were fitted with a chest strap HR transmitter (Polar H7) to measure and transmit HR data to the V800. The M430 was fitted on the participant's wrist according to the manufacturer's instructions. Participant's then completed four, 5-min bouts of exercise which consisted of the following; walking 3.5 mph at 0% grade, walking 3.5 at 5% grade, running at 5.5 mph at 0% grade, and running at 5.5 mph at 5% grade. Indirect calorimetry was used to measure actual ExEE.
RESULTS: There were no significant differences between the three methods when walking at 0% or 5%. When running at 0% there was a significant difference between methods (p=0.044), with the M430 underestimating ExEE when compared to indirect calorimetry (5.8±2.0 kcal, p=0.045). When running at 5% there was a significant difference between methods (p=0.001). The M430 underestimated ExEE when compared to the V800 (7.5±2.1 kcal, p=0.018) and when compared to indirect calorimetry (14.5±3.7 kcal, p=0.008).
CONCLUSIONS: The V800 provided accurate estimates of ExEE during each bout of exercise. The M430 provide accurate estimates of ExEE only when walking. When running, the M430 consistently underestimated ExEE and the underestimation increased with exercise intensity. At the highest exercise intensity, the M430 underestimated ExEE when compared to both the V800 and indirect calorimetry. Caution should be taken when using the ExEE values obtained from the M430 when running.

2723   Board #6   June 1 2:00 PM - 3:30 PM

Comparison of Exercise Energy Expenditure Values Obtained from the Garmin Forerunner 230 and 235

Courtney A. Willoughby, Olivia Hanzel, Joshua Patterson, Grace Shryack, Bryan Smith. *Southern Illinois University Edwardsville, Edwardsville, IL.*
(No relevant relationships reported)

The recent trend in activity tracking has increased the demand for smart watches that can provide estimates of exercise energy expenditure (ExEE) during different types of exercise based upon the heart rate response to that exercise. The Garmin Forerunner 230 (230) and Forerunner 235 (235) are similar watches with the only difference being how heart rate (HR) is measured. The 230 uses a wireless chest transmitter that is held in place with a chest strap while the 235 uses an optical sensor that is built directly into the watch. **PURPOSE**: The purpose of this study was to compare the ExEE values obtained from the 230 and the 235 to ExEE values measured using indirect calorimetry during different bouts of exercise. **METHODS:** Two females (BMI=24.2 ± 2.8 kg/m², age=20 ± 1.4 y) and ten males (BMI=26.1 ± 4.1 kg/m², age=22.8 ± 3.3y) reported to the Exercise Physiology Lab at Southern Illinois University Edwardsville where they were fitted with a wireless chest transmitter and chest strap for the 230. The 235 was fitted on the participant's wrist according to the manufacturer's instructions. The exercise consisted of two, 5-min walking intervals (3.5 mph + 0% incline and 3.5 mph + 5% incline) and two, 5-min running intervals (5.5 mph + 0% incline and 5.5 mph + 5% incline) with 3-min of rest between each exercise bout. Indirect calorimetry was used to measure actual ExEE. **RESULTS:** There were no significant differences between the three methods during the 5% walk or the 0% run. During the 0% walk, there was a significant difference between methods (p=0.048) with the 235 overestimating ExEE when compared to the 230 (7.2±3.2 kcal, p=0.044). During the 5% run, there was a significant difference between methods (p=0.002). Both the 230 and 235 underestimated ExEE when compared to indirect calorimetry (12.3±3.6 kcal, p=0.024 and 10.0±3.3 kcal, p=0.043, respectively). **CONCLUSION:** The 230, which uses a wireless chest transmitter, provides accurate estimates of ExEE in all but the most intense exercise bout. The 235, which uses an optical sensor, varies in its ability to estimate ExEE in that it overestimates at the lower exercise intensities

and underestimates at the highest exercise intensity. Caution should be taken when using ExEE values from both the 230 and 235 for weight management or exercise prescription purposes.

2724   Board #7   June 1 2:00 PM - 3:30 PM

Predicting Energy Expenditure of an Acute Bout of Resistance Exercise in Men and Women

Danielle M. Kravits[1], Brad S. Lambert[2], Jason R. Lytle[1], Stephen E. Martin[1], John S. Green, FACSM[1], Stephen F. Crouse, FACSM[1]. *[1]Texas A&M University, College Station, TX. [2]Houston Methodist, Houston, TX.* (Sponsor: Stephen F. Crouse, FACSM)
(No relevant relationships reported)

Energy expenditure from resistance exercise (RE) is an important consideration for exercise prescription, yet prediction models are lacking. **PURPOSE:** To develop regression equations to predict energy expenditure (kcal) for RE involving each major muscle group using commonly measured demographic & exercise variables as predictors. **METHODS:** Fifty-two healthy, active subjects (27 men, 25 women, age 20-58 yrs, height 174.1 ± 10.5 cm, weight 188.7 ± 42.6 kg, VO_{2max} 36.8 ± 9.2 ml/kg/min) were strength tested to determine their 3-5 repetition max (RM) on commercial pneumatic RE equipment 1 week prior to their experimental RE bout. Body composition was assessed using DEXA. For the experimental RE, a warm-up set followed by 2-3 sets of 8-12 reps at 60-70% predicted 1RM were performed for each exercise. Each set started every two minutes. Exercises progressed order: leg press, chest press, leg curl, lat pull, leg extension, triceps extension, biceps curl. VO_2 was measured continuously throughout the RE bout via automated metabolic cart. Total exercise volume (TV) was calculated as sets*reps*weight lifted. Multiple Linear Regression (Stepwise Removal) was used to determine the best model to predict kcal consumption based on the highest adjusted R^2 and least amount of variance inflation. **Results:** Table.

| EXERCISES | REGRESSION COEFFICIENT | | | | | | | | MODEL FIT | |
	HT (cm)	AGE (y)	GENDER (m=1, F=0)	FATMASS (kg)	LEANMASS (kg)	WEIGHT (kg)	VOLUME m3 (kg)	CONSTANT	R Square	SEE
TOTAL	0.874	-0.596		-1.016	1.638		2.461	-110.742	0.773	28.465
LEG PRESS	0.12	-0.093		-0.252	0.297		1.169	-13.837	0.83	4.40
CHEST PRESS	0.186	-3.173		-0.198	0.271		4.211	-28.468	0.68	4.70
LEG CURL		-0.129			0.245	-0.1	5.189	6.633	0.62	5.36
LAT PULL		-0.165		-0.128	0.187		4.725	8.483	0.67	4.96
LEG EXTENSION		-0.08	-1.635	-0.185	0.394		4.252	1.444	0.70	5.31
TRICEPS PUSH	0.255		-5.124	-0.239	0.39		1.919	-44.891	0.72	4.99
BICEPS CURL	0.292	-0.091	-7.068		0.351	-0.156	15.059	-44.262	0.62	5.603

CONCLUSIONS: Energy expenditure for a total RE bout and for specific RE exercises can be reasonably estimated in adult men and women using commonly measured demographic and RE variables. With regards to fitness, performance, and weight management, these equations will aid practitioners and exercising adults in documenting kcal expenditure from RE.

2725   Board #8   June 1 2:00 PM - 3:30 PM

The Garmin Vivosmart HR vs the Cosmed K4B2 Metabolic Backpack: Validating Measurement of Energy Expenditure

Brandi R. Washell. *Coastal Carolina University, Conway, SC.* (Sponsor: George Lyerly, FACSM)
(No relevant relationships reported)

Wearable fitness trackers are relatively cheap and convenient tools that track an individual's physical activity. Such qualities have led to an emergence of various fitness trackers available on the market for consumers, but does convenience and relatively low cost compromise accuracy? For this study, we compared Garmin Vivosmart HR (G) watch and the Cosmed K4b2 Metabolic backpack (C) to determine if the cheaper and more user friendly, G is as accurate as the laboratory "gold standard" C.
PURPOSE:The purpose of this study is to compare G and C's accuracy in determining energy expenditure via kcals (EE).
METHODS: 19 recreationally active students and professors volunteered to participate. Prior to the start of the study, participants had their height, weight, BP and resting HR recorded. The participants were asked to wear both G and C while walking at a low to moderate intensity on a treadmill for 10 minutes.
RESULTS: The mean EE for C was 49.91 ± 8.2 and G was 47.42 ± 19.7.
CONCLUSIONS: Our data indicate that there was no correlation between G and C with an r-value = -0.273; p = 0.273. Further research is warranted with a more extensive population to determine the accuracy of the Garmin Vivosmart HR, and by how many more calories.

Validating The Garmin Vivosmart Hr Vs The Actigraph Gt3x Accelerometer In Measuring Energy Expenditure.

Ethan Hayes. *Coastal Carolina University, Conway, SC.* (Sponsor: George Lyerly, FACSM)
(No relevant relationships reported)

In the field of exercise science, the Actigraph GT3X (A) accelerometer is regarded as one of the most accurate field measurement devices for physical activity (PA). Many PA devices have recently been added to the market to measure PA for individuals. The Garmin Vivosmart HR (G) watch is currently among the top devices on the market to measure PA. The underlying question that needs to be answered is; how accurate is the G watch? In this study, we compared the accuracy of the G to A in regards to measuring energy expenditure in kcals (EE). **Purpose:** To compare the accuracy of G to A in measuring EE. **Methods:** Individuals were recruited via word of mouth to participate in this study. The study required individuals to attach the G to the left wrist and A placed around the waist with the measuring device on the left side of the subject. The duration of the study consisted of a ten minute low-moderate intensity walk on a treadmill. Prior to exercise, weight, height, RBP, and RHR were obtained. We recruited 19 subjects, 18 years and older, of varying activity levels. **Results:** The mean EE from A was 83.92 ± 24.58, while G was 47.42 ± 19.72. **Conclusion:** The data showed no correlation between the two devices in regards to EE (r-value = -0.194; p-value = 0.456). Our data suggests further research is needed in order to determine which device is more accurate when measuring energy expenditure.

Haematological Response To Altitude And Differentiation From rHuEpo Abuse

Shaun Sutehall. *University of Cape Town, Cape Town, South Africa.* (Sponsor: Yannis Pitsiladis, FACSM)
(No relevant relationships reported)

Injections of recombinant human erythropoietin (rHuEpo) have been shown to increase endurance performance and has been banned by the World Anti-Doping Agency (WADA). Recently a study has identified several gene transcripts differentially expressed after rHuEpo administration (Wang et al, 2017). There is a lack of knowledge on the effect altitude has on these genes and if they can identify rHuEpo abuse from altitude exposure. **Purpose:** The primary aim of this study is to investigate the haematological and transcriptomic changes induced by altitude exposure. The secondary aim of this study is to compare these alterations with those caused by rHuEpo (analysis ongoing). **Methods:** Fourteen endurance trained athletes were recruited, blood samples were taken at sea level, during altitude exposure and after return to sea level. Subjects traveled to Suluta, Ethiopia (~2800 m) for 27 days and provided blood for 27 days on return to sea level. Samples were analysed for haemoglobin concentration (HGB), haematocrit (HCT) and reticulocyte percentage (RET%). **Results:** Compared with baseline, HGB significantly increased 9 days after arrival at altitude (14.1±0.7 vs 15.4±0.7 g dL^{-1}, $P<0.01$) and remained significantly elevated 27 days after return to sea level (14.7±0.7 g dL^{-1}, $P<0.01$). HCT significantly increased upon arrival compared with baseline (41.3±2 vs 43.8±2%, $P<0.01$) and remained significantly elevated 27 days after return (44.6±2%, $P<0.01$). There were no significant differences in RET%. These results show HGB and HCT increased by 14.2% and 13.6% respectively, which is similar to the increase following rHuEpo administration (10.5% and 11.5%, respectively, Wang et al, 2017). **Conclusion:** Following 27 days of altitude exposure, there are significant increases in HGB and HCT but a blunted response in RET%. There appears to be a similar response to altitude exposure and rHuEpo on HGB and HCT, further analysis is required. Ongoing analysis of transcriptomic markers may aid differentiation between altitude and rHuEpo abuse.
This work was supported in part by a grant from WADA.

Validity Of Pushup As Predictor Of Success In Law Enforcement

Paul O. Davis, FACSM. *First Responder Institute, Burtonsville, MD.*
(No relevant relationships reported)

Selection of prospective law enforcement officers can be facilitated with the use of simple, field-expedient fitness tests. Identification of qualified candidates has been demonstrated to significantly reduce costs for work-related injuries.
PURPOSE: Develop a simple, field expedient, pre-hire muscular fitness tool to predict success in effecting an arrest and other essential job functions in the form of a Criterion Task Test (CTT).
METHODS: A Job Task Analysis (JTA) was conducted via survey, on-site observations, and interviews of incumbent federal officers (n=1025) with the objective of creating a surrogate (CTT) for the essential function of foot pursuit and effecting an arrest. Respondents were asked to provide best estimates of distances, heights, and weights associated with critical and arduous tasks.
SUBJECTS: Applicants ($N = 641$, including 55 females (9%)) who presented for employment served as subjects for this study. Because they had received no prior physical screening these subjects represent a sample of applicants that was not range restricted on physical ability. A test for maximum pushups in 2-minutes was administered twice, separated by one day to determine test-retest reliability (intraclass coefficient= 0.95, $p <0.001$, $n = 444$).
RESULTS: Incumbent and supervisory personnel, (n = 77) acting as Subject Matter Experts (SMEs) independently reviewed and rated (acceptable or unacceptable) five representative paces of an actor performing the CTT. The cutpoint for graduation success was established through a consensus model (2/3rd agreement). A two-way contingency table for sensitivity and specificity was developed to demonstrate the predictive power of the 2-minute push-up test. There was no evidence of sex bias for any of the fitness predictors. The ability to perform pushups was highly correlated with success on the CTT (pushups predict 42% of the variance in CTT, $p <0.001$).
CONCLUSIONS: The ability to perform a minimum of 10 push-ups correctly predicted a pass rate of 89% (sensitivity); conversely, failure identified 100% (specificity) of those who failed the CTT.]

Diagnostic Value Of An Impedance-technology Based Health Risk Assessment For Hypertension, Hyperglycemia And Hyperlipidemia

Wang xiaofei[1], Zhu Weimo, FACSM[2], Zhang Bing[1]. *[1]Tsinghua University, Beijing, China. [2]University of Illinois, Urbana, IL.*
(No relevant relationships reported)

PURPOSE: To explore the diagnostic value of an impedance-technology based health risk assessment system (ITHRAS) for hypertension, hyperglycemia and hyperlipidemia, which is an important part of pre-exercise evaluation and assessment.
METHODS: 200 retirees(93 males, 117 females, age = 66.1±5.4 yr.)from Tsinghua University in China were tested using ITHRAS(subjects removed metal articles, took off their shoes and stockings, laying hands and feet on the electrode plate and two electrodes are attached to the head. During the test, the subjects kept quiet and relaxed.), which uses the electrical impedance tomography technology to obtain biomedical information related to human physiological and pathological conditions according to the electrical characteristics of human tissues and organs, their hypertension, hyperglycemia and hyperlipidemia were also tested by sphygmomanometer and blood biochemistry analyzer on the same day. Predictive validity of ITHRAS on hypertension, hyperglycemia and hyperlipidemia was evaluated by chi-square test and ROC curve.
RESULTS: There was no significant difference ($p > .05$) between the true health status and classified by ITHRAS , according to the chi-square tests (see Table 1 for details. The area under ROC curve (AUC) of the system for hypertension, hyperglycemia and hyperlipidemia were 0.947, 0.933, 0.808 (AUC>0.7), respectively. The results indicate that ITHRAS has high predictive validity in terms of the hypertension and hyperglycemia.

Table 1. Statistical Summary of Predictions by ITHRAS

	Hypertension	Hyperglycemia	Hyperlipidemia
True Health Status (%)	38.272	32.099	49.383
Prediction by ITHRAS (%)	40.741	35.802	45.679
Chi-square test (p-value)	0.774	0.629	0.581
ROC (AUC)	0.947	0.933	0.808

CONCLUSION: The predictive validity of ITHRAS in preliminary screening of hypertension and hyperglycemia was confirmed. But the accuracy of hyperlipidemia

detection also needs to be improved. Due to its non-invasive, short detection time, and non-radiation characteristics, ITHRAS should be applicable and welcomed in large-scale hypertension and hyperglycemia status screening.

Determining Consistency And Agreement Of Scores Across Two Measurements Of The Visual System: Test-retest Reliability

Stephanie Long[1], Suzanne Leclerc[2], David Tinjust[3], Russell Steele[1], Tibor Schuster[1], Ian Shrier, FACSM[1]. *[1]McGill University, Montreal, QC, Canada. [2]Institut National du Sport du Quebec, Montreal, QC, Canada. [3]Apexk Inc, Montreal, QC, Canada.*
(No relevant relationships reported)

Some authors have suggested concussion symptoms may be due to subtle visual problems because they are similar to those that occur with difficulty focusing the eyes. Although binocular vision tests (BVTs) are frequently used to evaluate visual symptoms, their reliability has not been evaluated. The 10 BVTs under investigation measure: 3D vision (gross stereoscopic acuity (GSA)), saccades, anatomic deviation (AD) at 30cm and 3m, and the eye's ability to move/focus in-sync [convergence motor punctum proximum (CMPP), binocular fusion with convergence (BFC) and divergence (BFD) at 30cm and 3m, convergence fusional proximum (CFP)]. **PURPOSE**: To determine the one-week test-retest reliability of 10 BVTs in healthy participants. **METHODS**: One clinician examined each participant at their earliest convenience (T1), and one week after their first visit (T2). We assessed test-retest reliability using intraclass correlation coefficient (ICC) and limits of agreement (LoA). We judged an ICC of $\leq$0.5 as poor, 0.51-0.74 as moderate, 0.75-0.89 as good, and $\geq$0.90 as excellent reliability. We present 95% LoA for the % difference i.e. the difference in scores (T1-T2) divided by the average of the scores (T1+T2)/2 times 100. **RESULTS**: We tested 20 participants (1 lost at T2, excluded from analysis). There were 10 males and 10 females with a mean age of 25.5 (SD = 4.0) years. Our ICC results suggest good reliability for AD 3m (0.88), and moderate reliability for GSA (0.62), AD 30cm (0.69), CMPP (0.54), BFC (0.54) and BFD (0.66) at 30cm, and CFP (0.64). There was poor reliability for saccade (0.34), and BFC (0.49) and BFD (0.43) at 3m. LoA was best for saccade ($\pm$34%) and worst for AD 30 cm ($\pm$121%), and ranged from $\pm$58% to $\pm$70% for 7/8 other tests. For AD 3m, LoA ($\pm$200%) did not provide an accurate summary as it assumes a Normal distribution of values. In fact, 18/20 pairs of measurements were identical, one paired scored 0 and 1, the other scored 0 and 2. **CONCLUSIONS**: Our results demonstrate moderate to good test-retest reliability for 7 out of 10 BVTs, and poor reliability for saccades, and BFC and BFD at 3m. LoA results suggest the effect of concussion must have a moderate to large effect on the scores of most of the tests if they are to be clinically helpful.

Hit Or Miss: Kinematic Predictors Of In-game Performance In Collegiate Pitching

Victoria R. Mitchell, William P. Lydon, J. Mark VanNess, John Mayberry, Joey Rossi, Courtney D. Jensen. *University of the Pacific, Stockton, CA.*
(No relevant relationships reported)

Baseball coaches, scouts, and statisticians argue over the variables that lead to a successful season. Among pitchers, earned run average (ERA), strikeouts per inning (SPI), and fielding-independent pitching (FIP) are useful metrics to evaluate the quality of a pitcher. Kinematic predictors of these measurements can provide strength coaches and athletic trainers with valuable information for exercise prescription. **PURPOSE**: To assess kinematic predictors of success in collegiate pitchers via SpartaTrac measurements. **METHODS:** We collected data on 30 Division 1 baseball pitchers. Independent variables were height, weight, year in school, Sparta force plate data (Load, Explode, and Drive), vertical jump, and pitch speed. SpartaTrac data were recorded as the best of six trials and were collected at multiple times throughout a season. Dependent variables were winning percentage, ERA, SPI, and FIP; each of these was calculated as a season statistic. Multiple linear regressions tested the SpartaTrac outputs on dependent performance variables, holding significant confounders constant. **RESULTS**: In our cohort of pitchers, winning percentage was 41.9% $\pm$ 26.2%, ERA was 6.5 $\pm$ 5.1, FIP was 6.0 $\pm$ 3.5, and SPI was 0.8 $\pm$ 0.5. Holding confounding variables constant, predictors of winning percentage were Load (β=0.004; p=0.047), Explode (β=-0.011; p<0.001), and Drive (β=-0.016; p<0.001); the overall model was significant (R2=0.516; p<0.001). Predictors of ERA were Load (β=-0.138; p=0.008) and Explode (β=0.213; p<0.001); the overall model was significant (R2=0.442; p<0.001). Predictors of SPI were Load (β=-0.095; p=0.013), Explode (β=0.267; p<0.001), and Drive (β=0.161; p=0.001); the overall model was significant (R2=0.501; p<0.001). Predictors of SPI were Load (β=0.012; p=0.039) and Explode (β=-0.034; p<0.001); the overall model was significant (R2=0.313; p<0.001). **CONCLUSIONS:** SpartaTrac data correlate with on-field performance of collegiate

pitchers, although the effects are not always encouraging. Out of the four evaluated performance metrics, Load and Explode each improved two and worsened two. Drive improved one, worsened one, and was irrelevant in two. Before coaches, scouts, and trainers can predict how Sparta data affect pitching performance, more analyses must be done on larger pools of pitchers.

Gender Differences In The Association Of Grip Power With Other Physical Strength Among Japanese

Yasushi Sera, Koichiro Azuma, Shiori Horisawa, Shogo Tabata, Masafumi Nagano, Hiroyuki Ishida, Hideo Matsumoto. *KEIO UNIVERSITY SCHOOL OF MEDICINE, Tokyo, Japan.*
(No relevant relationships reported)

Coming super-aging society, grip power has been regarded as a vital sign among older adults, since it can be evaluated with ease and safety and is associated with a lot of health-related consequences. **PURPOSE**: The purpose of the study is to evaluate the association between grip power and more time-consuming assessments of physical strength, especially focusing on the gender differences. METHODS: Among a total of 236 Japanese subjects (F127/M109, 59$\pm$14 yrs, BMI26.2$\pm$5.9), various physical strength including grip power, one foot standing (balance), finger-foot distance (FFD, flexibility), quadriceps muscle strength by hand-held dynamometer, 2 step length (surrogate index for gait speed), and peak oxygen uptake by stress test using gas-analyzer (aerobic fitness), were assessed. Quadriceps muscle strength and 2 step length were expressed as a percentage of body weight, and that of height, respectively. RESULTS: Despite of the similar age (F 59$\pm$14, M 59$\pm$14 yrs) and BMI (F 26.2$\pm$6.6, M 26.3$\pm$5.2), grip power, quadriceps/weight, 2 step/height, and peak oxygen uptake were much lower in women vs men (22.7$\pm$4.8 vs 36.1$\pm$8.7 kg, 44$\pm$13 vs 57$\pm$15 %, 1.37$\pm$0.18 vs 1.45$\pm$0.20, 22.8$\pm$6.1 vs 25.7$\pm$7.6 ml/min.kg, respectively, all p<0.01), whereas FFD was much greater in women vs men (4.1$\pm$10.3 vs -7.3$\pm$12.8 cm, p<0.01). The association of grip power with quadriceps/weight was much stronger in men (r=0.55, p<0.01), while it was not significant in women (r=0.18, ns). Similarly, grip power was associated with other physical strength to a lesser degree in women. This was partly due to negative association between BMI and various physical strength including quadriceps/weight (r=-0.42, p<0.01), only in women, while only grip power was positively associated with BMI (r=0.44 in women, r=0.33 in men, both p<0.01). **CONCLUSION**: Grip power was associated with other physical strength in men, whereas the association was not significant or present to a lesser degree in women, partly due to declined physical strength except grip power with increasing BMI.

The Validity Of Age-based Maximal Heart Rate Equations In Youth: A Systematic Review And Meta-analysis

Zackary S. Cicone, Clifton J. Holmes, Michael V. Fedewa, Haley V. MacDonald, Michael R. Esco, FACSM. *University of Alabama, Tuscaloosa, AL.*
(No relevant relationships reported)

Maximal heart rate (MHR) is an important physiological reference for prescribing and monitoring exercise in both clinical and sports settings. Because obtaining a true MHR via graded exercise test (GXT) is often impractical or undesirable, equations are used to predict MHR from age. Unfortunately, these equations were developed in adult populations, potentially limiting their applicability to youth populations. **PURPOSE:** The primary aim of this systematic review and meta-analysis was to examine the validity of age-based MHR prediction equations in children and adolescents. **METHODS:** Included studies were peer-reviewed, published in English, and compared measured MHR to predicted MHR using the Fox and/or Tanaka equations in participants <18 years of age. The difference between measured and predicted MHR was assessed using Hedges' d effect size (ES) to adjust for small sample bias, and random-effects models were used to calculate the mean ES and explore potential moderators. **RESULTS:** Six articles published between 2011 and 2015 met our inclusion criteria. The cumulative results of 18 effects indicated that MHR prediction equations may not be accurate in children and adolescents (ES = 0.7317, 95% CI 0.2967 to 1.1666). Post-hoc analyses indicated that the Fox equation (MHR = 220 - age) overestimated MHR by roughly 12.933 BPM, (k = 11, ES = 1.4131, 95% CI 1.1035 to 1.7227), and the Tanaka equation (MHR = 207 - 0.7*age) underestimated MHR by roughly 2.0999 BPM (k = 7, ES = -0.3850, 95% CI -0.7578 to -0.0122). **CONCLUSIONS:** The Tanaka equation resulted in smaller mean differences between measured and predicted MHR than the Fox equation. However, neither equation accounted for the large range in variability of MHR between subjects, which suggests that age may not be the only predictor of MHR in younger populations. Caution should be exercised when using these equations for prescribing and monitoring exercise intensity in children and adolescents.

Effect of Cold Water Immersion versus Phase Change Material Cooling On Core and Intramuscular Temperature

Susan Y. Kwiecien[1], Malachy P. McHugh, FACSM[1], Stuart Goodall[2], Kirsty M. Hicks[2], Angus M. Hunter[3], Glyn Howatson, FACSM[2]. *[1]Lenox Hill Hospital, New York, NY. [2]Northumbria University, Newcastle upon Tyne, United Kingdom. [3]University of Stirling, Scotland, United Kingdom.* (Sponsor: Malachy P. McHugh, FACSM)

(No relevant relationships reported)

PURPOSE: Lowering intramuscular temperature is thought to enhance recovery from strenuous exercise. Cold water immersion (CWI) is a popular form of cryotherapy but is limited by a short treatment duration due to safety considerations and the impracticality of repeated treatments. Phase change material (PCM) cooling packs fitted in wearable garments can provide prolonged post-exercise cooling that facilitates recovery without safety concerns; however, the efficacy of PCM cooling on body temperature is not clear. To compare intramuscular and core temperature changes with CWI versus PCM cooling treatments.
METHODS: In a randomized crossover design, 11 male subjects (27 ± 6 y, 184 ± 9 cm, 81 ± 12 kg) wore compression shorts fitted with either $15°C$ PCM cooling packs, covering the quadriceps for 3 h (PCM treatment) or were immersed to the iliac crest in a temperature regulated water bath maintained at $15\pm1°C$ for 15 min (CWI treatment). Vastus lateralis intramuscular temperature (at 1 and 3 cm) and core temperature were recorded during, and for 2 h after CWI, and for 3 h during, and 1 h after PCM cooling. Treatment effects were assessed using time by treatment repeated measures ANOVA.
RESULTS: Intramuscular temperature was decreased ($p<0.001$) with both CWI and PCM, with initially greater effects with CWI, and ultimately greater effects with PCM (Treatment by Time $P<0.0001$; Fig. 1). Core temperature was reduced with PCM and CWI treatments ($p<0.001$; $-0.23°C$ 30 min post CWI, $-0.19°C$ 2 h post CWI; $-0.16°C$ at 2 h post PCM application, $-0.24°C$ 1 h post PCM removal) with no difference between treatments. **CONCLUSIONS**: The PCM cooling provided substantial, prolonged, muscle cooling ($<30°C$ for 2.5 h at 3 cm and for 3.5 h at 1 cm) that was well tolerated, and compared very favorably to CWI ($<30°C$ for 0.75 h at 3 cm and 1.25 h at 1 cm). PCM cooling garments provide a practical means of delivering prolonged cooling to the musculature.

Vastus Lateralis Intramuscular Temperature

Validity Of A High Incline Vo$_2$max Walk Test

David E. Lankford, FACSM, Alexis D. Gidley, Nate Lewis, Keegan Huntsman, Tyler Hook, Cody Pexton, Haley Dimond, Justin Harris. *Brigham Young University Idaho, Rexburg, ID.*

Reported Relationships: D.E. Lankford: *Consulting Fee; Icon Health and Fitness.*

PURPOSE: The purpose of this study was to validate two high incline graded exercise VO$_2$max tests designed for individuals not accustomed to running on a treadmill. **METHODS**: Participants consisted of 31 (18 men, 13 women) individuals aged 18-29 yrs. All participants completed a Bruce Protocol VO$_2$max test as well as two high incline graded exercise tests in a randomized order. The high incline VO$_2$max tests were performed at a constant speed of 3.6 mph and increased in incline 5% every 3-minutes until volitional exhaustion. The difference between the two high incline protocols (5-5, 10-5) was the starting incline following a 30-second warmup. The first stage of the 5-5 test was 5% grade and the first stage of the 10-5 test was 10% grade. A 1x3 repeated measures ANOVA was used to compare VO$_2$max data between tests. Pearson Correlation and Bland-Altman plots were used to analyze relationships between the two high incline tests (5-5, 10-5) and the Bruce Protocol individually.

RESULTS: There were no differences in VO$_2$max between tests (Bruce= 46.9 ± 7.7, 5-5= 45.7 ± 7.9, 10-5= 44.7 ± 78.3, p = 0.51). VO$_2$max of the Bruce Protocol was strongly related to both 5-5 (r= 0.96) and 10-5 (r= 0.90) tests. Bland-Altman plots between 5-5 test and the Bruce Protocol revealed 93% of data falls within ± 4.5ml*kg^{-1}*min^{-1} and 100% fall within 5ml*kg^{-1}*min^{-1}. **CONCLUSIONS**: These results suggest that both the 5-5, and 10-5 tests are valid alternatives to the Bruce Protocol. Additionally, these results demonstrate that a non-running VO$_2$max test is effective in determining VO$_2$max in a healthy population.

Validity of Heart Rate Measurements for the Apple Watch and Fitbit Charge HR 2

Elizabeth Thomson. *Colorado State University, Fort Collins, CO.*

(No relevant relationships reported)

Abstract:
Only a few studies have examined the validity of heart rate (HR) measurements for the Apple Watch and Fitbit Charge HR devices. **PURPOSE**: This study examined the validity of heart rate measurements for the Fitbit Charge HR 2 (Fitbit) and the Apple Watch devices. **METHODS**: Thirty young adults (15 females, 15 males, age 23.5 ± 3.0) completed the Bruce Protocol while HR measurements were recorded from the electrocardiogram (ECG) and each device every minute. Average HR for each participant was calculated for very light, light, moderate, vigorous and very vigorous intensities based on ECG-measured HR. A concordance correlation coefficient (CCC, r_c) was conducted to examine the strength of the relationship between the ECG measured HR and the device measured HR. Relative error rates (RER) were calculated to indicate the difference in HR measurement between each device and ECG. **RESULTS**: The HR from the Apple Watch was significantly lower compared to the ECG HR (122.78 ± 13.40 vs. 128.83 ± 9.46 BPM, P<.01) for moderate intensity. For very vigorous intensity, the Apple Watch HR was significantly lower compared to the ECG HR for females (174.47 ± 8.79 vs. 180.3 ± 9.13 BPM, P<.05). The HR measured by the Fitbit Charge HR 2 was significantly lower compared to the ECG measured HR for light intensity (100.25 ± 6.93 vs. 104.24 ± 9.09 BPM, P<.01), for moderate intensity (116.66 ± 23.74 vs 127.79 ± 10.27 BPM, P<.01), for vigorous intensity for males (143.00 ± 13.61 vs 159.39 ± 9.58 BPM, P<.001) and for females (137.24 ± 18.86 vs 155.11 ± 9.86 BPM, P<.05) and for very vigorous intensity (157.47 ± 15.44 vs 181.35 ± 9.44 BPM, P<.001). The Apple Watch also showed lower RER (2.4%-5.1%) compared with the Fitbit (3.9%-13.5%) for all exercise intensities. For both devices, the strongest relationship between the device measured HR and the ECG measured HR was found for very light intensity with a very high CCC (r_c>.90). The strength of the relationship declined as exercise intensity increased for both the Apple Watch and the Fitbit. **CONCLUSION**: Our study indicated an inverse association between exercise intensity and HR measurement accuracy for the Apple Watch and the Fitbit Charge HR 2. The Apple Watch revealed lower error rates for all exercise intensities compared to the Fitbit Charge HR 2.

Wingate Test-Retest Variability in Healthy Subjects

Emily L. Roessel, Evelyn N. Delgado, Megan L. Darling, Nathaniel J. Holmgren, Courtney D. Jensen, J. Mark VanNess. *University of the Pacific, Stockton, CA.*

(No relevant relationships reported)

Learning effects, biological changes, and motivation contribute to variability in performance on standardized exercise tests. Performance improvement on short-duration, high-intensity tests, such as a 30-second Wingate test of anaerobic power, may be more sensitive to motivational and learning changes in novice, healthy subjects. **PURPOSE**: To examine performance changes during serial Wingate tests in healthy college-age students. **METHODS**: Twenty college students were recruited to do three 30-second Wingate tests over three days. They were given identical instructions before each test. Sleep and nutrition were controlled. Standard Wingate parameters were collected. Multivariate analysis was used to examine changes in performance parameters; data are highlighted for the singular variable: peak power. **RESULTS**: Eighteen subjects completed all three tests. The overall multivariate analysis for test number was not significant, and there were no significant differences across test days for peak power, power decline, average power, minimum power, power at max speed, or total energy expended. For peak power; averages for test 1 (1.72 ± 0.31 W/kg), test 2 (1.74 ± 0.28 W/kg), and test 3 (1.79 ± 0.32 W/kg) were similar, but examination of percent changes in performances illustrates why results appear homogenous. Thirteen of the subjects improved their performance with repeated trials. The average improvement in peak power for those subjects was 9.8 ± 5.2%. Five subjects had performance declines from the first trial of 4.9 ± 3.9%. One subject had no change in performance. **CONCLUSION**: The fluctuation from zero to as high as 22% illustrates high variability of these power measurements (power decline ranged as much as 97% within one subject). This degree of variability is well outside

what would normally be expected for biological variation and could be construed as problems with equipment calibration. Without application of criteria for subject effort, such as applied to cardiopulmonary exercise testing, it is difficult to make objective intra-group or intra-subject comparisons for Wingate testing.

Bilateral Deficit: A Comparison Of Maximal Strength Between The Bilateral And Unilateral Leg Press Exercise

James L. Ramsey[1], Justin Burley[2], Shel Levine[2], John W. Carbone[2], Rebecca W. Moore[2]. [1]*Eastern Michigan University, Ypsilanti, MI.* [2]*Eastern Michigan University, Ypsilanti, 48197, MI.* (Sponsor: Lanay Mudd, FACSM)
(No relevant relationships reported)

The bilateral deficit (BLD) is a phenomenon in which the maximal strength of both limbs contracting simultaneously is less than the sum of the weight lifted by each limb contracting in isolation. The connection between the BLD and how it influences performance is unknown.
Purpose: To determine if the BLD is present during a dynamic leg press in trained participants. **Methods:** Thirty volunteers (19 male, 11 female; 19-37 years old) reported to the EMU Running Science Laboratory on three separate occasions 72 hours apart. On day 1, participants performed a movement screening consisting of 8-10 repetitions at 30% of one repetition maximum (1RM) for both the bilateral and unilateral dynamic leg press training conditions to ensure that all exercises were safely performed. On day 2, participants were randomly assigned to either the maximal bilateral or maximal unilateral condition. For both conditions, participants performed 6-8 repetitions at 50%1RM, followed by a single repetition at 70% of 1RM. Afterwards, the amount of weight lifted was increased by 10% between each successful lift to ensure standardization. This process continued until participants could no longer increase weight for either testing condition. On day 3, participants completed whichever condition, maximal bilateral or maximal unilateral, that was not completed on day 2 following the same procedures. A paired samples t-test was conducted to determine if there was a significant difference between the maximal bilateral condition and the sum of the left and right maximal unilateral conditions ($p<0.05$).
Results: The 30 participants were 22.96 ± 3.72 years old, had a height of 170.1 ± 9.3 cm, and weighed 73.7 ± 11.50 kg. A significant difference was observed and the maximal strength was greater for the bilateral condition (495 ± 209 lbs) compared to the unilateral condition (387.7 ± 208 lbs). **Conclusion:** A BLD was not observed in this study. Research suggests that the BLD is associated with unilateral training while bilateral training reduces the phenomenon. The participants in this study reported the consistent use of bilateral training, which may explain the lack of BLD. Future investigations are necessary to determine how various resistance training protocols influence the BLD.

Inter-individual Variability in Metabolic and Neuromuscular Responses During Continuous Exercise Above and Below Critical Power

Haley C. Bergstrom[1], Terry J. Housh, FACSM[2], Kristen C. Cochrane-Snyman[3], Nathaniel D.M. Jenkins[4], M. Travis Byrd[1], Taylor K. Dinyer[1], Richard J. Schmidt[2], Glen O. Johnson, FACSM[2]. [1]*University of Kentucky, Lexington, KY.* [2]*University of Nebraska, Lincoln, NE.* [3]*California State University-Fresno, Fresno, CA.* [4]*Oklahoma State University, Stillwater, OK.*
Reported Relationships: H.C. Bergstrom: *Honoraria; GNC talk at the NSCA national conference.*

Theoretically, critical power (CP) reflects the demarcation of the heavy and severe exercise intensity domains, which are defined by distinct metabolic responses and motor control strategies. **PURPOSE:** This study examined the metabolic (oxygen consumption rate [VO_2]) and neuromuscular (electromyographic amplitude [EMG AMP]) responses during exercise above and below CP. **METHODS:** Six women and six men (mean $\pm$ SD age: 21 ± 2 year) performed a graded exercise test to exhaustion (GXT) to determine the VO_{2peak} and peak power output (W_{peak}). During separate visits, CP was determined from the 3-min all-out test followed by two, randomly ordered, rides to exhaustion at CP minus 10% ($CP_{-10\%}$) and CP plus 10% ($CP_{+10\%}$). The VO_2 and EMG AMP (measured from the vastus lateralis) as well as times to exhaustion (T_{lim}) were recorded during the GXT and continuous rides. The VO_2 at exhaustion from the $CP_{-10\%}$ and $CP_{+10\%}$ rides were compared with VO_{2peak} using a one-way repeated measures ANOVA and follow-up pairwise comparisons ($p < 0.05$). Linear regression was used to examine the individual VO_2 and EMG amplitude responses after the first 3 min to T_{lim}. **RESULTS:** The $CP_{-10\%}$ ($74\%W_{peak}$) and $CP_{+10\%}$ (90% W_{peak}) rides resulted in T_{lim} of 24.61 ± 9.29 min (range = 15.02 - 38.87 min) and 7.67 ± 4.08 (range = 3.65 - 15.57 min), respectively. The mean VO_2 at exhaustion for $CP_{-10\%}$ (3.086 ± 0.995 L·min⁻¹), but not $CP_{+10\%}$ (3.511 ± 1.170 L·min⁻¹), was significantly lower than O_{2peak} (3.488 ± 1.060 L·min⁻¹). Two of the 12 subjects at $CP_{-10\%}$ and 9 of the 12 subjects at

$CP_{+10\%}$ reached VO_{2peak} at exhaustion. The VO_2 increased for all 12 of the subjects from 3 min to T_{lim} at $CP_{-10\%}$ and for 9 of the 12 subjects at $CP_{+10\%}$. At $CP_{+10\%}$, there was no change over time for 3 of the 12 subjects and the VO_2 was maintained within 3% of VO_{2peak}. The EMG AMP increased for 6, decreased for 4, and did not change for 2 of the 12 subjects at $CP_{-10\%}$. At $CP_{+10\%}$, the EMG AMP increased for 6 and did not change for 6 of the 12 subjects. **CONCLUSION:** These findings suggested CP does not demarcate the heavy from severe exercise intensity domains for all subjects as ~17% of subjects reached VO_{2peak} at $CP_{-10\%}$. In addition, the EMG AMP suggested there was individual variability in motor control strategies (i.e., muscle activation) above and below CP and EMG AMP was dissociated from VO_2 for 50% of the subjects at both intensities.

Relationship Of %HRmax And %VO$_2$Max For Running And Cycling In Trained Triathletes

ILIAS ZACHAROGIANNIS, Paradisis Georgios, Papavasiliou Thomas, Poulos Stellios, Pilianidis Theofilos, Zacharogianni Aggeliki. *National and Kapodistrian University of Athens, ATHENS, Greece.*
(No relevant relationships reported)

Since relative maximum heart rate (%HRmax) correlates highly ($r\geq0.98$) with relative maximum oxygen uptake (%VO$_2$max) for all modes of exercise (cycling, running, swimming, kayaking, rowing) it can be used by athletes and coaches to accurately determine the usage of certain %VO$_2$max for training and racing purposes by knowing only the value of HRmax. The effect of equal cycle and running training (Triathlon) on the relationships of the %HRmax with %VO$_2$max for cycle and running exercise is not clear. PURPOSE: The purpose of this study was to examine the relationships among %HRmax and %VO2max in trained triathletes during running and cycling exercise. METHODS: Sixteen male trained triathletes (33.2 ± 4.3 yr 78.61 ± 3.42 kg, 12.6 ± 1.8 % body fat) performed an incremental maximal exercise test to exhaustion on cycle ergometer (30-watt increment 3min stages) and on a treadmill (1km.h⁻¹ increment 3min stages) with 3-4 days apart. Individual linear regressions based on HR and VO_2 values measured of each stage and maximum, were used to calculate slopes and intercepts, to predict %VO$_2$max from %HRmax, for given exercise intensities (50, 60, 70, 80, 90 and 100%HRmax). RESULTS: Mean prediction $\pm$ sd of the %VO$_2$max from %HRmax was significantly higher ($p<0.01$) during running compared to cycling exercise from 50-80%HRmax (50%: 32.03 ± 7.46 v 19.77 ± 6.75 ; 60%: 45.18 ± 5.85 v 35.80 ± 5.65; 70%: 58.53 ± 4.37 v 51.65 ± 4.54; 80%: 71.59 ± 3.03 v 67.45 ± 4.07). The prediction of the running %VO$_2$max was significantly ($p<0.01$) overestimated at 50, 60, 70 and 80% HRmax by 62.0, 26.2, 13.3 and 6.1% respectively compared to cycling. The regression equations are: Run%VO$_2$max = 0.738*%HRmax + 26.67 and Cycle%VO$_2$max = 0.620*%HRmax + 37.85 (R^2=0.99). Mean %VO$_2$max corresponding with 90 and 100%HRmax was not different ($p>0.05$) between exercise modes. CONCLUSIONS: For submaximal (<90%HRmax) exercise intensities during running and cycling the use of the above regression equations may produce reasonably accurate exercise intensity for training and racing purposes and help athletes better quantify training stimuli, stress and adaptations.

The Creation of Effective Standardized Instructions for a Novel Flexibility Test

Mark G. Cullum, Justin R. Bland, Kenneth R. Turley, FACSM. *Harding University, Searcy, AR.* (Sponsor: Kenneth R. Turley, FACSM)
(No relevant relationships reported)

Previous research has demonstrated the validity and reliability of a new test of hip and lower back flexibility that can be performed with minimal equipment.
PURPOSE: This study's purpose was to determine if an individual could perform the test correctly using only standardized instructions.
METHODS: 44 college age subjects attempted to perform the test procedures correctly, followed by a measurement by a trained technician. Based on the results, changes were made to the instructions to account for the most common errors. 45 new subjects then completed the revised procedures to the best of their ability, followed again by a measurement by a technician. The results of the individuals were compared to those of the technician by Pearson correlation and a Paired T-test.
RESULTS: For both groups, when the values of the individuals who performed the test correctly were compared to the technician's values, a very high correlation was found ($r=0.969$ for group 1, $r=0.868$ for group 2). The technician's scores tended to indicate greater flexibility, with a significant difference found for the first group ($p<0.01$ for group 1, $p=0.095$ for group 2). This was expected, as the technician's measurements were always made after the individual's effort, and with repeated stretches flexibility tended to improve. A noticeable number of subjects in the first group made an error (21 of 44 subjects), primarily mathematical in nature. When the instructions were revised, the mathematical error did occur less frequently, though overall more errors occurred (28 of 45), primarily not performing the procedure three

times. In some cases a mistake led to minimal error (e.g. performing the procedure only once), while in other cases the error completely invalidated the results (e.g. bending the knees). As expected, when all subjects were analyzed, significant differences (p<0.01 for groups 1 and 2) and poor correlations (r=0.265 and r=0.288 for groups 1 and 2, respectively) were found.

CONCLUSION: When performed correctly, individuals can obtain a score on the new test comparable to that of a trained technician. The study also demonstrates, however, that great care must be taken by both a test developer in the creation of instructions for a protocol, and by the test administrator in reading and adhering to the standardized instructions for a protocol.

Ramp Incremental Cycling Protocol Underpredicts VO$_{2max}$ in Sedentary Normal-Weight and Overweight/Obese Adults

Avigdor D. Arad[1], Kaitlyn Bishop[1], Peter Adintori[1], Deena Adimoolam[1], Jeanine B. Albu[1], Fred J. DiMenna[2]. *[1]ICAHN School of Medicine at Mount Sinai, Mount Sinai Hospital, New York, NY. [2]Teachers College Columbia University, New York, NY.*
(No relevant relationships reported)

The maximum rate of oxygen consumption (VO$_{2max}$) is the gold-standard index for assessing cardiorespiratory fitness. The presence of a VO$_2$/work-rate plateau at the highest work rates during incremental testing represents the primary way to confirm that a "true VO$_{2max}$" was attained; however, such a plateau is often lacking. Instead, VO$_{2max}$ is often confirmed using "secondary criteria" based on arbitrarily-determined values for heart rate, RPE, RER and/or blood-lactate concentration. A constant-work-rate "verification bout" can also confirm VO$_{2max}$; however, support for this practice comes predominantly from studies performed on recreationally-active/athletic populations. **PURPOSE:** To compare the peak VO$_2$ responses from an incremental and verification bout in sedentary normal and overweight/obese adults. **METHODS:** Twenty-eight sedentary, but otherwise healthy normal-weight (*n*=15; BMI, 22.6±1.4 kg/m^2) or overweight/obese (*n*=13; BMI, 31.3±2.9 kg/m^2) subjects (male/female, *n*=15/13; age, 28.1±4.9 years) performed a "ramp" incremental cycling test (15-20 W·min^{-1}) to limit of tolerance on a lower-body ergometer followed (10 minutes) by constant-work-rate cycling to limit of tolerance at the highest work rate attained. **RESULTS:** Intraclass correlation coefficient (.980) and coefficient of variation (4.64±3.69%) indicate good reliability for peak VO$_2$ measurement across protocols; however, the value was significantly higher during the verification bout (2.19±0.57 vs. 2.10±0.56 L/min; p=0.001) with 18 of 28 subjects demonstrating a value ≥ 2% above that derived from incremental testing. This implies that incremental testing does not reveal a true VO$_{2max}$ for a substantial proportion of these subjects. However, the peak incremental response would have been accepted as VO$_{2max}$ in all but eight subjects if the method often used (i.e., attainment of two of three criteria based on heart rate, RPE and RER) was employed. Indeed, despite the lower peak VO$_2$ response, peak heart rate and RPE were not lower for the incremental bout while peak RER was higher (1.23±0.09 vs. 1.18±0.09; p=0.003). **CONCLUSION:** The ramp incremental protocol revealed an underprediction of VO$_{2max}$ in normal and overweight/obese sedentary adults. Use of secondary criteria resulted in false VO$_{2max}$ acceptance in 32% of subjects.

Ultrasonic Device as a Novel Method for Assessing Muscular Power During Vertical Jump

Mario Leone[1], Maxime Allisse[1], Patrick Desjardins[1], Alain Steve Comtois[2], Hung Tien Bui[1]. *[1]University of Quebec in Chicoutimi, Chicoutimi, QC, Canada. [2]University of Quebec in Montreal, Montreal, QC, Canada.*
(No relevant relationships reported)

Purpose: Vertical jump can be assessed using a number of different methods including the Sargent jump, a force platform and methods based on the time-of-flight. The Sargent jump has the advantage of being simple and inexpensive, but is known to lack precision. The force platform is the most accurate method but is very costly. The methods based on time-of-flight offer a good compromise but are dependent on the take-off and landing positions. To alleviate this constraint, we propose a novel method of assessing vertical jump height using a low cost ultrasonic ranging technology. The proposed method consists of placing the system on the ceiling and continuously measuring the distance to the closest body part (head). The purpose of this study is to demonstrate the proposed principle and determine its validity. **Methods:** The validity of the device was tested both in a static and a dynamic context. Static tests were performed by placing the ultrasonic sensor at 10 known distances from the top of the participant's head, ranging from 20cm to 110cm. Average and maximum errors were calculated. In the dynamic portion of the test, a participant was asked to perform 5 test jumps and to land in the same position as the one during take-off. The height of each jump was evaluated using both a time-of-flight device and the proposed method. The measurements from both devices were compared using the Student t-test for repeated measures. **Results:** No significant differences were observed between the proposed

method (22.1±3.1 cm) and the time-of-flight method (22.6±3.1 cm). The correlation coefficient was excellent between the two types of measurement systems (r=0.97). **Conclusion:** The proposed device is not sensitive to the landing position (biggest drawback of the time-of-flight system). The main difficulty of the proposed device is to ensure that the participant remains in the area covered by the ultrasonic beam. Indeed, if the participant has a large horizontal displacement during the jump, it may provide incorrect measurements. A possible solution could be to perform a 2nd order polynomial curve-fitting in order to filter erroneous data. The proposed device is an excellent alternative to evaluate vertical muscular power. In addition to being low cost, the proposed device does not suffer from the drawbacks associated to time-of-flight methods.

Comparison of Physiological Stress in Two Different Step Test Exercise Protocols in Elderly People.

Lutz Baumgärtel, Martin Weigert, Nico Nitzsche, Christiane Lösch, Henry Schulz. *Chemnitz University of Technology, Chemnitz, Germany.*
(No relevant relationships reported)

Step tests are a simple and cost-effective method for determining cardiorespiratory performance. To estimate the maximum oxygen uptake in multi stage step tests, the linear relationship between workload, submaximal exercise heart rate (HR) and oxygen uptake (VO$_2$) based on the ACSM´s stair-stepping equation is used. Increasing the workload in multi-stage step tests is usually carried out by increasing the stepping frequency. Due to impairments, changing the stepping frequency can be a problem for elderly people.
PURPOSE
To examine whether an increase by the step height, representing the same physical performance like an increasing stepping frequency, lead to similar physiological responses in elderly people.
METHODS
33 elderly volunteers without cardiovascular diseases (67 ± 5 years, 170 ± 10 cm, 76 ± 15 kg) underwent two different step test protocols with five stages, in a randomized order. In protocol 1 (P1), the step height was constant at 25 cm. The load was increased by the climbing frequency (5 steps per minute (spm), every two minutes, from 10 to 30 spm). In protocol 2 (P2), the load was increased by the step height (5 cm, every two minutes, from 10 to 30 cm) at a constant stepping frequency of 25 spm. HR, VO$_2$, blood lactate (La) and evaluation of perceived exertion (RPE) was recorded before (T$_{Rest}$), at the end of each stage (T$_1$ - T$_5$) and three minutes afterwards (T$_{Recovery}$). For comparison of the differences, the root mean square error (RMSE) was calculated.
RESULTS
All five stages were achieved by 27 probands, five probands aborted at stage four and one at stage three. Between the protocols, the RMSE of the HR differed from 5.7 to 7.8 bpm independently of measuring time point. The lowest deviations of La were found in T$_{Rest}$, T$_1$, T$_2$ and T$_4$ (0.23 - 0.38 mmol/l), the highest differences were found in T$_3$, T$_5$, and T$_{Recovery}$ with 0.52 - 0.66 mmol/l. The VO$_2$ differs about 0.9 - 2.3 ml/min/kg, with the highest amount in T$_5$. RPE was significantly higher at T$_2$ in P2 (Wilcoxon p<0.05).
CONCLUSION
The measured differences are close to the expected day by day variations in step tests. Despite the modest differences in the protocols, both are suitable for practical application in elderly people. Considering the differences in HR between the protocols, an adaptation of the maximum oxygen uptake estimation could be necessary.

The Reliability of the Anaerobic Dummy Throw Test in High School Wrestlers: A Pilot Study

Eric Lopez[1], Abigail Larson[1], Ryan Luke[2], Chad Harris, FACSM[3], Kent J. Adams, FACSM[2], Mark DeBeliso, FACSM[1]. *[1]Southern Utah University, Cedar City, UT. [2]California State University Monterey Bay, Seaside, CA. [3]Metropolitan State University of Denver, Denver, CO.* (Sponsor: Mark DeBeliso, FACSM)
(No relevant relationships reported)

Anaerobic power (AP) output is an important physical characteristic that is required to succeed in sports such as wrestling. The Wingate test is considered the Gold Standard for assessing AP but is not specific to the sport of wrestling. **PURPOSE:** The purpose of this study was to examine the reliability of a novel field test known as the Lopez Dummy Throw Test (LDTT) for the assessment of AP. **METHODS:** The participants were male high school wrestlers (n=10: age: 17.0±0.8 yrs, mass: 70.9±10.2 kgs). The participants met on one occasion in order to complete the testing protocol. The protocol initiated with the participants completing a 10-15 minute dynamic warm-up (WU) that included three practice dummy throw attempts (dummy mass=31.75 kgs). Following the dynamic WU (≈5 minutes), the participants performed two trials of the LDTT. In order to perform the LDTT, wrestlers stood behind the wrestling dummy in a low squat position with legs bent at 90 degrees. Next the wrestlers wrapped their arms

Abstracts were prepared by the authors and printed as submitted.

around the waist of the dummy and on the signal "go" the wrestlers quickly exploded up, lifting the dummy by getting triple extension with the ankles, knees and hips as one would in a power clean. After the wrestler was fully extended, he turned in midair in order to drive the dummy onto its stomach on the ground, where the wrestler was on top of the back of the dummy (a common position after an opponent has been thrown). The participant then repositioned the dummy to the original position to execute another throw. The participants completed as many dummy throws as possible during the one minute trials. The LDTT trials were separated by 15 minutes. **RESULTS:** The trial scores were 15.6±2.5 and 17.2±1.5 throws respectively. The interclass and intraclass reliability coefficients were r=0.84 and ICC=0.80. The standard error of the measure was SE_m=1.0 throws with 90% confidence limits of U_L: 1.7, L_L: 0.7. The mean difference between trials was 1.6±1.4 throws (90% confidence limits of U_L: 2.4, L_L: 0.8). Bland-Altman plots suggested agreement between trials with no evidence of heteroscedasticity. **CONCLUSION:** The LDTT exhibits moderate to high reliability as an assessment of AP. The inclusion of additional dummy throw trials to the assessment protocol may enhance the degree of reliability of the dummy throw test as a measure of AP.

2746 Board #29 June 1 2:00 PM - 3:30 PM

Test-retest Reliability of Velocity Assessments for Free Weight and Machine Exercises

Karolina J. Koziol, Ryan M. Miller, Eduardo D. S. Freitas, Aaron D. Heishman, Japneet Kaur, Michael G. Bemben, FACSM. *The University of Oklahoma, Norman, OK.* (Sponsor: Dr. Michael G. Bemben, FACSM)

(No relevant relationships reported)

Muscular power is the rate at which work can be performed and is evaluated by obtaining velocity measurements. Currently, there are several devices available to measure muscular power through velocity measurements, including the Tendo Fitrodyne Sports Power Analyzer (Tendo Sports Machines, Slovakia). However, the ability for such devices to produce consistent results is still questioned. Additionally, the reproducibility of measurement between free weight and machine exercises has yet to be examined. **PURPOSE:** To determine the test-retest reliability of peak velocity during barbell bench press and leg press exercises at 20-80% of one repetition maximum (1RM). **METHODS:** Fifteen men (height 183.1 ± 10.0 cm; weight 85.3 ± 12.4 kg) and fifteen women (height 169.6 ± 7.0 cm and weight 68.9 ± 7.7 kg) performed 1RM testing for the bench press and leg press (total n = 30, $\bar{x}$ leg press = 189.5 ± 49 kg and bench press 66.8 ± 32.4 kg; females n = 15, $\bar{x}$ leg press = 163.2 ± 33.3 kg and bench press = 40.9 ± 13.8 kg; males n = 15, $\bar{x}$ leg press = 206.3 ± 53.6 kg and bench press = 90.2 ± 30.5 kg). Following at least 48 hours, each subject returned to perform one repetition at 20, 30, 40, 50, 60, 70, and 80% of their 1RM for each exercise, in randomized order with the Tendo Unit attached to each device. To determine test-retest reliability, the subjects returned to the lab one week later to perform the velocity assessment again at each intensity, in randomized order. **RESULTS:** The test-retest intraclass correlation coefficients (ICC) at each percentage of 1RM, averaged across all subjects were 0.982, 0.951, 0.892, 0.884, 0.722, 0.638 and 0.777 for leg press and 0.935, 0.945, 0.981, 0.981, 0.970, 0.952 and 0.816 for the bench press. When reliability was assessed based on gender, the average ICC for leg press and bench press was 0.816 and 0.689 for females and 0.832 and 0.745 for males, respectively. **CONCLUSION:** The findings from this study found stronger correlation coefficients for lower percentages of 1RM (20-60%) compared to higher loads (70-80% 1RM), especially for the leg press compared to the bench press. Additionally, males had slightly stronger test-retest correlations compared to the females.

2747 Board #30 June 1 2:00 PM - 3:30 PM

Development and Validation of an Equation to Estimate Peak Power from Vertical Jump in Youth

Matthew T. Mahar, FACSM[1], Gregory J. Welk, FACSM[2], Patrick M. Rider[3], Michael J. Duncan[4]. *[1]San Diego State University, San Diego, CA. [2]Iowa State University, Ames, IA. [3]East Carolina University, Greenville, NC. [4]Coventry University, Coventry, United Kingdom.*

(No relevant relationships reported)

Lower body muscular power is related to bone density in youth and is therefore a component of health-related physical fitness. **PURPOSE**: To develop and validate an equation to estimate peak power from vertical jump performance, body mass, age, and sex. **METHODS**: Peak power (PP) and vertical jump (VJ) were assessed on 217 youth between the ages of 9 and 18 years (mean = 14.5 ± 2.5 years). Two samples were combined for analyses. In one sample VJ was assessed with a Vertec and PP was assessed with a triaxial force plate. In the other sample, PP and VJ were assessed with a Quattro Jump Portable Force Platform System. Participants performed three maximal effort countermovement jumps. The highest of the three trials was used for statistical analyses. Multiple regression analysis was used to develop an equation to predict PP on a random sample of two-thirds of participants (n = 145). The resulting equation was cross-validated on the remaining one-third (n = 72). Two previously published equations were also cross-validated for comparison. Paired t-tests, effect size estimates, and regression were used to quantify the relationships between measured and estimated PP. **RESULTS**: Results from the validation sample indicated that estimates of PP from VJ and body mass were accurate (R = .95, SEE = 405 W). Age and sex did not add substantially to the model. Upon cross-validation, accuracy was maintained (R = .96, SEE = 429 W) and similar to previously published equations from Sayers et al. (R = .95, SEE = 490 W) and Duncan et al. (R = .95, SEE = 458 W). A small mean bias was observed for the Sayers et al. (p = .04, ES = 0.08) and Duncan et al. (p < .01, ES = 0.15) equations, but not for the new equation (p = .98, ES = 0.00). **CONCLUSIONS**: The following equation developed on the entire sample (N = 217) can be used to estimate PP: Watts = -1613.26 + (59.54 * VJ [cm]) + (34.89 * body mass [kg]), R = .95, SEE = 414 W. This equation was developed on youth participants and can be considered for use by teachers and practitioners in field-based settings where measurement of PP from a force platform is not available.

2748 Board #31 June 1 2:00 PM - 3:30 PM

Countermovement Jump Reliability when Performed With and Without an Arm Swing in NCAA Division 1 Basketball Players

Aaron D. Heishman, Ryan M. Miller, Eduardo D.S. Freitas, Japneet Kaur, Bianca A.R. Galletti, Karolina J. Koziol, Michael G. Bemben, FACSM. *University of Oklahoma, Norman, OK.* (Sponsor: Michael Bemben, FACSM)

(No relevant relationships reported)

The countermovement jump (CMJ) is routinely used to quantify adaptions to training, as well as monitor neuromuscular readiness and fatigue in athletes. However, controversy remains in whether to incorporate an arm swing during the CMJ or keep the hands placed on the hips. Some suggest incorporating the arms yields a higher degree of sport-specificity that may produce improved reliability, especially in skilled jumpers. Conversely, others suggest the hands-on-hips approach isolates lower extremity force production and eliminates potential arm-swing variation. **PURPOSE: :** To establish the reliability of CMJ performance metrics obtained during a single CMJ performed with and without the arm swing. **METHODS:** Twenty-two (men=14, women=8) NCAA Division 1 collegiate basketball players performed 3 CMJs with an arm swing and 3 CMJs without an arm swing, in a randomized order. To assess the test-retest reliability, participants returned one week later to perform 3 more CMJs with an arm swing and 3 without. Intraclass correlation coefficients (ICC) and coefficients of variation (CV) were utilized to assess intraday and interday reliability for the various CMJ metrics. **RESULTS:** A variety of CMJ metrics for both CMJ with an arm swing and without an arm swing demonstrated high levels of intraday and interday reliability. Flight time displayed the highest levels of reliability for both arm swing (men: ICC=0.808, CV=5.9%; women: ICC=0.728, CV= 5.3%) and without an arm swing (men: ICC=0.906, CV=5.4%; women: ICC=0.736, CV= 5.8%), while eccentric mean power demonstrated the lowest reliability for both the arm swing (men: ICC=0.316, CV=41.0%; women: ICC=0.442, CV=25.8%) and without the arm swing (men: ICC=0.527, CV= 25.8%; women: ICC=0.793, CV=30.0%). **CONCLUSIONS**: The present study supports the reliability of select variables of CMJ when performed with either an arm swing or without an arm swing. Neither CMJ protocols emerged as clearly superior in displaying a higher degree of reliability in the various CMJ measurements observed.

Characterizing The Ventilatory Response To Constant Load Exercise Above And Below Critical Power

Keren Constantini, Cameron A. Nowrouzi, Courtney E. Wheelock, Robert F. Chapman, FACSM. *Indiana University, Bloomington, IN.* (Sponsor: Robert F Chapman, FACSM)

(No relevant relationships reported)

Critical power (CP) is considered a distinct exercise threshold, where at workloads above CP a metabolic steady state is not achieved causing task-failure to occur in a predictable manner. During exercise at intensities below CP, a steady state in whole-body and intra-muscular metabolic parameters is thought to be achieved, allowing exercise to be maintained for a long duration (>30 min). The ventilatory responses to constant load exercise below and above CP are yet to be determined. **Purpose:** to characterize ventilatory responses during cycling exercise performed at workloads 10% below and above CP. **Methods:** Ten highly trained subjects (6M/4W; age: 24 ± 4 yrs; height: 1.76 ± 0.10 m; weight: 66.3 ± 9.1 kg; VO_2max: 59.1 ± 7.3 ml/kg/min) performed a ramp incremental test, a 3MT (275 ± 75 W), and two constant load cycling trials to exhaustion at 10% below (CP_{-10}) and 10% above (CP_{+10}) CP. CP was determined as the mean power output over the last 30 s of the 3MT. Ventilatory [e.g. minute ventilation (VE), breathing frequency (fb), tidal volume (TV), end-tidal partial pressure of CO_2 ($PetCO_2$), ventilatory equivalents for O_2 (VE/VO_2) and CO_2 (VE/VO_2)] and metabolic

parameters, dyspnea and arterial oxyhemoglobin saturation (SpO_2) were compared at 25, 50, 75 and 100% of time to exhaustion (TTE) *within* each trial. The same variables were compared *between* CP_{-10} and CP_{+10} at exhaustion.
Results: TTE was 1215 ± 396 and 288 ± 95 s for CP_{-10} and CP_{+10}, respectively. Within each constant load trial heart rate, fb, VE/VO_2 and VE/VCO_2 were significantly ($p <$ 0.05) higher and $PetCO_2$ significantly ($p < 0.05$) lower at 75 and 100% compared to 25% of TTE. During CP_{-10} VE, TV, VO_2 were also different ($p < 0.05$) between 75 and/ or 100% compared to 25% TTE. However, measured variables were not different at 75 and 100% of TTE within each trial indicating a delayed steady state was achieved at both CP_{-10} and CP_{+10}. VE, TV, $PetCO_2$, VE/VCO_2, SpO_2, VO_2 were different ($p < 0.05$) at exhaustion between CP_{-10} and CP_{+10}.
Conclusion: Despite reaching different values at exhaustion, ventilatory parameters stabilized during exercise at 10% below and above CP. Furthermore, subjects reached exhaustion, on average, within <25 min at CP_{-10}, suggesting CP may be overestimated in highly trained subjects when CP is defined using the 3MT.

(No relevant relationships reported)

Evaluation of the Accuracy of the ACSM Walking Metabolic Equations During the Bruce Protocol
Kayla E. Brennan, Patricia I. Fitzgerald, Kristofer S. Wisniewski, Saint Francis University, Loretto, PA
The metabolic equations from the American College of Sports Medicine (ACSM) are used to determine energy expenditure during exercise. However, the equations have been shown to overestimate the measured value of oxygen uptake (VO_2). **PURPOSE:** To determine the validity of the ACSM walking metabolic equations in predicting the VO_2 during stages 1-3 of the Bruce Protocol Treadmill Test. **METHODS:** 50 subjects (25 males, 25 females) aged 31.6 ± 13.1 years and BMI of 25.0 ± 3.4 kg/m² completed a maximal treadmill test using the Bruce Protocol. A Parvo Medics TruOne 2400 system was calibrated before each test and used to collect and measure VO_2. Steady state, defined as a heart rate ± 5 bpm for the last 2 minutes of each stage, was attained in all subjects. The measured VO_2 values during the last minute of each stage were compared to predicted values calculated using the ACSM walking metabolic equation. **RESULTS:** Dependent t-tests were used to compare predicted against measured VO_2 values for each stage. Predicted and mean measured values ± SD of stages 1-3 were 16.3 ml/kg/min and 15.5 ± 1.8 ml/kg/min (p < 0.05), 24.7 ml/kg/min and 22.3 ± 2.3 ml/kg/min (p = 0.0001), and 35.6 ml/kg/min and 32.0 ± 4.2 ml/kg/min (p = 0.0001), respectively. The equation overestimated VO_2 during stages 1-3 in 38 (76%), 47 (94%), and 44 (91.7%) subjects, respectively. **CONCLUSION:** The ACSM walking metabolic equation consistently overestimated the measured VO_2 for all three stages. The ACSM states the metabolic equations can have up to 7% error. However, the predicted VO_2 for stages 2 and 3 were both 11% greater than the measured. Due to the variability between the predicted and measured VO_2 values, caution should be taken when using the ACSM walking metabolic equation to estimate VO_2 during stages 1-3 of the Bruce protocol.

[4]University of Rome Foro Italico, Rome, Italy.*
(No relevant relationships reported)

PURPOSE: The current study was aimed to examine the reproducibility of estimated peak power (PP) and estimated pedal velocity (PV) in a multi-trial 10-s all-out cycling test among adult athletes of different sports. **METHODS:** The sample comprised 22 adult male athletes (23.50±4.73 years). Stature, sitting height and body mass were measured. Leg length was estimated as stature minus sitting height. Thigh volume was estimated from anthropometry. Body volume was obtained from air displacement plethysmography and was subsequently converted to fat mass. Fat-free mass was derived. The short-term power outputs were assessed from the force-velocity test (FVT), using a friction-braked ergometer on two repeated occasions. Differences between repeated measurements were examined with paired t-test and effect sizes calculated. **RESULTS:** Mean values for session 1 (898 Watt, 142 rpm) and session 2

(906 Watt, 142 rpm) did not differ (p>0.05). Moreover, test-retest procedure evidenced reasonable intra-individual stability for estimated PP output. Technical error of measurement (TEM) was 31.9 Watt; % coefficient of variation (CV) was 3.5% and intra-class correlation coefficient (ICC) was 0.986. For PV, TEM was 5.4 rpm, %CV was 3.8 and ICC was 0.924. **CONCLUSIONS:** Estimated PP derived from the optimal load and correspondent PV outputs seemed to be reproducible in adult athletes. Future research may examine the agreement between the estimated outputs from the Force-Velocity Test (FVT) and measured outputs using the Wingate Anaerobic Test protocol using the optimal load from the FVT.

A Validated Model to Predict Maximal Oxygen Consumption Using a 9-minute Walk Test
Taylor Rowley, Chris Cho, Ann Swartz, FACSM, Nora Miller, Scott Strath, FACSM. *University of Wisconsin- Milwaukee, Milwaukee, WI.* (Sponsor: Dr. Scott Strath, FACSM)
(No relevant relationships reported)

Introduction: Assessing maximal oxygen consumption (VO_{2max}) is not always feasible, so alternative testing methods to predict VO_{2max} have been established. The purpose of this study was to assess and validate a field test to predict VO_{2max} using measures obtained during a 9-minute walk test. **Methods:** A subsample of 147 adults, age 18-79 years, completed this test. Demographic variables included resting heart rate (RHR), age, gender, and body mass. Participants completed three 3-min walking stages at a less than, normal and greater than normal walking pace. Heart rate (HR), distance covered, and gait speed was calculated for each stage. Recovery HR was collected every 30-seconds for 2-minutes after the end of the 9-min test. Hierarchal multiple regression analysis was used to predict VO_{2max}, utilizing variables of age, gender, and mass, and variations of heart rate, distance, speed, and recovery data. The validity of the final prediction equation to estimate VO_{2max} was assessed using jackknife cross-validation. Root mean square error (RMSE) and percent bias was calculated. **Results:** 57.7% of the sample was female, with an average age of 46.4 ± 17.2 years, BMI 25.8 ± 4.6 kg/m², VO_{2max} 34.7 ml/kg/min, and RHR 60.5 ± 9.2 bpm. Model 1 included age, gender, and body mass (R^2=.717). Model 2 included variables from model 1 entered in step 1, with the addition of gait speed for each 3-min stage (R^2=.740). The final model included all steps from model 2, and recovery HR after 30-seconds. This model accounted for 80.4% of the variance in VO_{2max} (R^2=.804, RMSE=4.651 ml/kg/min). Bias between the original model and the jackknife sample (R^2=.804, RMSE=4.651 ml/kg/min, Bias Adjusted RMSE=4.6220 ml/kg/min) was <0.1% for each variable entered into the model. **Discussion:** The final model accounts for ~80% of the variance in VO_{2max}, which is in line with previously published field tests.

Your Activities of Daily Life, YADL_Ballet: An Image-based Survey Technique for Healthy and Injured Dancers
Marijeanne Liederbach[1], Evangelos Pappas[2]. *[1]NYU Langone Orthopedic Hospital, New York, NY. [2]University of Sydney, Sydney, Australia.* (Sponsor: Malachy P. McHugh, FACSM)
(No relevant relationships reported)

Under ideal circumstances, clinicians and educators seek to detect risk for injury prospectively, often through screening efforts. It is known that screening has been very useful for rapport building, improving health literacy and facilitating entryways to local healthcare systems. However screening, as we have been conducting it, has still not proven to be predictive of injury despite implementation of preventative interventions such as pre-season conditioning programs. This may be due, at least in part, to the fact that most screenings are annual in their periodicity whereas athlete schedule loads and health status changes are very dynamic. PURPOSE: To describe a daily monitoring approach to assess patient self-rated outcome (PRO) using a personal device, image-based patient reported survey functional measure (YADL_Ballet) that possesses concurrent validity with the SF-12 Physical Component Summary, which when measured by factor analysis, explains 61.2% of percent return to activity following injury (p<0.000). METHODS: 241 elite classical dancers (21.5±5.0 years; 69 men, 172 women) who received regular onsite care consented to participate in preseason screenings, ongoing PRO monitoring and injury surveillance. Data were analyzed with a multivariate logistic regression model for the outcome variables "injured in subsequent season" and "visits in subsequent season". RESULTS: PRO variables were associated with the primary outcome variables (p=0.003, R^2=0.492, R^2=0.242, adjusted R^2=0.205). CONCLUSION: Compliance with personal device image-based survey data capture was excellent, further suggesting that injury prevention screening tactics for dancers should include serial PRO score assessments to predict those at greatest risk for time loss injury. <!--EndFragment-->

The Test-retest Reliability And Learning Effect Of The Modified Ctsib Balance Protocol

Harold S. Kieffer, FACSM, Paula Johnson, Ashley Carroll, Emily Walter, Emily Brocht. *Messiah College, Mechanicsburg, PA.*

(No relevant relationships reported)

PURPOSE: The purpose of this study was to determine the test-retest reliability of the modified Clinical Test of Sensory Integration and Balance (CTSIB) test on a clinical balance system. A secondary purpose was to study if short term balance training could improve proprioceptive integration that could be used for studying populations that are prone to balance difficulties. **METHODS:** Twenty individuals who were free of concussion, lower leg injury or balance conditions volunteered to participate in the study. The participants were randomly separated, and counterbalanced for gender, into an experimental group (n=10) and a control group (n=10). All testing was conducted on the Biodex Balance System SD to determine center of pressure sway using the modified CTSIB protocol which consisted of four 30-second trials under different conditions; eyes-open firm surface (EO-S), eyes-closed firm surface (EC-S), eyes-open soft surface (EO-U) and eyes-closed soft surface (EC-U). Both groups were tested on days one, two and seven; however, the experimental group received two ten-minute balance training sessions on hard and soft surfaces between days two and six. A 3 (day) x 4 (condition) x 2 (group) ANOVA with repeated measures was conducted to determine significance (p < 0.05). **RESULTS:** The main effect of day was not significant (p = 0.43). The main effect of group was significant (p < 0.001). The training group had less sway than the control group (1.04 $\pm$ 0.03 vs (1.18$\pm$ 0.03). The main effect of condition was significant (p < 0.001). A Fisher LSD was used to follow up this effect. As balance conditions became more difficult sway increased. EO-F (0.54$\pm$ 0.04) had less sway than EC-F and EO-S (0.85$\pm$ 0.04 and 0.87$\pm$ 0.04, respectively) which were lower than EC-S (2.81$\pm$ 0.04). There were no interaction effects. **CONCLUSION:** The modified CTSIB demonstrated strong reliability for multiple day comparisons suggesting no learning effect between trials. In addition, the results suggest that a short term (1 week) training program could result in reduced sway. Finally, the CTSIB uses multiple conditions across the testing protocol which stresses the sensory feedback system needed to maintain balance. The results indicate that sway increases as sensory input is challenged this could have application translate to balance training or rehabilitation.

Adapted Wii Fit Controller for Active Videogaming in Individuals with Mobility Impairments

Laurie A. Malone, FACSM, Sangeetha Padalabalanarayanan, Mohanraj Thirumalai. *UAB/Lakeshore Research Collaborative, Birmingham, AL.*

(No relevant relationships reported)

Individuals with physical disabilities have few choices for enjoyable physical activity. One option is playing active video games (AVG), but many are inaccessible or offer limited play options. Making AVGs accessible offers an innovative approach to overcoming many barriers to participation. **PURPOSE:** To examine energy expenditure and enjoyment in persons with mobility impairment during AVG play using an off-the-shelf (OTS) and an adapted Wii Fit balance board (WFBB). **METHODS:** Participants completed a functional assessment and familiarization period. Metabolic data (COSMED) were collected during 20-minute baseline, followed by four 10-minute bouts of game play. Participants performed two 10-minute bouts of select Wii Fit Plus games on the OTS and adapted WFBB. During rest participants completed the PACES enjoyment scale. Data were analyzed by player ability game play groups: 1) both boards standing (StdStd), 2) seated OTS board, standing adapted board (xStd), and 3) seated on OTS board only (xSit). **RESULTS:** Sample included 58 participants, 31 men, mean age 41.21 (±12.70) yrs. Energy expenditure (METs) during game play was significantly greater than rest for all players. Only 17 participants (StdStd group) were able to play using the OTS board. During game play on the adapted WFBB average MET values for the three groups on the two game sets respectively were: xSit (n=31) 2.26±0.72, 2.23±0.75 kcal/kg/hour; xStd (n=10) 3.15±1.03, 2.99±1.12; StdStd (n=17) 2.89±0.82, 2.88±0.90. PACES scores indicated that all players enjoyed the AVGs with median scores of 4 on a 5-point scale. **CONCLUSION:** The adapted WFBB provided an opportunity for persons with mobility impairments, including wheelchair users, to engage in AVG. All participants were able to utilize and enjoyed the adapted WFBB activity. Although average MET values achieved during AVG represented light intensity exercise, several participants

achieved moderate intensity (3-6 METs) on at least one game set. Factors not accounted for that may have influenced exercise intensity include: 1) game selection, 2) limited familiarization, and 3) discomfort wearing COSMED system. Next step includes further development of adapted gaming controller and assessment of associated health and fitness outcomes. Supported by NIDLRR grant 90RE5009-01-00.

Differences of Skin Temperature during a Treadmill Test in High vs Moderately Fit Male Triathletes

Jonathan Galan Carracedo[1], Myriam Guerra Balic[1], Andrea Suarez Segade[2]. *[1]Blanquerna, Ramon Llull University, Barcelona, Spain. [2]Clinical Center, Cornella, Barcelona, Spain.* (Sponsor: Dr. Bo Fernhall, FACSM)

(No relevant relationships reported)

Skin temperature (Tskin) is the predominant input for the heat balance maintenance and temperature regulation during rest and exercise, providing negative and positive auxiliary feedback to the thermoregulation system. During exhausting exercise it depends on the individual's metabolic rate and capacity for heat exchange with the environment. Depending on the type of exercise, the effectiveness of the thermoregulatory response is influenced by the individual's acclimatization state and aerobic fitness. **Purpose**: To evaluate the thermoregulatory response through the Tskin, and the aerobic capacity in high (HT) and moderately fit (MT) male triathletes. Further, we aimed to determine the relationship between Tskin peak and cardiorespiratory fitness for these groups. **Methods**. Ninety-two trained male triathletes were classified into HT (n=37; age 33±9 yrs.; VO₂peak 57.1±3.4 ml/kg/min) and MT (n=55; age 39±7yrs; VO₂peak 47±4.4 ml/kg/min). HT and MT levels were defined by their cardiorespiratory fitness classification (VO₂peak) based on ACSM. Tskin (left upper chest) and cardiovascular data were continually monitored during a progressive treadmill running, followed by a recovery period of five minutes. All the tests were performed in a controlled environment (humidity= 40-60% and temperature=23-24 ºC). **Results**. MT exhibited lower VO₂peak (p=.000), Tskin peak (p=.026), peak run speed (p=.000), HR (p=.001); VE (p=.000), Tskin baseline (p=.003) and were older (p=.004) with higher BMI (p=.000) compared with HT. Tskin peak correlated with VO2peak, age and RER (p<0.05). **Conclusion**. Our data show that higher levels of VO2 peak are positively associated with a better thermoregulatory response, while age has a negative association with temperature control in male triathletes. These data may have implications for exercise safety in hot environments in male triathletes.

Table 1. Cardiorespiratory Fitness and Skin Temperature data for HT and MT groups

Variables	HT (n=37)	MT (n=55)	p

Use Of Player Worn Sensors To Identify Fatigue During A USA Select National Hockey Development Camp

D Stojanov, K Martel, A Workman, S J. McGregor. *Eastern Michigan University, Ypsilanti, MI.* (Sponsor: Mark Peterson, FACSM)

(No relevant relationships reported)

Purpose: To monitor national team development camp ice hockey players with player worn sensors (PWS) to identify fatigue by reduced on-ice accelerations and changes in heart rate. **Methods:** 46 (15 yr; 174.83 ± 7.53 cm; 72.17 ± 11.80 kg) USA Hockey 15 national development camp participants consented to procedures approved by the EMU-HSRC. PWS measured tri-axial accelerations (ACC) and heart rate (HR) (Zephyr, MD) for each on-ice session (n=7) during the 5-day camp. Exponentially weighted Dynamic Accelerations (DYNA) were calculated from raw ACC. Three traditional games (G1, G2 and G3) were played on days 2, 4 and 5 and a 3v3 small-sided game on day 3. Peak ACC (g's) were divided into neuromuscular (NM) (10 sec), anaerobic (AN) (20, 30,40, 60 sec) and aerobic (AE) (90, 120, 180, 300, 600, 1200, 1800, ⋯ 3600s) time domains to determine relevant physiological fatigue factors. DYNAs (g's) were determined for time frames longer the AN domain. Peak HR (bmp) were divided into AN and AE domains at same time frames as ACC. MANOVAs for G only, P only and G vs P were performed (α = .05), in the case of significance a Tukey's *post hoc* was performed using SPSS 24.0 (IBM, NY). **Results:** ACC were greater for G vs P in the NM (10 s), AN (20-60 s) and AE (90 -180 s), while P were greater than G for ACC from 300 - 3600 s; (p<.05). DYNAs were greater for G than P for AN (60 s) and AE (90 - 180; 1200 - 1800 s; p<.05) respectively. HR was greater at AE (300 - 1200 s; p<.05) domain for P vs G. Non-significant, small effects (η_p^2= .01 - .042) were seen for reduced accelerations in the NM (10 s), AN (20-60 s) and AE domains (90-2700 s) from G1 to G3. Significant decreases in ACC were observed in NM (10 s) AN (20-60 s), AE (90 - 2400 s) and DYNAs in the AN (60 s), AE (90 and 2400 s) domains from P1 to P3 (p<.05). HR also declined in the AE domain (60 - 1200 s; p<.05) from P1 to P3. **Conclusion:** Games elicited increased ACCs and DYNAs for majority of the time points observed between 10 and 180 s, while practices elicited greater ACC and HR for durations longer than 300 s. Along with the fact that DYNAs were higher for games vs practices, these data indicate that games exhibit a more intense exertion profile with greater emphasis on anaerobic energy systems than practices. Although not as profound as expected, effects for declining ACC and DYNA from G1 to G3 indicate fatigue was evident.

The Accuracy of Wrist-Worn Heart Rate Monitors Across a Range of Exercise Intensities

Paul Hough. *St Mary's University, Twickenham, United Kingdom.*

(No relevant relationships reported)

PURPOSE: This study investigated the accuracy of four wrist-worn HR monitors (Apple Watch Series 1, Fitbit Charge, TomTom Touch, and Mio Fuse). **METHODS**: Eighteen adults completed three trials on a cycle ergometer wearing a chest-worn HR monitor (Polar). Trial 1 established the HR-power output relationship, and resting and maximum HR. In trials 2 and 3, participants were fitted to an electrocardiogram (ECG) and completed a step test consisting of 5 x 3 minute stages at 40 - 80% of HR reserve (determined in trial 1) whilst wearing two wrist-worn HR monitors.
RESULTS: Relative to ECG, there were no differences in HR between the devices during exercise (p = 0.239), and no device × exercise intensity interaction (p = 0.370). There were no instances where ECG and Polar data differed by ≥ 5 b·min-1. Conversely, there were two instances (2.2%) with the Apple, four (4.4%) with the Mio, 10 (11.1%) with the TomTom, and 19 (21.1%) with the Fitbit.
CONCLUSIONS: A chest-worn HR monitor offers greater accuracy compared to wrist-worn devices.

Validity And Reliability Of A Shirt-based Integrated Gps Sensor

Gabrielle E. W. Giersch[1], Robert A. Huggins[1], Courteney L. Benjamin[1], William M. Adams[2], Luke N. Belval[1], Ryan M. Curtis[1], Jussi T. Peltonen[3], Yasuki Sekiguchi[1], Douglas J. Casa, FACSM[1]. *[1]University of Connecticut, Storrs, CT. [2]University of North Carolina at Greensboro, Greensboro, NC. [3]Polar Electo Oy, Jyväskylä, Finland.*

(No relevant relationships reported)

PURPOSE: To examine the validity and reliability of a novel shirt-based 10Hz GPS and inertial movement device (TeamPRO®, Polar Electro Oy., Finland) for the assessment of distance during linear and agility-based movements.
METHODS: Fifteen male collegiate soccer players (mean± SD, age 20±1 years; height 177.0±7.5 cm; mass 71.57±7.17 kg) volunteered to participate in this study. Subjects performed a linear task consisting of two trials at each velocity: walking 4.8-7.9 km·h^{-1} (W), jogging 8.0-12.7 km·h^{-1} (J), running 12.8-20.0 km·h^{-1} (R), and sprinting >20.1 km·h^{-1} (S) with timing gates placed at 40m and 100m. Peak velocities were verified using a laser gun. Subjects also performed two trials of an agility task (team-sport simulated circuit, TSSC) through a 120m course, at various velocities, accelerations, decelerations, changes in direction, and stopping. Validity of total distance (TD) during the linear tasks and TSSC were established using the mean difference (MD) and independent t-tests (p<0.05) compared to criterion measures. Reliability for TD was determined independently during linear and TSSC tasks via coefficient of variation (%CV).
RESULTS: TD during the 40m was significantly less than the criterion measure during the J (MD±SD, -1.04 ±1.18m, p<0.001), R (-1.48±1.22m, p<0.001), and S (-2.78±2.99m, p<0.001). TD during the 100m was overestimated during the W (1.18±1.18m, p<0.001), but underestimated during the S (-2.28 ±2.63m). With the exception of the S during the 40m (%CV=8.02), the reliability (%CV) of the units for measuring TD during the 40m and 100m tasks was <5% for the W, J, R, and S. The device did not differ compared to criterion (tape measured distance) for TD during the TSSC (0.23±1.15m; p=0.339) with a very small error (<1.0%). TD during the TSSC was found to be reliable (CV=0.96%).
CONCLUSIONS: Overall these results indicate that the novel shirt-based GPS device was a valid measure of TD during the 100m for the R and J velocity zones. As velocity increased, MD for TD was also increasingly underestimated. Reliability data for TD suggest that the shirt-based sensor demonstrated good levels of consistency in all but one linear (40m S) and sport-specific tasks. The practical value of this device for athletes and coaches should be noted despite the statistically significant differences.

Using the Hexoskin Smart Garment to Measure Cardiorespiratory Variables During High Intensity Functional Training

Terence A. Moriarty[1], Yuri Feito, FACSM[2], Jessica Monahan[2], Cassie Williamson[2]. *[1]University of New Mexico, Albuquerque, NM. [2]Kennesaw State University, Kennesaw, GA.* (Sponsor: Dr Yuri Feito, FACSM)

(No relevant relationships reported)

Wearable devices are common in the health and fitness industry, and provide valuable information to improve and achieve fitness goals. **PURPOSE**: The purpose of this pilot study was to compare the Hexoskin smart garment (Hx) to established methods during a maximal graded exercise test (GXT) and a High-Intensity Functional Training (HIFT) session. **METHODS**: Eight healthy individuals (31.0 ± 7.6 years, 76.4 ± 11.4 kg; 1.7 ± 0.1 m) volunteered for this study and completed a GXT and a HIFT exercise session. During both testing sessions, respiratory measures [Respiratory Rate (RR), and Respiratory Volume (RV)] were assessed using a portable metabolic system (Cosmed K$_4$b^2; K$_4$), and heart rate (HR) was determined via ECG in a standard 12-lead configuration. The Hx was worn during both sessions. HR, RR, and RV were collected and monitored continuously at rest (Rt), throughout both exercise bouts (GXT & HIFT) and during cool down (Cd). **RESULTS**: Repeated measures ANOVA revealed significant differences between Hx and K$_4$ for RR-Rt (15.5 ± 5.3 vs. 33.0 ± 4.8 breaths/min, p< 0.001) and RR-Cd (29.5 ± 4.8 vs. 44.4 ± 7.0 breaths/min, p<0.001) during the GXT, as well as for RV-GXT (57.8 ± 14.9 vs. 77.3 ± 18.2 L/min, p = 0.004). During HIFT, HR-HIFT was significantly lower for the Hx when compared to ECG (141.5 ± 36.5 vs. 167.0 ± 13.2 beats/min, respectively; p = 0.038). Additionally, differences existed between the Hx and K$_4$ for RR-Rt (18.4 ± 3.9 vs. 35.6 ± 4.9 breaths/min, p< 0.001) and RR-Cd (27.8 ± 9.8 vs. 47.7 ± 7.9 breaths/min, p = 0.001). **CONCLUSION**: The results of this pilot study suggest that the Hx smart garment may be suitable to measure cardiorespiratory data during a GXT (i.e. HR & RR) and HIFT bout (i.e. RR & RV). However, additional studies should be conducted to elucidate the differences seen in HR measurement during HIFT.

Abstracts were prepared by the authors and printed as submitted.

Not All Are Created Equal: A Meta-Analysis of Wearable Devices for Tracking Physical Activity.

Jaehun Jung, Chun Wai Leung, Layne Katherine Case, Joonkoo Yun. *Oregon State University, Corvallis, OR.*

(No relevant relationships reported)

TITLE: Not All Are Created Equal: A Meta-Analysis of Wearable Devices for Tracking Physical Activity.
Wearable physical activity trackers have become popular and many vendors introduce various products. Currently, there are more than fifteen vendors competing in a share-market that projected over $19 billion by 2018. Physical activity trackers are being used in research studies as well as self-monitoring, reinforcement, and measurement. Many previous studies have examined the quality of commercially available devices. However, fragmentary results from individual studies may not help users when selecting physical activity trackers for multiple purposes, including tracking and monitoring their daily physical activity patterns. **PURPOSE:** To compare convergent validity of different commercially available trackers from various vendors using meta-analysis. **METHODS:** Four databases including Medline, were searched using key words representing physical activity tracker, physical activity, and validation studies. Inclusion criteria were the studies examining convergent validity evidence between consumer wearable activity trackers and research graded accelerometers (e.g., ActiGraph GT3X+). Physical activity trackers that had less than two previous independent studies were excluded. A total of 70 studies were identified through the systematic search and thirteen articles met the inclusion criteria, including nine different products introduced by seven different vendors. **RESULTS:** The sample sizes from individual studies were varied, ranging from 19 to 99. A wide range of confidence intervals (CI) in several products was found. Using the criteria of convergent validity coefficient of .8, three products demonstrated good validity and had both the mean validity coefficient and CIs were above the criteria. The mean validity coefficients of four products were the above .8, but lower limits of CIs were bellow the criteria while the mean validity coefficients of two products were below expected value. Interestingly, the cost of these trackers was not related to the strength of validity evidence. **CONCLUSION:** Since the accuracy of physical activity trackers is a contributing factor to continue engaging in physical activity (Kaewkannate & Kim, 2016), it is important to carefully examine validity evidence.

Accuracy Of The Polar M430 To Predict VO^2_{max} Using Optical Technology

Grace Shryack, Joshua Patterson, Olivia Hanzel, Courtney Willoughby, Bryan Smith. *Southern Illinois University - Edwardsville, Edwardsville, IL.*

(No relevant relationships reported)

There are a number of fitness watches currently on the market that can predict VO^2_{max} based upon resting heart (HR) values. Traditionally these watches have measured HR using a wireless chest transmitter but the Polar M430 uses optical technology which is built into the watch to measure HR. There is evidence that suggests this optical technology will accurately measure resting HR but there is limited information that suggests this new technology will accurately estimate VO^2_{max}. **PURPOSE:** The purpose of this study was to compare predicted VO^2_{max} values obtained from the Polar M430 watch (M_{max}) and actual VO^2_{max} values (A_{max}) obtained from indirect calorimetry. **METHODS:** Seven females (age = 24.0 ± 4.5 y, BMI = 26.3 ± 5.9 kg/m^2) and fourteen males (age = 24.9 ± 4.5 y, BMI = 28.1 ± 5.2 kg/m^2) reported to the lab, provided their informed consent, and then were instructed to lie in a supine position to rest for 10 minutes. During this time, their information (age, height, weight, gender, self-reported training hours) was entered into the watch. Following the rest, the M430 was then fitted to the participant according to the manufacturer instructions and the resting fitness test was started in order to obtain (P_{max}). A treadmill ramp protocol using indirect calorimetry was used to obtain A_{max}. **RESULTS:** There were no significant differences between M_{max} and A_{max} (48.2±13.5 and 45.3±9.4 ml/kg/min, respectively). In males, there were no significant differences between M_{max} and A_{max} (52.5±13.6 and 50.4±5.8 ml/kg/min, respectively). In females, there were no significant differences between M_{max} and A_{max} (41.8±10.4 and 38.1±10.5 ml/kg/min, respectively). **CONCLUSIONS:** This evidence suggests that the optical technology used in the M430 provides an estimate of VO^2_{max} based upon resting HR that is comparable to a VO^2_{max} obtained via indirect calorimetry. The ability to accurately estimate VO^2_{max} under resting conditions removes many of the barriers that are associated with a true VO^2_{max} test. Removing barriers of a true VO^2_{max} test will allow individuals to quantify and make their training more efficient.

2763   Board #46   June 1 2:00 PM - 3:30 PM

Comparison of Two Heart Rate Technologies to Predict VO_{2Max}

Joshua Patterson, Olivia Hanzel, Grace Shryack, Courtney Willoughby, Bryan Smith. *Southern Illinois University Edwardsville, Edwardsville, IL.*

(No relevant relationships reported)

Currently, there are heart rate (HR) monitors manufactured by Polar® that estimate VO_{2max} from resting conditions. A majority of these monitors measure HR via a wireless chest transmitter but they also have monitors that measure HR via optical sensors that are built directly into the watch. Although the optical sensors have the ability to accurately measure resting HR when compared to a wireless chest transmitter, it is not known if the VO_{2max} estimates from optical sensors are comparable to the values obtained from a wireless chest transmitter. **PURPOSE:** The purpose of this study was to compare VO_{2max} estimates obtained from the Polar M430 which utilizes optical sensors (O_{max}) to measure HR to values obtained from the Polar V800 which utilizes a wireless chest transmitter (CT_{max}) to measure HR. **METHODS:** Seven females (BMI = 26.3 ± 5.9 kg/m^2, age = 24.0 ± 4.6 yrs) and 14 males (BMI = 28.1 ± 5.2 kg/m^2, age = 24.9 ± 4.5 yrs) reported to the lab and then were instructed to lie in a supine position to rest for 10-min. Following the 10-min rest, participants were fitted with a wireless chest transmitter which was held in place with a chest strap. This transmitter sent HR information to the V800. The M430 was then fitted to the participant's wrist according to the manufacturer's instructions. Once HR values were being displayed on all watches, the resting fitness test was started in order to obtain VO_{2max} values from each watch. At the end of the test, the VO_{2max} values were recorded from the watch. **RESULTS:** There were no significant differences between O_{max} and CT_{max} (48.2±13.5 and 48.3±12.9 ml/kg/min, respectively). In males, there were no significant differences between O_{max} and CT_{max} (52.0±14.2 and 51.9±13.8 ml/kg/min, respectively). In females, there were no significant differences between O_{max} and CT_{max} (41.8±10.4 and 42.2±9.2 ml/kg/min, respectively). **CONCLUSIONS:** This data shows that there are no significant differences between the VO_{2max} estimates based upon resting HR values obtained from optical sensors (M430) or from a wireless chest transmitter (V800). Although both technologies produce similar estimates of VO_{2max}, this project does not examine the accuracy of these estimates when compared to an individual's actual VO_{2max}.

Comparing Positional Differences In Physical and Performance Assessments Among Acrobatics and Tumbling Athletes

Nicole J. Uccello, Courtney L. Stack, Michael J. Ryan, Paul D. Reneau, Shinichi Asano. *Fairmont State University, Fairmont, WV.*

(No relevant relationships reported)

Physical and physiological profiles are biomarkers of athlete's performance level. The fitness profile of positional differences has been described in collegiate football, basketball, and soccer, but not in Acrobatics and Tumbling (A & T). A & T is a new and emerging collegiate sport for competitive female athletes, thus there is not enough physical and performance data. **PURPOSE:** The purpose of this study was to compare the anthropometric characteristics and fitness levels of A & T athletes based on the two positions which include tops (T) and bottoms (B). **METHODS:** Subjects were 21 Fairmont State University female athletes who participated in the sport Acrobatics and Tumbling (20±0.9 years of age). A test of the five-fitness component's, which included body composition, flexibility, muscular endurance and strength and cardiorespiratory endurance, was given to each participant. **RESULTS:** The mean value of flexibility (cm ± SD) was significantly higher in tops (T=43.9±2.2, B= 37.5±7.0, $p< .05$). Body Composition (% ± SD) showed a difference between the groups Body composition showed a significant difference ($p<0.05$) within the tops and bottoms (T=23.7±2.2, B=26.4±2.2, $p< .05$). Muscular strength and endurance, cardiovascular endurance and vertical jump height do not show significant differences. **CONCLUSIONS:** The current study describes the important positional differences in body composition and flexibility in collegiate A & T athletes. Coaches can use these physical and physiological profiles to determine which positions that the athletes are suited for.

Accuracy Of VO$_{2max}$ Prediction Using A GPS Watch Following A 15-minute And Three Subsequent Runs

Andrew G. Pearson, Brandon Bastianelli, Andrea D. Workman, Christopher W. Herman, Jeff Schulz, Andrew Cornett, Rebecca W. Moore. *Eastern Michigan University, Ypsilanti, MI.* (Sponsor: Lanay Mudd, FACSM)

(No relevant relationships reported)

Commercially available GPS sports watches are now able to estimate VO$_{2max}$. **Purpose:** To examine predicted VO$_{2max}$ from a GPS watch compared to measured VO$_{2max}$. A secondary purpose was to determine if fitness level affects the ability of the watch to predict VO$_{2max}$. **Methods:** Twenty-eight participants, (14 M, 14 F; age 18-55 yr) came to the laboratory on two occasions. On day one, participants completed a treadmill graded exercise test to determine measured VO$_{2max}$ (MVO$_{2max}$). Participants completed the test using a self-selected pace while grade increased 2% every two minutes until exhaustion. On day two, participants were fitted with a GPS watch and completed a 15-minute submaximal outdoor run to determine predicted VO$_{2max}$ (PVO$_{2max}$). PVO$_{2max}$ was predicted based on subject characteristics, distance, pace, time, and heart rate measured at the radial pulse. Participants were then required to record three additional runs of at least 30 minutes on their own time to produce a modified VO$_{2max}$ (ModVO$_{2max}$). Participants were separated into two groups determined by MVO$_{2max}$ (high (n=17, VO$_{2max}$ > 50 ml/kg/min) or low (n=11, VO$_{2max}$ < 50 ml/kg/min)). A two-way repeated measures ANOVA was conducted to determine if there was a significant difference among MVO$_{2max}$, PVO$_{2max}$, and ModVO$_{2max}$. A one-way repeated measures ANOVA was conducted to determine if a significant difference in recorded VO$_{2max}$ values was observed within groups ($P < 0.05$). **Results:** The 28 participants were 24.7 ± 5.7 yr, 169 ± 7 cm tall, and weighed 67 ± 15 kg. Overall, there were significant differences between all VO$_{2max}$ variables (MVO$_{2max}$: 55 ± 10 ml/kg/min, PVO$_{2max}$: 52 ± 5 ml/kg/min, and ModVO$_{2max}$: 51 ± 6 ml/kg/min, $P < 0.05$ for all). After participants had been separated by fitness, a significant difference remained between MVO$_{2max}$ and PVO$_{2max}$ (mean difference = 6.9 ml/kg/min, $P < 0.05$) and MVO$_{2max}$ and ModVO$_{2max}$ (mean difference = 7.6 ml/kg/min, $P < 0.05$) in only the high fitness group. No significant difference was observed between any values in the low fitness group ($P > 0.05$). **Conclusion:** In healthy adults, the GPS watch was unable to accurately predict VO$_{2max}$. After subjects had been stratified into groups based on measured VO$_{2max}$, the GPS watch was able to accurately predict VO$_{2max}$ in the low fitness group but was unable to accurately predict VO$_{2max}$ in the high fitness group.

The Validity Of A Commercially-available, Low-cost Accelerometer In A Free-living Setting

Andrew Newton[1], Ellen Glickman, FACSM[2], Curtis Fennell[3], Jacob E. Barkley[2]. *[1]Jacksonville State University, Jacksonville, AL. [2]Kent State University, Kent, OH. [3]University of Montevallo, Montevallo, AL.*

(No relevant relationships reported)

Wearable activity monitors are a popular tool for the measurement of physical activity in the consumer market. However, much of the existing evidence assessing the validity of these commercially-available activity monitors is laboratory-based. Because these monitors will typically be used by consumers outside of a laboratory setting additional research assessing the validity of wearable activity monitors in free-living environments is warranted. **Purpose:** To assess the ability of a low cost, wearable activity monitor marketed to consumer (Movband 3) to measure physical activity behavior in a free-living setting against a previously-validated, research-grade accelerometer (Actigraph GT1M). **Methods:** Sixteen participants (n = five females, 27.0 ± 6.0 years old) were given both the commercially-available Movband (mounted on the wrist) and the research-grade Actigraph (mounted on the waist) to wear over the period of one week during free-living activity. Participants were required to simultaneously wear the two monitors for a minimum of five hours per day on five of the seven days. Participants completed daily diaries indicating the time of day in which the two monitors were worn. Physical activity data from each monitor was then divided by the duration of time participants wore the two monitors. Therefore, physical activity data for each monitor was expressed as activity counts/minute worn for each day. Pearson's correlation analyses were then performed to assess the relationship between counts/minute of the two monitors for each participant individually across all days the two devices were worn for a minimum of five hours. These individual correlation coefficients were then averaged across all participants and presented as a single value. **Results:** There was a large, positive effect size for the association (r = 0.57) between Movband and Actigraph activity counts/minute during free-living activity. In other words, as physical activity counts/minute increased in the Movband, activity also increased in the Actigraph. **Conclusion:** The low-cost, commercially-available wearable activity monitor (Movband) appears to provide a valid assessment of physical activity behavior in a free-living setting.

Validating Heart Rate In The Garmin Vivosmart HR Monitor Versus The Cosmed K4b2 Metabolic Backpack

Alexandra Lucas. *Coastal Carolina University, Conway, SC.* (Sponsor: George Lyerly, FACSM)

(No relevant relationships reported)

In today's fitness society, the growth of activity monitors is becoming more notable. The Cosmed K4b2 (K4) is one of the most highly accurate systems used to measure heart rate (HR), while the Garmin Vivosmart HR (GV) is one of the newest and more advanced activity monitors on the market. The GV has yet to be tested to prove its accuracy of its heart rate monitor in comparison to the K4B2. With a growing number of people relying on these activity monitors to give them accurate data on their activity levels, it should be known how accurate the data being given is. PURPOSE: To determine the accuracy of the heart rate monitor of the GV to that of the K4b2. METHODS: 19 individuals wore both the GV and the K4 while walking on a treadmill for 10 minutes. The measures taken were HR on both devices. Prior to exercise, participants had their weight, height, BP, and HR measured. Participants were asked to walk normally and not hold on with GV hand. RESULTS: The mean HR for the K4B2 was 102.00 ± 13.77, while GV was 100.26 ± 12.66. CONCLUSION: Our data indicated a positive correlation found between the K4B2 and GV with an r-value = 0.550; p-value = 0.022. Thus, the data suggests that the GV is as accurate as the K4 in measuring heart rate. The data also suggests that the GV may be a cheaper alternative to the K4 for tracking HR with researchers. Further testing with a larger population is warranted to help determine the accuracy between both pieces of equipment.

Validation Of Step Frequency Estimation From A Wearable Device On A Treadmill And Indoor Track

Rhiannon M. Seneli, Stephanie N. Driskell. *St. Ambrose University, Davenport, IA.*

(No relevant relationships reported)

Wearable fitness tracking devices have become common tools for runners of all levels. Using accelerometers, GPS, and heart rate, these devices are able to estimate running variables such as maximum oxygen capacity, step frequency, stride length, and ground contact time which can be used to evaluate technique and performance. PURPOSE: The purpose of this study was to validate the step frequency estimation on a Garmin Forerunner 630 for both treadmill and indoor track running. METHODS: Six male and 5 female volunteers (23 ± 4.1 years, 171.8 ± 9.0 cm, 73.9 ± 12.5 kg) performed five total running trials in random order, two on a 200 m indoor track (jogging pace and sprint pace) and three on a treadmill (6 mph, 7 mph, and 8 mph). Each trial was video recorded to count strides for 15 s which were converted to steps per minute and then compared to the estimated step frequency by the Garmin wearable device. Paired t-tests were used to compare the actual measurements to the estimated data for each of the running trials. RESULTS: There was no significant difference between any of the running trials actual step frequency count and the Garmin wearable device's estimated step frequency (Table 1). CONCLUSION: The Garmin Forerunner 630 is an accurate estimate of running step frequency when using it in an indoor setting, both on the treadmill and an indoor track.

	Step Frequency (steps·min^{-1})				
	Treadmill 6 mph	Treadmill 7 mph	Treadmill 8 mph	Indoor Track Jog	Indoor Track Sprint
Actual	160.0 ± 9.8	165.8 ± 11.4	172.7 ± 12.4	168.7 ± 10.6	213.5 ± 18.0
Garmin	161.6 ± 9.3	166.5 ± 10.8	171.7 ± 12.1	169.1 ± 10.1	206.7 ± 24.5
Significance	.08	.21	.31	.45	.27

Table 1. Mean ± SD of actual step frequency and estimated step frequency from the Garmin wearable device for each of the 5 running trials.

Abstracts were prepared by the authors and printed as submitted.

Use of Mesenchymal Stem Cells to Treat Muscle Strain Injuries

Megan Lerner, Shama R. Iyer, Joseph P. Stains, Frank Henn, III, Craig H. Bennett, Richard M. Lovering. *University of Maryland School of Medicine, Baltimore, MD.* (Sponsor: E.G. McFarland, FACSM)

(No relevant relationships reported)

Muscle strains are one of the most common complaints treated by physicians. Standard therapy for acute muscle strains usually involves rest, ice, and nonsteroidal anti-inflammatory medications, but currently there is no clear consensus on how to accelerate recovery. It is now known that mesenchymal stem cells (MSCs) have myogenic potential by contributing to development of new muscle and enhancing satellite cell function. A treatment that shortens recovery time could have a large impact in athletics, but could have a tremendous impact in patients with muscular dystrophies. **PURPOSE:** To determine the effects of MSCs on injured muscle. We tested the hypothesis that MSC delivery at the site of muscle injury will shorten recovery time. **METHODS:** The tibialis anterior muscles (TAs) of anesthetized Sprague-Dawley rats (N=9) were injured by lengthening contractions. The injured TA was injected with either MSCs (1E5, Lonza Biotechnologies), "sham" treatment (equivalent volume of sterile saline), or received no treatment (N=3 per group). Maximal torque was measured at optimal muscle length pre- and post-injury, and at days 1, 3, 5, 7 and 9 after injury until recovery was complete. **RESULTS:** All animals sustained almost identical loss of muscle force after injury (60 +/- 2%). MSC-treatment had a beneficial effect at within 3 days after injury, resulting in a faster, and overall greater, recovery of function compared to sham and no treatment groups. The sham injections had no effect compared to no treatment. **CONCLUSIONS:** We conclude that MSC injection may be a promising treatment option for muscle strain injuries. Our long-term goal is to inject injured muscle with MSCs containing superparamagnetic iron oxide nanoparticles (SPIONs), which can be tracked by MRI and delivered to a targeted sites in-vivo for predetermined periods of time. This method could further improve muscle regeneration and subsequent functional recovery of the injured muscle.

The Effect of Tissue Temperature on Ligament Laxity in Healthy Individuals

Stacey Chen, Everett Plocek, Kathy Liu. *University of Evansville, Evansville, IN.*

(No relevant relationships reported)

The use of heat and ice is commonly used in the clinical setting. Heating before exercise is reported to increase range of motion and tissue pliability while icing after exercise is reported to decrease the inflammatory response and pain. **PURPOSE:** To examine the effects of hot and cold on ligament laxity of the ankle joint. **METHODS:** Seventy-five subjects (39 females, 36 males, age = 20.1 ± 1.7 yrs; height =173.8 ± 9.5 cm, mass = 71.2 ± 13.8 kg) with no history of an ankle sprain were recruited for this study. Participants were randomly divided into three groups (hot, cold, control) and an ankle was randomly selected for testing. The experimental groups either received a hot pack or an ice bag wrapped around their ankle for the 20 minute intervention period. Prior to the intervention, anterior displacement (AD) and inversion-eversion rotation (IE) was measured by an ankle arthrometer. Next, participants received the intervention of their assigned group. After the intervention, another measurement was taken. Three trials of each measurement was taken and averaged. Data were analyzed using a repeated measures ANOVA among the three groups between the pre-and post-measurements. **RESULTS:** A significant main by group interaction was found for AD (p=0.004), but not IE (p=0.859). In the AD direction, there was a significant increase in ligament laxity in the hot group and a significant decrease in ligament laxity in the cold group. However, no changes were detected in the IE direction in any groups. **CONCLUSION:** As expected, the application of heat increased tissue pliability while cold decreased it. However, changes were only found in the AD direction but not the IE direction. Ankle joint motion can be restricted by both ligaments and muscles. Perhaps, alterations from temperature changes differ among different tissue types. However, further research is necessary to determine the molecular changes in different types of tissue (connective, muscular) with temperature changes.

Means, SD, and p-values among groups					
	Pre-AD (mm)	Post-AD (mm)	p-value	Pre- IE (degrees)	Post-IE (degrees)	p-value
Hot	8.97 ± 2.71	9.77 ± 2.92	0.029	43.75 ± 11.49	44.22 ± 12.67	0.613
Cold	9.28 ± 2.43	8.54 ± 2.65	0.023	41.67 ± 11.94	41.48 ± 10.73	0.875
Control	9.30 ± 3.34	9.36 ± 3.40	0.767	45.59 ± 13.14	46.54 ± 10.82	0.703

Artificial CO_2-water Leg-bath Facilitates Recovery From Muscle Hardness Caused By Resistance Exercise

Noriyuki Yamamoto[1], Tadashi Wada[2], Fumiko Takenoya[3], Masaaki Hashimoto[4]. *[1]Japanese Red Cross Hokkaido College of Nursing, Kitami, Japan. [2]Kokushikan Univ., Tokyo, Japan. [3]Hoshi Univ., Tokyo, Japan. [4]Teikyo. Univ. Sci., Tokyo, Japan.*

(No relevant relationships reported)

Facilitation of the blood stream and oxygen consumption of the muscle by a local immersion of the extremities into high concentration carbon dioxide water (CO_2-water, $CO_2 \geq 1000$ppm), suggests an improvement of muscle performance and joints flexibility. **PURPOSE:** In the present study, we investigated whether the immersion of extremities including agonist muscles into artificially made CO_2-water influenced recovery of the increased muscle hardness induced by a resistance exercise. **METHODS:** The healthy male college students (n=11, age; 18-19 yrs, height; 168.6±4.5 cm, weight; 66.2±9.3 kg) participated in this study. The subjects performed 100 times calf raise resistance exercise and immersed lower legs into tap-water or artificial CO_2-water at 35 °C for 10 minutes immediately after the exercise. Blood flow in the immersed skin (BF_{skin}) and electrocardiogram (ECG) were recorded continuously throughout the experiment. Hardness of the gastrocnemius medialis (MG) was evaluated using ultrasound real-time tissue elastography. Visual analog scale test on muscle pain (VAS) and muscle hardness measurements were performed at 3 time points (prior to exercise, immediately after exercise, at 10 min after exercise). The strain ratio (SR) between the MG and a reference material was calculated. **RESULTS:** BF_{skin} in the CO_2-water leg-bath was significantly higher than that in the tap-water leg-bath (CO_2-water vs. tap-water, 5.5±1.8 vs. 2.1±1.2 ml·min^{-1}·100g^{-1}, p<0.05). At 10 min after exercise, CO_2-water treatment compared with the tap-water treatment, SR decreased significantly quicker (1.37±0.28 vs. 0.67±0.08, p<0.05). In addition, VAS at recovery 10 min became smaller in the CO_2-water than the tap-water (18.1±10.2 vs. 33.9±16.2 mm, p<0.05). **CONCLUSIONS:** We reported previously that the muscle blood flow in the immersed part was larger in CO_2-water than tap-water of a same temperature. In addition to a local effect of CO_2, suppression of muscular sympathetic activity may also contribute to the increase in local blood flow. Facilitation of muscle hardness recovery shown in this study might be caused by the increased muscle blood flow. The present study suggested that high concentration artificial CO_2-water immersion may contribute to rapid recovery from the high intensity exercise-induced muscle fatigue.

Cold-Water Immersion Attenuated Muscle Soreness after Plyometric Training while having no Impact on Sprint Performance.

Michael J. Ryan, Courtney Webb, Shinichi Asano, Paul Reneau. *Fairmont State University, Fairmont, WV.*

(No relevant relationships reported)

PURPOSE: This study aimed to test the effectiveness of lower body cold-water immersion (CWI) on Delayed Onset Muscle Soreness (DOMS) and sprint performance after acute plyometric exercise in Division II athletes. **METHODS:** Female (n=12) and male (n=6) Division II athletes, aged 20.6 ± 1.3 (n=18) were asked to perform two maximal 40-yard (36.58m) dash trials. After which the times were averaged together to determine a pre-treatment value. Twenty-four hours after the 40-yard dash trials all athletes returned and asked to rate their level of soreness on a 1-10 visual analog scale (VAS). Then each athlete participated in a plyometric workout consisting of a warm-up, workout (210 ground contacts), and cool-down. The control group (Con) sat in a chair for 10 mins and the experimental group (CWI) sat submerged to their waste in a cold-water tank (15.5°C or 60°F) for 10 mins. Participants returned 48 hrs after Con or CWI treatment and asked to rate their perceived muscle soreness on the same VAS. For the post-treatment values, participants performed the same warm-up, 40-yard dash trials, and cool-down. All procedures were approved by Fairmont State University's IRB and informed consent was given by each participant. **RESULTS:** The average VAS for muscle soreness increased (p≤0.05) from pre-workout (1.2 ± 0.42) to post-workout (2.2 ± 0.43) to 48hrs post workout (6.4 ± 1.8). The 48hrs post workout Con group also reported greater (p≤0.05) levels of soreness as compared to 48-hrs post workout CWI experimental group (8.1 ± 0.78 vs 4.67 ± 0.5). There was no significant difference (p≤0.05) found between the Con or CWI group in the pre-treatment 40-yard dash (5.66 sec ± 0.47 vs 5.53 sec ± 0.53). Furthermore, there was no significant

difference (p≤0.05) found between the Con or CWI group in the post-treatment trials (5.52 sec ± 0.52 vs 5.57 sec ± 0.53). **CONCLUSIONS:** Forty-eight hours after high-intensity plyometric training, perceived muscle soreness was elevated when compared to pre-workout values. Cold-water immersion attenuated the reported increase in DOMS but did not prevent reports of elevated soreness. However, the increase in perceived DOMS had no significant effect on 40-yard dash time 48 hours after high-intensity plyometric training in either the control or cold-water immersion group.

Effects of Two Maximal Isometric Contractions Attenuate Eccentric Exercise-induced Muscle Damage on Surface Electromyographic Activity

Ming-Ju Lin[1], Chin-Yun Huang[2], Jia-Jhen Cai[1], Jia-Wei Chen[1], Ching-Fei Wang[1], Yu-Wei Hsu[1], Fu-Chen Yang[1]. [1]*National Chiayi University, Chiayi County, Taiwan.* [2]*Nanhua University, Chiayi County, Taiwan.*
(No relevant relationships reported)

Tseng et al. (2016) reported that changes in MaxECC-induced muscle damage (EIMD) of the preconditioning MVC training of the knee extensors (KE) for untrained men was significantly smaller than control group. No studies have recruited untrained participants, and targeted on hamstring muscle strains in which are the most frequent sporting injuries to clarify whether non-damaging exercise of MVC can be attenuated muscle damage induced by MaxECC of knee flexors (KF). **PURPOSE:** This study investigated the neural factors (surface electromyography, EMG) of two maximal isometric contractions (2MVC) at 20° knee flexion on changes in indirect muscle damage markers following 60 MaxECC of KF performed 2 days later. **METHODS:** Sixteen untrained young males were randomly placed into the control group (CON) that did not perform 2MVC, or the experimental group (2d, n = 8 per group) who performed 2MVC 2 days before MaxECC. Changes in muscle soreness (SOR), non-dominant upper thigh circumference (CIR), resting knee angle (RANG), maximal voluntary isokinetic concentric contraction (MVC-CON), and surface EMG [median frequency (MF), root mean square (RMS)] before, immediately after, and 1-5 days after MaxECC were compared between groups by a mixed-design of two-way ANOVA. **RESULTS:** 1). Significant (p < .05) changes in some dependent variables after 2MVC compared to baseline for the 2d group; 2). Changes in the muscle damage variables (e.g. MVC-CON: -13.1%; CIR: +1.5 mm) following MaxECC immediately for the 2d group were smaller than CON group (-22.4%; +4.8 mm); 3) Changes in the surface EMG activity following MaxECC for the 2d group showed smaller changes (MF: 60.2 ± 9.1 Hz) than CON group (70 ± 13.2 Hz). **CONCLUSION:** These results suggest that protective effect conferred by non-damaging exercise of 2MVC against subsequent MaxECC-induced muscle damage is likely to be related to neural adaptations. Therefore, the RBE protocol of this study may provide some useful information for men to minimize muscle damage when they start to participate exercise. It is also required to further understand the underpinning mechanisms of the repeated bout effect in both physiological and pathological contexts.

Systemic and Local Alterations in Extracellular RNA (exRNA) Following Traumatic Knee Injury Implicate Catabolic and Inflammatory Pathways

Anthony J. Griswold, Natalia K. Hofmann, Thomas M. Best, Jeffery M. Vance, Margaret A. Pericak-Vance, Lee D. Kaplan. *University of Miami, Miami, FL.* (Sponsor: Thomas Best, FACSM)
(No relevant relationships reported)

Traumatic injuries are strong risk factors for future osteoarthritis (OA) of the knee. Molecular changes initiated soon after the trauma may lead to this increased susceptibility. Identification of these pathways could lead to early intervention and potential limitation of damage. One such mechanism may be the release of RNA molecules by the affected tissues. **PURPOSE**: This study set out to characterize systemic extracellular RNA (exRNA) by characterizing RNA from plasma following traumatic injury. **METHODS**: Our cohort consisted of 14 subjects (ages 19 to 47) undergoing ACL and/or meniscal repair surgery (0.5 to 180 months post injury). Radiograph analysis found no existing OA at the time of surgery, though Outerbridge chondral damage assessment indicated average scores across four knee compartments ranging from 0-1.25. Plasma was isolated from whole blood via centrifugation to remove cells and platelets. Total RNA was extracted from .05mL of plasma and analyzed via massively parallel sequencing for quantification and characterization of exRNA. Generalized linear models were used to identify RNA differentially present in low vs high (0.5) average Outerbridsge scores and acute vs chronic duration of injury (4 months). **RESULTS**: exRNA profiles indicated more than 10,000 types of RNA present including fragments of protein coding genes and miRNAs. Profiles were consistent across the samples with no differences when comparing Outerbridge scores or injury

duration. There was noted expression of inflammatory genes (*CXCL5, CCL5,* and *IL16*), catabolic genes (*MMP -21, -17, and -13,* and *ADAMTS8*), and previously reported miRNA biomarkers of arthritis (*MIR16, MIR20b,* and *MIR146a*). **CONCLUSIONS**: There is an unmet need for determining the etiology and potential novel treatment approaches in patients with knee trauma to mitigate future progression of OA. This study demonstrates that exRNA can be isolated and characterized from plasma in a high throughput manner. Our results indicate that plasma from subjects with injured knees contains inflammatory, catabolic, and potential arthritic biomarkers. Future studies are required to more fully characterize the biological roles of these exRNA and the timing and cadence of their respective release that may lead to translational treatment options for patients with post-traumatic OA.

Effects of Isometric Contractions on Eccentric Exercise-induced Muscle Damage of the Knee Extensors

Kun-Xian Lin[1], Hsiu-Hua Wang[2], Kuo-Wei Tseng[1], Wei-Chin Tseng[1], Ming-Ju Lin[3]. [1]*University of Taipei, Taipei City, Taiwan.* [2]*National Chung Cheng University, Chiayi County, Taiwan.* [3]*National Chiayi University, Chiayi County, Taiwan.*
(No relevant relationships reported)

The previous studies proposed that two maximal voluntary isometric contractions (2MVCs) at 20° elbow flexion did not change any variables for exercise-induced muscle damage (EIMD) and delayed onset muscle soreness (DOMS) (Chen et al., 2012, 2013). These results may not apply for real outcomes resulting from the lower limb [ex: knee extensors (KE)].
PURPOSE: To investigate the protective effect conferred by MVCs of the KE on changes in muscle damage markers and pulse wave velocity (PWV) by maximal eccentric contractions of the same muscle performed 1 day later. **METHODS:** Twenty untrained male students were randomly assigned to a control group that did not perform 2MVCs or 1d group who performed 2 MVCs at 120° knee flexion 1 day before 60 maximal isokinetic (30°/s) eccentric exercise (MaxEC). Changes in maximal isokinetic contraction torque (MVC-CON), range of motion (ROM), DOMS, PWV and blood creatine kinase (CK) activity were compared between the groups by two-way repeated measures ANOVA. **RESULTS:** No significant changes in any variables were evident after 2MVCs (p < .05). The changes in all variables after MaxEC showed smaller for the 1d group compared with control group. **CONCLUSION:** The results of this study show that isometric contraction of KE at a longer muscle length did not induce muscle damage and produced a protective effect.

Nitric Oxide Donor Treatment Affects Skeletal Muscle Myeloperoxidase And Fibronectin After Contusion Injury In Rats

Kathryn H. Myburgh, FACSM, Christopher Reeves, Carine Smith. *Stellenbosch University, Stellenbosch, South Africa.*
(No relevant relationships reported)

Trauma to skeletal muscle results in tissue and membrane damage and an inflammatory response. Current treatments are merely management strategies. Nitric oxide (NO)-donation has shown therapeutic promise in mouse models of muscular dystrophy, and therefore, may be beneficial for the treatment of acute muscle injuries. **PURPOSE:** To clarify the role of treatment-derived NO on muscle tissue response to trauma. **METHODS:** Using a contusion injury model (n=10 uninjured controls and n=58 injured), rats were treated with either placebo (Plac) or NO-donor administered with gelatine blocks immediately and one day after the injury. Time points for sample collection were 1, 3, 5 and 21 days post-intervention. Content of two selected proteins in the injured tissue homogenates were assessed with Western blots and band density normalized to uninjured untreated control samples. Myeloperoxidase (MPO) and fibronectin (45+50 kDa bands combined) were used to assess inflammatory and membrane damage respectively. Data presented in arbitrary densitometric units (AU) as mean ± standard deviation. Statistical analysis: Mixed Models ANOVA with post-hoc LSD test. **RESULTS:** MPO peaked five days after injury in placebo (D1: 0.73 ±0.32 AU; D3: 0.47 ±0.45; D5 8.36 ±4.92; p < 0.0001) and NO-treated groups (D1: 1.00 ±0.23 AU; D3: 0.32 ±0.29; D5 5.57 ±6.80; p < 0.01) and resolved by D21 in both groups (Pla: 0.97 ±0.70 and NO-donor: 1.21 ±0.71 AU). The modulation of MPO on D5 by NO-donor was 33% with large individual variation between animals (Pla versus NO-donor D5: not significant). Fibronectin was >1000-fold elevated on D5 in both groups (Plac: 1290 ±1441 and NO-donor 1024 ±549 AU), but fibronectin resolved better with NO-donor by D21 (Plac: 12.4 ±5.6 versus NO-donor: 3.7 ±0.8; p<0.005 between groups). **CONCLUSION:** Five days after injury, NO-donor treatment reduced evidence of inflammation and membrane damage. This may be due to enhanced clearance of inflammatory radicals from injured muscle and less secondary injury.

The Effect Of Nitric Oxide Donor Treatment On Skeletal Muscle Repair Following Contusion Injury In Rats

Tracey Ollewagen, Kathryn H. Myburgh, FACSM. *Stellenbosch University, Stellenbosch, South Africa.* (Sponsor: Prof KH Myburgh, FACSM)
(No relevant relationships reported)

Muscle injuries often lead to structural and functional deficits and recurrent injuries. Nitric oxide (NO) is an endogenous bioactive molecule with multiple physiological roles. Pharmacological NO inhibition negatively effects regeneration, with excessive fibrosis, suggesting that treatment with NO may prove to be beneficial. **PURPOSE:** To assess a) anti-fibrotic and pro-regenerative roles of NO following muscle trauma and b) muscle function recovery following injury by treating with either NO donor or inhibitor. **METHODS:** The gastrocnemius of adult male rats were contusion injured (250g drop-mass) followed by one of four treatments (placebo, NO-donor, NO-inhibitor or combination) administered immediately and one day post-injury and in un-injured controls. Rats were sacrificed at 5 (D5) and 21 (D21) days after intervention (n=6/group; total n=78). *In situ* mechanics testing was done pre-injury and before sacrifice to determine plantar flexor contractility. Fibrosis staining was done using Masson's trichrome and Sirius red. Embryonic MHC (eMHC) was used to identify new and regenerating muscle fibers, including cross-sectional area (CSA). **RESULTS:** Maximal isometric force was significantly reduced D5 post-injury (19.5 ±3.1 N/kg) compared to pre-injury (26.0 ±2.5 N/kg; p < 0.0001). D21 maximal force was significantly higher in the NO-donor group (27.2 ±3.3 N/kg) versus L-NAME (21.7 ±3.7 N/kg; p < 0.05) and combination (21.6 ±3.8 N/kg; p < 0.05). NO-donor significantly increased eMHC protein expression (5.29 ±2.64 AU versus Plac: 0.65 ±0.64; L-NAME: 0.58 ±0.51; Comb: 0.45 ±0.9 AU; p < 0.001) and new fiber CSA (501 ±34 um^2) versus other treatments (Plac: 421 ±27 p< 0.01; L-NAME: 240 ±38 p<0.001; Comb: 313 ±36 um^2; p<0.001). Picrosirius red staining indicated that NO-donor treatment reduced fibrosis (7.33 ±1.87 %; Plac: 18.28 ±3.94; p< 0.0001). Masson's trichrome staining indicated a significant increase in fibrosis following NO inhibition (22.88 ±1.57 %; p<0.01). **CONCLUSION:** Maximal force production recovered fully 21 days after injury in placebo-treated rats. NO influenced recovery of physiological function resulting in further increased maximal force production at D21, compared to a reduction following L-NAME treatment. This may be due to improvement in regenerative myogenesis and reduction in fibrosis.

Myotonometric Effect of Foam Rolling Following Strength Training

Ruediger Reer[1], Jan Schroeder[1], Linda Lueders[1], Mike Schmidt[1], Serge P. von Duvillard, FACSM[2], Klaus-Michael Braumann[1]. [1]*University of Hamburg, Hamburg, Germany.* [2]*University of Salzburg, Salzburg, Austria.*
(No relevant relationships reported)

Foam Rolling (FR) is widely used as an intervention therapy device to alleviate, treat, and possibly prevent myofasciatic condition in exercise and in high performance sports. Its use may be beneficial on the pressure sensitive muscle tissue via regeneration therapy; however, these effects have not been sufficiently investigated. **PURPOSE:** The aim of this investigation was to assess whether the use of FR may benefit muscle tissue compliance via myotonometric intervention training (MMT) and subsequent muscle regeneration after exhausting high intensity strength training experiment (EXP). **METHODS:** Twenty sport students (7 male and 13 female; age 24.7±2.9 yrs, BMI 22.2±2.4 kg.m²) performed a single exhausting strength training session (leg extension with both legs) followed by FR session (using right leg only). The FR session (2x45s) was conducted again after 24, 48 and 72 hours. The left leg served as a control (CON). Prior to exhaustion and after every FR session, we determined muscle tissue compliance of rectus femoris muscle (MMT). We utilized Hz-frequency analysis to assess tissue compliance. **RESULTS:** The time effect was as follows: (pre: EXP 14.53±1.12, CON 14.37±0.99; post 0: EXP 14.60±1.28, CON 14.63±1.01; post-24: EXP 14.56±1.31, CON 14.25±1.11; post-48: EXP 14.36±1.22, CON 14.33±1.16; post-72: EXP 14.33±1.31, CON 14.25±1.15 Hz). The investigation revealed significant increase in Hz-frequency (greater compliance) immediately post exhausting strength training session but returned to base values day after (*P*=0.006). There was no significant main effect between EXP and CON (*P*=0.8). There was also no interaction effect for FR (*P*=0.399). **DISCUSSION:** Although scientific literature report fatigue and recovery effects; however, we did not find regenerative effects of FR when using MMT. From practical point of view, we were able to document at least partially the regenerative use of MMT immediately after the EXP but we were not able to ascertain that even repeated FR treatment daily will beneficially effect muscle compliance and the desired outcome. Future studies utilizing different dose, duration, and repetitions may yield results that are more promising.

Dysregulated Inflammation And MAPK Signaling In Aged Human Muscle Following Exercise-induced Damage

Jacob R. Sorensen, Caitlin Skousen, Alex Holland, Kyle Williams, Robert D. Hyldahl. *Brigham Young University, Provo, UT.* (Sponsor: Allen Parcell, FACSM)
(No relevant relationships reported)

The remarkable capacity of skeletal muscle to adapt and repair following injury is attenuated with age. Studies in young organisms suggest that acute changes in both extrinsic and intrinsic factors in the muscle environment are critical in regulating reparative potential. **Purpose:** To uncover potential factors involved in the impaired regenerative response of aged human skeletal muscle, we comprehensively assessed the molecular stress response following muscle damage in young and old individuals. **Methods:** 11 young (22.7 ± 2.25 yrs) and 8 physically active old (70.9 ± 7.5 yrs) subjects completed a bout of 300 lengthening contractions (LC) on a Biodex dynamometer. Functional tests were performed as an indirect assessment of muscle damage and muscle biopsies were taken pre-exercise and at 3, 24, and 72 hours post-exercise. High throughput multi-plexing bead assays were used to analyze biopsy samples for content of inflammatory cytokines and protein concentrations of the mitogen activated protein kinase (MAPK) signaling pathway. **Results:** After the bout of LC's, muscle damage was evident by the loss of isometric force production in both groups (Young: 54.11 ± 22 and Old: 33.86 ± 17%). Old muscle displayed higher expression of MCP-1 (group, p=0.019) that appeared at the later 24 and 72 hour time points. There was also a rapid increase in NF-kb activity in the old following the bout of lengthening contractions (group x time, p=0.05). In the old, p38 protein content increased significantly at the 3 hour time point (Young: 0.8 ± 0.09 vs Old: 1.70 ± 0.47 fold) before returning to pre-exercise levels (group x time, p=0.0043). Additionally, by 3 hours post-exercise total JNK protein levels increased only in the old (Young: 1.6 ± 0.26 vs Old: 5.1 ± 0.77 fold) and remained significantly elevated (Young: 0.76 ± 0.20 vs Old: 4.5 ± 0.46 fold) 24 hours post-exercise (group x time, p=0.038) before returning to pre-exercise levels. **Conclusion:** skeletal muscle of physically active older individuals is characterized by a dysregulated and asynchronous inflammatory and MAPK response, each of which may individually or collectively contribute to the deterioration of muscle repair mechanisms that accompanies aging.

Risk Factors for Knee Arthroplasty in Patients with Knee Osteoarthritis Treated with Hylan G-F 20

Maria Runa[1], Kevin Ong[1], Edmund Lau[2], William Daley[3], Roy Altman[4]. [1]*Exponent Inc., Philadelphia, PA.* [2]*Exponent Inc., Menlo Park, CA.* [3]*Sanofi, Bridgewater, NJ.* [4]*University of California, Los Angeles, Los Angeles, CA.*
Reported Relationships: M. Runa: *Salary; Exponent Inc..*

PURPOSE: Knee osteoarthritis (OA) is a common condition that often results in knee arthroplasty (KA), a costly procedure with potentially adverse clinical sequelae. Viscosupplementation with hyaluronic acid (HA) derivatives such as hylan G-F 20 can be used to treat knee OA pain. Data from a large medical claims database were analyzed to identify factors associated with KA risk for patients with knee OA treated with hylan G-F 20.
METHODS: Health claims data from the Optum Clinformatics Data Mart database from 2006-2016 were used. Patients were aged ≥18 years, had data for 6 months before and ≥6 months after knee OA diagnosis, and had ≥1 treatment course of hylan G-F 20 (hylan G-F 20 or hylan G-F 20 single intraarticular injection) as the only HA therapy. Patients were grouped by treatment with hylan G-F 20, hylan G-F 20 single intraarticular injection, or both. Kaplan-Meier curves were generated for the adjusted risk of KA with propensity scores from the first treatment with hylan G-F 20 to KA. KA risk factors were determined using multivariate Cox regression adjusted for age, race, region, gender, treatment group, year of HA therapy, Charlson comorbidity index (CCI) score, number of HA courses, arthroscopy, physical therapy, ultrasound use, and prescriptions for non-steroidal anti-inflammatory drugs, opioids, or corticosteroids. **RESULTS:** From 4,027,848 knee OA patients, 62,033 were treated with hylan G-F 20 and/or hylan G-F 20 single intraarticular injection; 76% treated avoided KA over the 10-year study period. Kaplan-Meier analysis showed that 60-64% of patients treated with hylan G-F 20 and/or hylan G-F 20 single intraarticular injection were able to avoid KA at 8 years following their first injection. Risk factors for KA from first hylan G-F 20 treatment were increased age (hazard ratio [HR] ranging from 2.84-8.20 for ≥40 years of age vs 18-39 years; P<0.001 for all), fewer hylan G-F 20 treatments (HR 0.63, 0.47, 0.38, and 0.36 for 2, 3, 4, or ≥5 treatments, respectively, vs 1 treatment; P<0.001 for all), and no use of ultrasound (HR 0.93 with ultrasound; P<0.001). **CONCLUSIONS:** In this analysis of a large claims database over a 10-year period, younger patients, those who had more courses of hylan G-F 20 treatment, and those who received hylan G-F 20 injections with ultrasound guidance were less likely to receive KA. Efficient Concentration of Plasma and Platelet-WBC-Rich Plasma Proteins Using a Polyacrylamide Device

Sean M. Muir, Michael Baria, Natalie Reisbig, Christopher C. Kaeding, FACSM, Alicia L. Bertone. *The Ohio State University, COLUMBUS, OH.* (Sponsor: James Borchers, FACSM)
(No relevant relationships reported)

Concentration of functional proteins has used methods such as dialysis, precipitation, and freeze-drying, which are poorly scalable, not compatible with cell viability, and often damages proteins. Currently, platelet-poor-plasma (PPP) is a discarded waste product of platelet-rich plasma (PRP) and may contain valuable chondrogenic proteins. PURPOSE: to determine the efficiency of a novel patient-side method of concentrating plasma and platelet- and white blood cell (WBC)-rich plasma as a potential adjunctive therapy for OA. METHODS: A laboratory study was conducted, with IRB and IACUC approval, using residual human clinical plasma (PPP) and equine blood samples. Samples and products were characterized for platelet, WBC, and total protein content then quantified by enzyme-linked immunosorbent assays specific to IGF-1, TGF- ß, IL-1ra, and IL-1 ß as anabolic and inflammatory mediators to cartilage. RESULTS: Plasma total and IGF-1 protein were concentrated by the device in both human (P<0.001) and equine (P<0.0001) plasma. TGF- ß, IL-1 and IL-1ra were very low in plasma. The polyacrylamide concentrator device highly concentrated platelets, WBCs, and plasma proteins over PRP and whole blood, most dramatically TGF- ß (P<0.001; 29-fold over blood) and IL-1ra (P<0.001; 70-fold over plasma) resulting in a > 2000-fold increase in IL-1/Il-1ra ratio over plasma (P<0.001) and 1668-fold increase over PRP (P<0.001). Interestingly, patients with OA had a lower anabolic protein profile (IGF-1 and TGF- ß) and a higher inflammatory-related protein profile (IL-1 ß and IL-1ra) compared to healthy equine athletes without OA. This work identified concentrated plasma as a unique resource for IGF-1 not found in PRP and that further protein concentration of PRP can produce greater platelet proteins such as TGF- ß and greater anti-inflammatory proteins such as IL-1ra. CONCLUSION: the polyacrylamide device efficiently concentrated plasma and PRP proteins and is commercially available as an injectable biotherapy.

Hip Muscle Strength Analysis of Individuals with Chronic Low Back Pain

Minjia wang, Yushi Hu, Yuanpeng Liao, Kaiwen Li, Siqi Song, Xiaofan Pang. *Chengdu Sport Institute, Chengdu, China.*
(No relevant relationships reported)

Chronic Low back pain (CLBP) is a common clinical disease, and most individuals require long-term treatment.
PURPOSE:Analysis the hip joint muscle characteristics of individuals with CLBP, in order to provide reference for rehabilitation and prevention of chronic low back pain. METHODS: 64 subjects with CLBP (age: 35.2±1.5 years, 34 males and 30 females, body weight: 66.5±3.7kg) were recruited as C group (experimental group), while 29 health subjects (age: 39.2±1.8 years, 16 males and 13 females, body weight: 64.8±3.2kg) were recruited as Y group (control group). Recorded the degree of pain (VAS, Visual Analogue Scale/Score) questionnaire, and used the isokinetic muscle testing System (Contrex System Top) to test the hip isokinetic muscle strength. Analysis the differences between C group and Y group, and the differences between the CLBP ones with different degree of pain (according to the VAS).
RESULTS: 1) There were no differences of hip flexor, extensor or adductor between C group and Y Group(P> 0.05); 2) Hip flexor/ extensor ratio (isokinetic strength) of C group were significant higher than Y group bilaterally, about 2.2 times higher(p < 0.01); This interesting result indicated that although the flexor or extensor as an independent index shows no difference between CLBP individuals and healthy individuals, but when it comes to consider the flexor and extensor as a functional group of body posture and movement, the CLBP individuals show a decrease of extensor compares with the flexor, and this also indicate the coordination of these two muscle groups maybe decrease in the CLBP ones ; 3) Hip abductor isokinetic muscle strength of Y group was significantly higher than C group, about 26% higher (p < 0.05), which means muscle strength of hip abductor of the CLBP individuals dereased; 4) In C group, according VAS score, the strength of flexor, extensor and abductor of mild ones(VAS 0-3) were significantly higher than moderate ones(VAS 4-7) (P< 0.05), the differences were 37%, 38% and 31% respectively.
CONCLUSIONS: The significant reduce of muscle strength of hip abductor is related to CLBP; CLBP individuals show a decrease of extensor compares with the flexor, and this indicate the coordination of these two muscle groups maybe decrease in the CLBP ones; And the more pain of CLBP, these muscle strength decrease more.

High Incidence Of Lumbar Intervertebral Disk And A Possible Risk Factor For Collegiate Weightlifters

Kenshiro Ohya[1], Koichi Nakazato[1], Koji koyama[2], Kazuo Funato[1], Naoyuki Kobatake[1], Toshiya Kita[1], Seiji Kubo[1], Fukuju Goto[1], Kenji Hiranuma[1]. *[1]Nippon sport science university, tokyo, Japan. [2]Tokyo Ariake University of Medical and Health Science, tokyo, Japan.*
(No relevant relationships reported)

Weightlifters experiences high mechanical stresses in their lumbar region. The intervertebral disks act as shock absorbers between each of the vertebrae in the spinal column. The disks of weightlifters may be injured by repetitive overload during weightlifting maneuvers. Previous studies have shown that excessive trunk rotation is a major risk factor for lumbar intervertebral disk degeneration (LIDD) in athletes. Although trunk rotation is not included in most weightlifting maneuvers, we hypothesized that there would be a high incidence of LIDD in collegiate weightlifters. PURPOSE: The purpose of this study was to examine the prevalence of LIDD in collegiate weightlifters. We also investigated possible risk factors for LIDD, except for excessive trunk rotation. METHODS: Forty Japanese collegiate weightlifters (25 men and 15 women; age, 19.6±1.1years; starting age, 15.1±0.9years; height, 164.7±8.0cm; weight, 71.9±14.kg). LIDD were evaluated using T2-weighted magnetic resonance images. Pfirrmann's classification was used to define LIDD and classify the subjects into either the LIDD group or the non-LIDD group. We also investigated physical characteristics such as body composition (height, weight, muscle mass, fat mass), joint range of motion (thoracic, lumbar, and hip), and lumbosacral alignment (lumbar angle, sacral angle, and lumbosacral angle). Student's t-test and logistic regression were used for statistical analyses. **RESULTS:** The prevalence of LIDD among weightlifters was 55.0%(22/40).Weight(77.3±16.40 vs. 65.7±10.24, $p=0.02$), fat mass(18.5±8.07 vs. 12.5±4.15, $p=0.07$), and body mass index(27.7±4.78 vs. 24.71±2.10, $p=0.02$) in the LIDD group were significantly higher than those in the non-LIDD group. Hip flexion angle (left: 121.5±10.10 vs. 126.9±6.15, $p=0.05$; right: 121.9±8.00 vs.127.9±7.06, $p=0.04$) and lumbar angle(18.3±6.04 vs. 24.2±4.65, $p=0.01$) were lower in the LIDD group compared to the non-LIDD group. By using logistic regression analysis including sex differences, lumbar angle was found to be a significant independent variable for LIDD (odds ratio, 1.34; 95%confidence interval 1.08-1.67, $p=0.01$). **CONCLUSION:** A high incidence of LIDD was observed in Japanese collegiate weightlifters. Lumbar angle is a possible risk factor.

Relationship Between Rotator Cuff Strength & Functional Scores After Bankart Repair

Geon Park[1], Wonhah Park[1], Dokyung Kim[1], Abhishek Gupta[2]. *[1]Samsung Medical Center, Seoul, Korea, Republic of. [2]JLN Medical College, Rajasthan, India.*
(No relevant relationships reported)

PURPOSE: The anterior instability is representing approximately 95% of all shoulder instabilities that mainly caused by an abduction, extension, and external rotation of the shoulder movement. However capsular laxity and unstable glenohumeral joint which make the most frequently dislocated joint in shoulder have closely related with rotator cuff weakness. This study examines the association between strength and functional indices in patients with Bankart repair. The purpose of the study is the relationship between internal rotator and external rotator muscle strength, shoulder functional indices (ROWE and ASES scores) post one year of the Bankart repair.
METHODS: This was a cross sectional study comprising of 40 patients, all males (24.5±13.5 yrs, ht 169.3±8.5 kg, and wt 67.8±11.4 kg) with Bankart lesion who may be treated arthroscopically. Isokinetic internal rotator(IR) and external rotator(ER) strength were evaluated with a CSMI dynamometer, with the subject seated and the shoulder abducted 45 in the scapular plane. Tests were performed at 60 /sec concentric mode for both sides. Shoulder strength was analyzed by comparison between involved side strength deficit and uninvolved side (side-to-side differences). Preoperatively and postoperatively, all the ROWE and ASES(American Shoulder and Elbow Surgeons) score was recorded that included subscores for ROM, muscle strength, pain, motion, and function.by the same exercise physiologist.
RESULTS: The patients were divided into 4 groups for comparison in muscle strength deficit- Q1 (less than 20% difference in muscle strength deficit), Q2 (21-35% deficit), Q3 (36-50% deficit), and Q4 (more than 50% difference in muscle strength deficit). In our study, ROWE and ASES score (r = - .305; r = - .382) were significantly correlative difference in Q1 (less than 20% deficit) group with IR and ER muscle strength.
CONCLUSIONS: This study suggests that muscle strength of the shoulder after Bankart repair will affect the functional ability more than any other factor. The muscle strength deficits in shoulder joint have significant negative consequences for the long term functional outcome after Bankart lesion. Therefore, it is deemed necessary to measure the muscle strength of the rotator cuff and continue rehabilitation exercise needed for recovery of muscle strength.

Kinesio Tape Fails to Affect Characteristics of Skeletal Muscle Recruitment

Cali A. VanValkenburg, Angela R. Nuccio, Angela M. D' Souza, Samantha Jamosmos, Cynthia Villalobos, Courtney D. Jensen. *University of the Pacific, Stockton, CA.*

(No relevant relationships reported)

Kinesio Tape (KT) is a popular therapeutic intervention in sports, aimed at optimizing athletic performance and preventing musculoskeletal injury. The manufacturers of KT claim it can alter characteristics of skeletal muscle recruitment, facilitating or inhibiting contraction depending on the nature of its application. Evidence of this claim is conflicted. **PURPOSE**: To assess the effectiveness of KT in changing recruitment properties of the rectus femoris. **METHODS**: Twenty college-aged, recreationally-active men and women with no history of injury were enrolled (11 men, 9 women). A Cybex Humac Norm dynamometer measured force output in the dominant leg in 3 taping conditions: 1) No tape applied (control), 2) KT applied to enhance muscle recruitment (facilitation), and 3) KT applied to impair muscle recruitment (inhibition). Subjects were tested on 3 separate days with 48 hours of rest between each; they performed no other exercise prior to and throughout the testing protocol. Subjects performed all 3 trials (control, facilitation, and inhibition) during each testing session, with randomization of the testing order. A certified KT practitioner applied the tape to each subject; subjects were blinded to the orientation of the tape (facilitation vs. inhibition). Mixed-design ANOVA tested differences in taping conditions (and taping conditions by gender) on force output. The between-subjects factor was gender; the within-subjects factor was taping condition. Differences in the within-subjects factor were tested with the Bonferroni post hoc correction. **RESULTS**: There were no differences between taping conditions (F=0.190; P=0.829) nor effects of treatment group by gender (F=1.634; P=0.226). Post hoc tests using the Bonferroni correction revealed no differences between any two treatment groups (p=1.000 for each comparison). **CONCLUSIONS**: The application of KT did not elicit changes in muscle recruitment patterns. KT neither facilitates skeletal muscle contraction nor inhibits it based on its application.

Comparison Between Platelet-rich Plasma Hyaluronic Acid Treatment For Talar Osteochondral Lesions; A Network Meta-analysis Of Randomized Controlled Trials

Wei Li. *Taipei medical university hospital, Taipei, Taiwan.*

(No relevant relationships reported)

Background: Both platelet-rich plasma (PRP) and hyaluronic acid (HA) with or without surgical intervention can enhance healing and improve function in talar OCLs. However, recent studies on OCLs have not thoroughly investigated the effects among PRP, HA, and conventional treatment.

Purpose: To synthesize evidence by comparing the effects (pain score and foot and ankle condition scores) among PRP, HA, and conventional treatment strategies for talar OCLs with or without surgical intervention.

Methods: All relevant research articles were included using related terms in the PubMed, EMBASE, Web of Science, ScienceDirect, and Cochrane library databases from their inception to June 2017. The screening criteria for this systematic review were as follows: randomized controlled trials (RCTs) that compared PRP with HA, PRP with control, or HA with control in patients with talar OCLs. The risk of bias in the included studies was assessed using the Cochrane Risk of Bias Tool. Data were extracted and recorded as weighted mean difference (WMD) and their standard deviations (SDs) with 95% confidence intervals (CI), consistency H, and I²for continuous data in the network meta-analysis.

Results: A total of 1199 references were identified, of which five RCTs were included in the final synthesis. These studies randomized 197 patients into the PRP, HA, and control groups. PRP caused higher reductions in the visual analog scale score than HA and conventional treatment, and the WMDs were −1.109 (95%CI: −1.716, −0.502) and −2.301 (95%CI: −2.825, −1.777). Moreover, PRP improved the American Orthopedic Foot and Ankle Society score more than the other treatment methods, and the WMDs were 12.448 (95%CI: 7.224, 17.672) and 18.617 (95%CI: 13.536, 13.698).

Conclusion: PRP reduced pain and improved ankle conditions to a greater extent than HA and conventional treatment. Therefore, PRP might be recommended for the treatment of talar OCLs. Further investigation is required to guarantee the safety and efficacy of different surgical treatments.

F-55   Free Communication/Poster - **Chronic Ankle Instability**

Influence of Prophylactic Ankle Tapes on Lower Extremity Kinematics during Stop-jump in Chronic Ankle Instability

Songah Chae[1], Youngmin Chun[1], Adrian Pettaway[1], Emi Takahashi[1], Russell Baker[1], Sae Yong Lee[2], Hyung-Pil Jun[1]. *[1]University of Idaho, Moscow, ID. [2]Yonsei University, Seoul, Korea, Republic of.* (Sponsor: Lee Brown, FACSM)

(No relevant relationships reported)

Nuremous tape applications have been used with patients who suffer from chronic ankle instability (CAI). The goal is to control the increased mechanical laxity associated with their condition during dynamic activity. The effect of these prophylactic ankle tapings on lower extremity kinematics has not been fully identified at this time. **PURPOSE:** To investigate the effects of traditional tape (TT), fibular repositioning tape (FRT), and kinesiology tape (KT) on peak joint angles of the lower extremity in individuals with CAI. **METHODS:** 14 individuals with CAI (age: 24.07±4.46 years; height: 175.06±5.09 cm; weight: 82.24± 10.38 kg; CAIT = 17.64 ± 4.14; FAAM-ADL = 86.69 ± 6.71; FAAM-SS = 75.45 ± 6.70) participated in the study. The Foot and Ankle Ability Measure Activity of Daily Living (FAAM-ADL), the FAAM Sports Subscale (FAAM-SS), and the Cumberland Ankle Instability Tool (CAIT) were used to screen subjects for CAI. The order of application of the taping conditions (TT, FRT, and KT) was randomly assigned. Peak angles of the hip, knee, and ankle joint during a stop-jump task, with and without the tape application, were collected using a 3D motion capture system. The following peak angles were measured: hip flexion (Flex), hip adduction (ADD), hip internal rotation (IR), knee Flex, knee abduction (ABD), knee IR, ankle dorsiflexion (DF), ankle inversion (IV), and ankle ADD. To examine differences across the conditions (Baseline, TT, FRT, KT), a repeated measures ANOVA was performed. **RESULTS:** A statistically significant difference in peak angle of each joint across the conditions was not found (hip Flex.: $F_{(3,39)}$ = .85, p = .47; hip ADD: $F_{(3,39)}$ = 1.90, p = .15; hip IR: $F_{(3,39)}$ = .67, p = .58; knee Flex.: $F_{(3,39)}$ = 1.85, p = .15; knee ABD: $F_{(3,39)}$ = 1.02, p = .39; knee IR: $F_{(3,39)}$ = .44, p = .73; ankle DF: $F_{(3,39)}$ = .66, p = .58; ankle IV: $F_{(3,39)}$ = 0.85, p = .47; ankle ADD: $F_{(3,39)}$ = 2.23, p = .10). **CONCLUSION:** The application of different taping techniques did not significantly change peak joint angles of the lower extremity during a stop-jump task. The results contradict previous research suggesting ankle taping restricts joint range of motion. Therefore, further investigation is needed to examine the influence of different prophylactic ankle taping techniques on sports performance, as well as muscle activation, during dynamic tasks.

Bracing Effects on Lower Extremity Movement Dynamics in Individuals With and Without Chronic Ankle Instability

Adam E. Jagodinsky[1], Rebecca Angles[1], Christopher Wilburn[2], Wendi H. Weimar[2]. *[1]Illinois State University, Normal, IL. [2]Auburn University, Auburn, AL.* (Sponsor: David Q. Thomas, FACSM)

(No relevant relationships reported)

INTRODUCTION: Ankle bracing is used ubiquitously as an injury prophylactic in both healthy and chronic ankle instability (CAI) populations. However, research shows that during walking ankle bracing diminishes coordination variability in the lower extremity in individuals with and without CAI, potentially limiting the adaptability of the motor system. An understanding of the systemic kinetic adaptations that drive coordination patterns is necessary to bolster aforementioned findings. Analysis of support moment (MS) variability during walking can provide information of systemic kinetic adaptations that occur in response to constraints acting on the system. **PURPOSE:** Examine bracing effects on MS variability during walking in healthy (H), ankle sprain "coper" (LAS), and CAI groups. **METHODS:** 48 individuals (16 per group) participated in the study. Participants performed 15 trials of walking during NB and B conditions. Position data were collected using a motion capture system, and reaction forces were obtained from force platforms. Joint kinetics were calculated using inverse dynamics, and the MS was calculated as the sum of ankle, knee, and hip moments in the sagittal plane. Variability of the MS was expressed as the percent coefficient of variation (%CV) across stance phase. A mixed ANOVA was conducted to compare the effects of condition across groups. **RESULTS:** A significant condition by group interaction was observed [F(2, 45) = 7.51, p = .002, partial η² = .25]. Paired samples t-tests revealed that for H, %CV was significantly lower during

---

B (11.85±3.06%) compared to NB (16.17±8.61%) (p =.02). For LAS, %CV was significantly greater during B (23.66±9.84%) compared to NB (20.06±6.48%) (p =.05). **CONCLUSION:** Bracing had a diminishing effect on %CV in the H group suggesting a limited capacity to adapt to task and environmental perturbation. Bracing had the opposite effect in the LAS group, suggesting that the motor system of "copers" may be more attuned to adaptation in response to neuromusculoskeletal constraints. More research is needed to explore how individual joint kinetic adaptations contribute to the %CV measure across groups and in response to bracing.

History of Ankle Sprains Related to Hindered Proprioception in College-Age Male Soccer Players

Paul N. Whitehead[1], Kim Beals[2], Mita Lovalekar[2], Kentaro Onishi[2], Takashi Nagai[3], Chris Connaboy[2]. [1]The University of Alabama in Huntsville, Huntsville, AL. [2]University of Pittsburgh, Pittsburgh, PA. [3]Mayo Clinic, Rochester, MN.
(No relevant relationships reported)

A deficit in proprioception following lateral ankle sprains (LAS) has been observed using various methods. The majority of studies on ankle proprioception focus on joint position sense, which measures the accuracy of position replication. However, threshold to detect passive motion (TTDPM) assesses one's ability to detect a change in positional homeostasis and tests the sensitivity of the slow-adapting mechanoreceptors required to adequately signal musculature to contract correctly during perturbations. **PURPOSE:** To examine the role of ankle injury history on TTDPM. **METHODS:** Fifty-eight male, club-level soccer players were divided into two equal groups: those with chronic ankle instability as a result of LAS (CAI-LAS; n=29, 22.8±4.5 yr, 78.1±11.1 kg, 180.0±8.7 cm) and those with no history of ankle injuries (CON; n=29, 21.5±3.1 yr, 78.2±11.6 kg, 180.6±6.7 cm). Subjects were positioned in an isokinetic dynamometer testing chair to align the heel with the axis of rotation. Visual and auditory cues were masked during testing. Trials were initiated at ~7 degrees of inversion, with the dynamometer moving at 0.25°/sec. When movement could be detected, subjects pressed a button to stop the dynamometer. Six successful trials were randomly collected and averaged for inversion and eversion. The primary outcome variable was angle error, measured as the number of degrees toward inversion or toward eversion from the initial position. Higher TTDPM values indicate worse proprioception. Following tests for normality of data distribution, Mann-Whitney U tests were used to compare group differences. Alpha level of 0.05, 2-sided was set *a priori* as a significance level. **RESULTS:** There was a significant difference between groups for inversion (p=0.016), with a 56.5% greater median angle error in CAI-LAS. Although there was not a statistically significant difference for eversion (p=0.181), CAI-LAS had 24.1% greater median angle error compared to CON. **CONCLUSION:** If TTDPM is used as a screening tool, it may highlight individuals at an increased risk of injury, signifying the requirement for corrective balance and/or strength training to be implemented as a means of preventing injury occurrence.

Effects of Three Prophylactic Tape Methods on Kinematics and Muscle Pre-activation in Chronic Ankle Instability

Adrian Pettaway[1], Youngmin Chun[1], Emi Takahashi[1], Songah Chae[1], Russell Baker[1], Sae Yong Lee[2], Hyung-pil Jun[1]. [1]University of Idaho, Moscow, ID. [2]Yonsei University, Seoul, Korea, Republic of. (Sponsor: Lee Brown, FACSM)
(No relevant relationships reported)

Prophylactic taping of the ankle is commonly used to prevent ankle sprains. Data supports the use of ankle taping strategies for limiting excessive range of motion often associated with ankle injuries. However, there is a paucity of evidence regarding the effects of ankle taping techniques on kinematics and muscle pre-activation in patients with chronic ankle instability (CAI). **PURPOSE:** To observe the effects of traditional tape (TT), fibular repositioning tape (FRT), and kinesiology tape (KT) on kinematics and muscle pre-activation during a stop-jump task in individuals with and without CAI. **METHODS:** A total of 28 subjects (14 healthy: age = 27.57 ± 3.23 years, height = 169.61 ± 8.33 cm, weight = 76.98 ± 17.95 kg; 14 CAI: age = 24.07 ± 4.46 years, height = 175.06 ± 5.09 cm, weight = 82.24 ± 10.38 kg) participated in the study. After collecting EMG data of reference voluntary contraction (RVC) by maximal vertical jump, all 6 EMG signals (tibialis anterior [TA], soleus [SOL], rectus femoris [RF], peroneus longus [PL], biceps femoris [BF], gluteus medius [GM]) were normalized by RVC. % RVC and lower extremity kinematics in the frontal and sagittal planes were collected at 100 ms prior to initial contact. All participants were assigned to three different tape applications applied in a randomized order. Participants executed the stop-jump task baseline assessment without tape and then with TT, FRT, and KT respectively. To examine differences in muscle pre-activation and kinematics, a 2-way mixed ANOVA (2 groups * 4 condition) was performed. **RESULTS:** A significant

interaction was observed in soleus pre-activation ($F_{(3,78)} = 5.913$; p < .05; $\eta^2 = .185$). The CAI group demonstrated significantly decreased SOL pre-activation after applying FRT and KT (baseline = 3.76 ± 2.41%; FRT = 1.40 ± 1.22 %, P< .05; KT = 1.45 ± 1.08 %, P < .05). The healthy group only displayed significantly reduced SOL pre-activation after receiving the KT application (baseline = 2.70 ± 1.47 %; KT = 1.20 ± 1.14 %, P< .05). No significant differences in joint angles were found between condition or group. **CONCLUSION:** In contrast to previous findings, KT application reduced SOL pre-activation. Further research is needed to examine if reduced SOL pre-activation after KT and FRT influences joint mechanics, which may affect the efficacy of the taping techniques.

2791   Board #74   June 1 3:30 PM - 5:00 PM

Prolonged Kinesiotaping Does Not Improve Balance and Functional Performances in People with Chronic Ankle Instability

Hoon Kim[1], Kota Z. Takahashi[2], Terry L. Grindstaff[3], Adam B. Rosen[2]. [1]Marquette University, Milwaukee, WI. [2]University of Nebraska at Omaha, Omaha, NE. [3]Creighton University, Omaha, NE.
(No relevant relationships reported)

Individuals with chronic ankle instability (CAI) often have balance and performance impairments. The use of Kinesio Tape (KT) to address these impairments has mixed findings with little evidence beyond immediate effects.
PURPOSE: To assess the prolonged use of KT versus a sham tape on static balance and functional performance in individuals with CAI.
METHODS: Twenty people with CAI (Age: 23.4±3.1 years; height: 169.3±8.3 cm; mass: 71.7±12 kg; Cumberland Ankle Instability Tool: 19.3±3.5) were randomly assigned to the KT (n= 10) or sham (a non-elastic) tape (ST) (n=10) group. Both groups had tape applied in consistent manner on the tibialis anterior, fibularis longus, and from the medial malleolus, across the plantar surface of the foot, to the lateral malleolus. The tape was worn for 3 days. Participants performed a single limb standing balance test (SLSB) on a force plate for 20s with eyes closed and a side hop test (SHT) 10 times laterally and medially. They were tested before (T1), immediately after (T2), and 3 days after taping (T3). Primary outcome measures included the velocity (cm/s) of the center of pressure in the mediolateral direction ($VCOP_X$), anteroposterior direction ($VCOP_Y$), and total excursion ($VCOP_T$) during SLSB and total time (s) to perform SHT. A two-way repeated measure multi-analyses of variance was used for data analysis.
RESULTS: There was no significant interaction effect between time points in the KT compared to ST groups on SLSB and SHT (p >.05). While $VCOP_X$ (T1: 5.02±1.46, T2: 4.53±1.71, T3: 4.13±1.91), $VCOP_Y$ (T1: 6.19±2.6, T2: 5.3±2.54, T3: 4.79±2.66), $VCOP_T$ (T1: 8.83±3.08, T2: 7.7±3.25, T3: 7.02±3.57), and the total time (T1: 11.47±4.21, T2: 10.12±3.36, T3: 9.48±2.95) decreased steadily over time in KT group, this was not a significant decrease compared to ST group $VCOP_X$ (T1: 5.08±1.69, T2: 4.83±1.93, T3: 5.32±2.43), $VCOP_Y$ (T1: 6.62±3.36, T2: 6.36±3.41, T3: 5.99±2.7), $VCOP_T$ (T1: 9.32±3.92, T2: 8.87±4.1, T3: 8.93±3.89), and total time (T1: 8.9±1.49, T2: 8.11±1.34, T3: 7.67±1.19) with *p*-values of .48, .58, .43, and .09 for each variable.
CONCLUSION: The prolonged use of KT on the ankle joint is not helpful to improve static balance and functional performance in people with CAI.

2792   Board #75   June 1 3:30 PM - 5:00 PM

Altered Movement Dynamics Between Individuals With and Without Chronic Ankle Instability Before and After Bracing

Rebecca S. Angles[1], Adam E. Jagodinsky[1], Christopher Wilburn[2], Wendi H. Weimar[2]. [1]Illinois State University, Normal, IL. [2]Auburn University, Auburn, AL. (Sponsor: Dave Thomas, FACSM)
(No relevant relationships reported)

INTRODUCTION: Sports medicine paradigms stress the importance of introducing variability into interventions aimed at improving function in individuals with chronic ankle instability (CAI). However, questions remain surrounding systemic variability patterns exhibited by CAI groups, particularly when additional constraints (i.e. brace) are imposed on the system. Analysis of support moment (MS) variability during walking can provide information of systemic kinetic adaptations that occur in response to neuromusculoskeletal constraints acting on the system. **PURPOSE:** Examine MS variability characteristics during walking in healthy (H), ankle sprain "coper" (LAS), and CAI groups during brace (B) and no brace (NB) conditions. **METHODS:** 48 individuals (16 per group) participated in the study. Participants performed 15 trials of walking during NB and B conditions. Position data were collected using a motion capture system, and reaction forces were obtained from force platforms. Joint kinetics were calculated using inverse dynamics, and the MS was calculated as the sum of ankle, knee, and hip moments in the sagittal plane. Variability of the MS was expressed

---

Abstracts were prepared by the authors and printed as submitted.

as the percent coefficient of variation (%CV) across stance phase. A mixed ANOVA was conducted to compare group effects during B and NB conditions. **RESULTS:** A significant condition by group interaction was observed [$F(2, 45) = 7.51$, $p = .002$, partial $\eta^2 = .25$]. Post-hoc tests for NB revealed that CAI ($13.04\pm3.46\%$) had significantly lower %CV compared to LAS ($20.09\pm6.48\%$) ($p = .011$). For B, CAI ($13.06\pm2.93\%$) and H ($11.85\pm3.06\%$) had significantly lower %CV compared to LAS ($23.66\pm9.84\%$) ($p < .001$). **CONCLUSION:** Individuals with CAI exhibit less %CV compared to LAS during stance phase of walking. This finding suggests that dysfunction leading to CAI may be associated with more rigid kinetic patterns following ankle injury. Additionally, bracing added to the disparity in %CV between CAI-LAS groups, and H-LAS groups. It is possible that LAS individuals have a greater capacity to adapt to imposed neuromusculoskeletal constraints (e.g. bracing) compared to healthy and CAI populations. More research is needed to explore how individual joint kinetic adaptations contribute to the %CV measure across groups and in response to bracing.

Effects of Three Tape Methods on Static Postural Control of Individuals with Chronic Ankle Instability

Youngmin Chun[1], Jinah Kim[2], Songah Chae[1], Emi Takahashi[1], Adrian Pettaway[1], Russell Baker[1], Sae Yong Lee[2], Hyung-pil Jun[1]. [1]*University of Idaho, Moscow, ID.* [2]*Yonsei University, Seoul, Korea, Republic of.* (Sponsor: Lee Brown, FACSM)
(No relevant relationships reported)

Individuals with chronic ankle instability (CAI) display poor static postural control due to impaired proprioception. While previous researchers have reported specific ankle tape applications enhance neuromuscular control, many clinically used applications have not been evaluated in patients with CAI. **PURPOSE:** To examine the effects of traditional tape (TT), fibular repositioning tape (FRT), and kinesiology tape (KT) on static balance control in individuals with CAI. **METHODS:** A total of 14 subjects with CAI (age = 24.07 ± 4.46 yr; height = 175.16 ± 5.10 cm; weight = 82.24 ± 10.38 kg; CAIT = 17.64 ± 4.14; FAAM-ADL = 86.69 ± 6.71; FAAM-SS = 75.45 ± 6.70) participated in the study. Participants performed three trials of a single-leg balance task on a force plate with a 10 second eyes-open (EO) and 10 second eyes-closed (EC) condition. The task was performed before and after applying TT, FRT, and KT. Dependent variables were standard deviation of the mean center of pressure (COP) displacement (SD_{ML}, SD_{AP}), COP excursion ($Range_{ML}$, $Range_{AP}$), the velocity of COP (Vel_{ML}, Vel_{AP}) in mediolateral ($_{ML}$)and anteroposterior ($_{AP}$) directions, and area of COP excursion (COP area). A repeated measure ANOVA was performed to examine differences across the conditions (baseline [BL], TT, FRT, KT). **RESULTS:** A significantly reduced Vel_{ML} was observed after applying FRT (BL = 2.67 ± 0.29cm/s; FRT = 2.34 ± 0.36cm/s; p<.05) with EO. With EC, a significant decrease in Vel_{ML} (BL = 5.21 ± 0.83 cm/s; FRT = 4.43 ± 0.68 cm/s; p<.05) and Vel_{AP} (BL = 4.47 ± 0.70 cm/s; FRT = 3.85 ± 1.01 cm/s; p<.05) was also found. The application of KT significantly reduced Vel_{ML} (BL = 5.21 ± 0.83 cm/s; KT = 4.60 ± 0.69 cm/s; p<.05). Significant differences between BL and tape interventions were not found for SD_{AP}, $Range_{AP}$, and COP area. The application of TT produced increased SD_{AP} (TT = 1.33 ± 0.20 cm, FRT = 1.20 ± 0.16 cm; p<.05), $Range_{AP}$ (TT = 5.98 ± 0.98 cm; FRT = 5.67 ± 0.68 cm; p<.05), and COP area (TT = 26.52 ± 6.33 cm², p<.05; FRT= 22.83 ± 4.86 cm, p<.05) compared to FRT application. **CONCLUSION:** Based on our findings, FRT is a more effective technique to enhance static postural control than TT, KT, or no tape. Further study is needed to investigate the effect of FRT on dynamic postural control, as well as kinematics during specific movements, to guide FRT application in clinical practice.

Altered Movement Neuromechanics during Jump Landing and Cutting in Patients with Chronic Ankle Instability

Hyunsoo Kim[1], S. Jun Son[2], Matthew K. Seeley[2], J. Ty Hopkins, FACSM[2]. [1]*West Chester University, West Chester, PA.* [2]*Brigham Young University, Provo, UT.* (Sponsor: J. Ty Hopkins, FACSM)
(No relevant relationships reported)

Lateral ankle sprains are common lower extremity injury during sport activities, which often lead to chronic ankle instability (CAI). However, no one has comprehensively examined the effects of CAI on lower extremity movement neuromechanics during a multiplanar, single-leg landing and cutting task for CAI patients. **PURPOSE**: To investigate the effect of CAI on landing and cutting lower-extremity kinematic, electromyography (EMG), and ground reaction force (GRF). **METHODS**: 100 CAI patients (22 ± 2 yrs, 174 ± 10 cm, 71 ± 14 kg, $82\pm9\%$ FAAM ADL, $62\pm13\%$ FAAM Sports, 4.5 ± 2.6 ankle sprains) and 100 controls (22 ± 3 yrs, 172 ± 13 cm, 72 ± 18 kg, 100% FAAM ADL & Sports) participated. Participants performed five successful trials of a jump landing and cutting task. Sagittal and frontal planes of ankle, knee and hip joint angles, EMG activation, and GRF were collected during jump landing and cutting. Functional analyses of variance (FANOVA) were used to evaluate between-group differences for these dependent variables throughout the entire ground contact

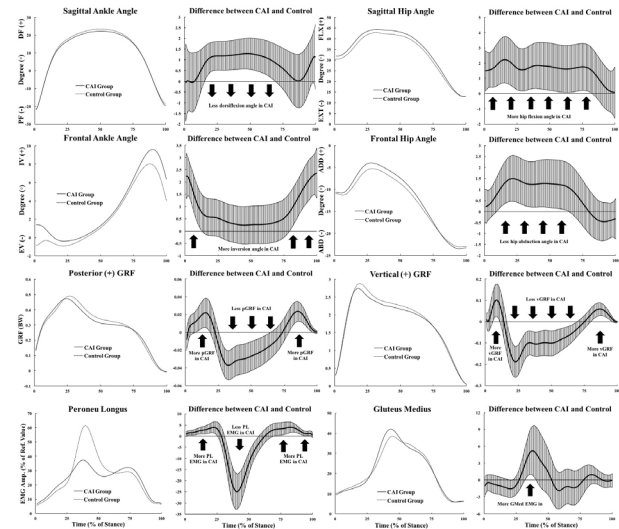
phase of the task. **RESULTS**: Figure 1. Relative to the control group, the CAI group revealed (i) reduced dorsiflexion and hip flexion angles, (ii) increased inversion and reduced hip abduction angles, (iii) increased posterior and vertical GRF during initial landing, and reduced posterior and vertical GRF, and (iv) increased EMG activation of peroneus longus, and gluteus medius during mid-landing and cutting phase. **CONCLUSION**: Our data suggest that CAI patients demonstrated different movement strategies during jump landing and cutting. Compared to controls, patients with CAI utilized the proximal (hip) joint with heightened corresponding muscle activation to compensate for a potentially unstable distal (ankle) joint (e.g., more inversion and less dorsiflexion angle) in an attempt to reduce ground impact force. This apparent compensation may be due to sensorimotor deficits in the ankle.


Figure 1. Plantarflexion/dorsiflexion (PF/DF), hip flexion/extension (FLX/EXT), inversion/eversion (IV/EV), hip abduction/adduction (ABD/ADD) angle, posterior and vertical ground reaction force (GRF), and EMG amplitude for peroneus longus (PL) and gluteus medius (GMed) during stance phase of jump landing/cutting tasks. Mean differences (bold solid curve) and corresponding 95% CI (shaded area) are plotted as a function of time. When the shaded area does not overlap with the zero line (bold horizontal line), a significant difference (p <0.05) is indicated between groups.

Dorsiflexion Range of Motion Alters Energy Absorption and Generation during Landing/Cutting in Chronic Ankle Instability

Andrew Harris, S. Jun Son, Dustin Bruening, Brent Feland, Matthew Seeley, Ty Hopkins, FACSM. *Brigham Young University, Provo, UT.* (Sponsor: J. Ty Hopkins, FACSM)
(No relevant relationships reported)

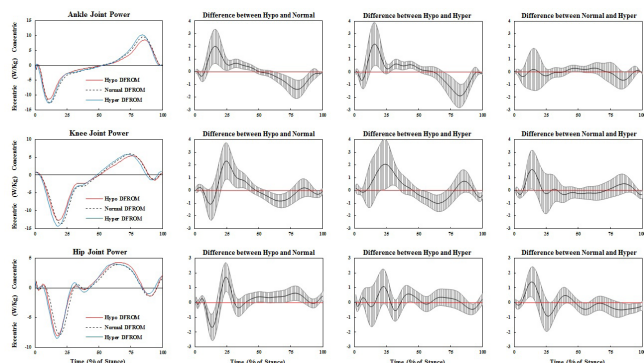
Decreased dorsiflexion range of motion (DFROM) has been identified as a risk factor for ankle sprains. Patients with chronic ankle instability (CAI) demonstrate reduced DFROM during walking, running, landing, and cutting. However, variation in DFROM exists within a CAI population. It remains unclear whether varied DFROM affects lower extremity joint energetics during a jump landing/cutting task. **PURPOSE**: To examine a relationship between varied DFROM within the CAI population and lower extremity energy absorption (eccentric power) and generation (concentric power) during jump landing/cutting. **METHODS**: 100 CAI subjects were classified into 3 subgroups based on DFROM, measured by the weight-bearing lunge test: a Hypo (14M, 10F; $\leq 39°$; $35\pm2.5°$, 23 ± 2 yrs, 176 ± 13 cm, 80 ± 13 kg), Normal (25M, 32F; 40-50°; $46\pm2.6°$, 21 ± 2 yrs, 174 ± 7 cm, 72 ± 14 kg), and Hyper DFROM group (11M, 8F; $\geq 51°$; $54\pm3°$, 22 ± 2 yrs, 175 ± 11 cm, 74 ± 14 kg). Subjects performed 5 jumps consisting of a max vertical jump-landing plus a side-cut. Functional liner models were used to detect between-group differences. If 95% confidence intervals did not cross zero, differences were significant. **RESULTS**: Figure 1 shows that CAI subjects with Hypo DFROM showed decreased ankle and knee energy absorption and generation power and increased hip absorption and generation power compared to Normal and/or Hyper DFROM groups (p < 0.05). **CONCLUSIONS**: While CAI subjects with Normal and Hyper DFROM show similar lower extremity energetic patterns during the task, CAI patients with Hypo DFROM appear to have a limited ability to absorb and generate kinetic energy in the ankle and knee, which seems to increase a kinetic compensation at the hip (greater energy absorption and generation). These kinetic alterations may increase injury risk and performance deficits.


Figure 1. Grand ensembles for sagittal-plane joint energetics in the lower extremity during a jump landing/cutting task between the Hypo, Normal, and Hyper DFROM groups. 0% of stance indicates initial foot contact, 50% of stance indicates peak ankle dorsiflexion and knee flexion, and 100% of stance indicates toe-off during the task. When 95% confidence intervals (shaded area) did not cross the zero (horizontal red line), between-group differences were significant.

Immediate Effects of Ankle Tapes on Dynamic Postural Control and Kinematics in Chronic Ankle Instability

Emi Takahashi[1], Youngmin Chun[1], Jinah Kim[2], Adrian Pettaway[1], Russell Baker[1], Sae Yong Lee[2], Hyung-pil Jun[1]. [1]University of Idaho, Moscow, ID. [2]Yonsei University, Seoul, Korea, Republic of. (Sponsor: Lee Brown, FACSM)
(No relevant relationships reported)

Numerous taping methods have been used to prevent ankle sprains in patients with chronic ankle instability (CAI). The effects of different taping methods on dynamic postural control in patients with CAI, however, are not fully understood. **PURPOSE**: To examine the effects of traditional taping (TT), fibular repositioning taping (FRT), and kinesiology taping (KT) on joint angles and modified Y-balance test (YBT) performance in participants with and without CAI. **METHODS**: A total of 28 subjects (14 CAI: age = 24.07 ± 4.46 yr, height = 175.16 ± 5.10 cm, weight = 82.24 ± 10.38 kg; 14 Healthy: age = 27.57 ± 3.23 yr, height = 169.61 ± 8.33 cm, weight = 76.98 ± 17.95 kg) participated in the study. Subjects performed three trials of the modified YBT before and after receiving TT, FRT, and KT. Hip, knee, and ankle joint angles in sagittal and frontal planes at the moment of maximum reach distance in the anterior (Ant), posterolateral (PL), and posteromedial (PM) directions were collected. Each reach distance was measured and a composite score (CS) was calculated. A 2-way mixed ANOVA (2 groups * 4 conditions) was performed to examine differences across treatments (baseline [BL], TT, FRT, KT). **RESULTS**: Significant interactions were not found. However, a significant decrease in PM reach distance was found across all tape applications for both groups ($F(1.97, 51.16) = 55.58$, $p < .05$, $\eta2 = .68$). KT and FRT resulted in significant improvement in the modified YBT CS compared with TT (Healthy: KT = $92.24 \pm 5.72\%$, $p < .05$, TT = $89.76 \pm 5.97\%$; $p < .05$, FRT = $91.83 \pm 6.53\%$; $p < .05$; CAI: KT = $90.01 \pm 6.49\%$; $p < .05$, TT = $86.63 \pm 6.83\%$; $p < .05$, FRT = $87.88 \pm 8.39\%$; $p < .05$). The CS was also significantly increased when comparing KT to BL (Healthy: BL = $90.91 \pm 7.28\%$; $p < .01$, KT = $92.24 \pm 5.72\%$, $p < .05$; CAI: BL = $87.47 \pm 6.62\%$; $p < .05$, KT = $90.01 \pm 6.49\%$). Analysis of kinematic data revealed a significant increase in dorsiflexion during the PM reach when KT was applied ($F(2.26, 58.66) = 3.89$, $p < .05$, $\eta2 = .13$). **CONCLUSIONS**: Even though PM reach distance significantly decreased after applying any of the tape conditions, only KT significantly increased DF and an improved YBT CS compared to BL. The findings suggest KT might enhance dynamic postural control more than the other tape applications. Further research is necessary to explain the mechanism for these changes after KT application.

Joint Stiffness Alterations, Grouped by Movement Strategy, in Chronic Ankle Instability

J. Ty Hopkins, FACSM[1], S. Jun Son[1], Hyunsoo Kim[2], Matthew K. Seeley[1]. [1]Brigham Young University, Provo, UT. [2]West Chester University, West Chester, PA.
(No relevant relationships reported)

Subgroups of ankle instability (AI) subjects, based on specific movement strategies, allow for evaluation of neuromechanical deficits that are specific to the adopted movement. Joint stiffness provides important information as to stability and loads directed to each of the lower extremity joints. **PURPOSE**: to describe lower extremity stiffness of 6 subgroups (clusters) of patients with AI compared to an uninjured control group. **METHODS**: 200 CAI patients (22 ± 2.2 yrs, 174 ± 10 cm, 73 ± 14 kg, $84 \pm 7\%$ FAAM ADL, $65 \pm 11\%$ FAAM Sports, 4.1 ± 2.4 ankle sprains) and 100 controls (22 ± 3 yrs, 172 ± 13 cm, 72 ± 18 kg, 100% FAAM ADL & Sports) participated. Participants performed five successful trials of a jump landing/cutting task. Lower extremity sagittal and frontal plane kinematics (ankle, knee, and hip) were reduced to single

representative curves using principle component analysis, and the resultant curves were simultaneously used to cluster movement with a Dirichelet process. Six distinct clusters were identified, and joint stiffness values for each of the clusters were calculated and compared to a control group using functional linear models ($P<0.05$). **RESULTS**: Table 1. Several clusters demonstrated reduced stiffness at the ankle (C1, 3, 5), reduced stiffness at the knee (C1-4), and increased stiffness at the hip (C1, 2, 6). **CONCLUSIONS**: Multiple, distinct joint stiffness patterns were identified in clusters of AI subjects. Generally, distal joint stiffness was less than controls, while proximal joint stiffness was greater than controls, supporting the idea that the hip plays a key role in controlling lower extremity movement in AI subjects. Joint stiffness varies according to the movement strategy adopted by each AI subject, and alterations in joint stiffness patterns are a potential source of acute and chronic (re)injury.

Table 1. Joint stiffness means ± SD (Nm/kg/°) for each of the clusters.
* Represents different from control ($P \geq 0.05$).

Cluster	Ankle	Knee	Hip

Recommended Number of Trials for Balance and Hopping Tests between Male and Female CAI Subjects

Jordan R. Read[1], S. Jun Son[2], Dustin Bruening[2], Brent Feland[2], Matthew Seeley[2], Ty Hopkins, FACSM[2]. [1]University of North Texas Health Science Center, Fort Worth, TX. [2]Brigham Young University, Provo, UT. (Sponsor: Ty Hopkins, FACSM)
(No relevant relationships reported)

The recommended number of practice trials for the Biodex static balance (3 trials) and star excursion balance test (SEBT; 4-9 trials) are available in the literature, but, previous studies on these tests did not report the recommendations for male and female and used a small sample size (n = 16-20). Moreover, no data are available for the recommended number of practice trials for triple cross-over hop and figure 8 hop tests. Considering physiological differences in gender, a large sample size is necessary to clarify this issue. **PURPOSE**: To determine the number of practice trials necessary to achieve functional performance for static and dynamic balance and hopping tests between male and female. **METHODS**: 50 male (22 ± 2 yrs, 182 ± 8 cm, 81 ± 12 kg) and 50 female (21 ± 2 yrs, 166 ± 6 cm, 67 ± 12 kg) subjects with chronic ankle instability (CAI) performed 6 practice and 3 test trials of the Biodex static balance test (single-leg), SEBT (anterior, posterolateral, posteromedial), triple cross-over hop for distance test, and figure 8 hop for time test, 2-3 days apart. The order of the tests were randomized. One-way repeated-measures ANOVAs with multiple comparisons using Dunnett's Method were used to detect time and gender effect ($p < 0.05$). **RESULTS**: Table 1 shows that the required number of practice trials for the hopping tests is 3-4 for male and 2-3 for female subjects prior to testing. The number of required trials for the SEBT is 2-5 for male depending on the direction and 3 for female. For the Biodex static balance, 5 practice trials are needed for both male and female prior to testing. **CONCLUSIONS**: Considering physiological differences in gender, the required number of practice trials appears to vary in the SEBT, triple cross-over and figure 8 hop test between genders. Male subjects may need more practice trials than female to achieve their best performance. Researchers should allow subjects to perform practice trials based on gender to obtain accurate data on these functional performance tests.

Table 1. Results of the recommended number of practice trials for each of four functional tests.

	Practice 1		Practice 2		Practice 3		Practice 4		Practice 5		Practice 6		Test 1

Force- and Velocity-Profile Differences Between Good and Poor Countermovement Vertical Jumpers

John R. Harry[1], Leland A. Barker[2], Janet S. Dufek, FACSM[2], C. Roger James, FACSM[3]. [1]Texas Tech University, Lubbock, TX. [2]University of Nevada, Las Vegas, Las Vegas, NV. [3]Texas Tech University Health Sciences Center, Lubbock, TX. (Sponsor: Janet S. Dufek, FACSM)
(No relevant relationships reported)

Good countermovement vertical jump (CMVJ) performers, as defined by CMVJ height, exhibit quicker countermovements than poor jumpers via quicker unloading phases. Still, it is unknown how good jumpers manipulate ground reaction force (GRF) and velocity to more quickly complete unloading. **PURPOSE:** To assess GRF and velocity profiles between good and poor jumpers. **METHODS:** 12 men (27.3 ± 3.0 y; 88.1 ± 16.4 kg; 1.8 ± .1 m) performed 8 CMVJ as GRF data were obtained. Velocity was computed from GRF. Data were normalized to 101 data points to define the time from unloading to takeoff. Mean and standard deviation profiles were computed per participant. Good (n = 6; .45 ± .05 m) and poor (n = 6; .33 ± .05 m) groups were determined by the median CMVJ height ($v_{to}^2/2g$) for the sample. Groups were compared at each data point using effect sizes (large ≥ .80). The unloading, eccentric, and concentric phase times were compared visually from the mean GRF and velocity data. **RESULTS:** Good jumpers unloaded less bodyweight and showed shorter unloading and longer concentric phases (Fig 1). For GRF and velocity, trivial, small, moderate, and large differences were detected for 25%, 42%, 26%, and 8% and for 18%, 64%, 11%, and 8% of the CMVJ, respectively (Fig 2). **CONCLUSION:** Good jumpers perform quicker unloading phases by unloading lesser bodyweight. Thus, they achieve greater GRF and velocity prior to takeoff. Poor jumpers might benefit from performance cues promoting quicker unloading and enhanced eccentric braking. Such cues might allow for enhanced CMVJ performance.
Partially supported by a National Strength and Conditioning Association Foundation Grant.

Medial Post Foot Orthotic Influences Knee Valgus Angle Excursions During a Vertical Jump Task

Jerry Zoubek, Timothy Kranz, Lindsay Perotti, Elle Stark, Michelle Stella, Adam S. Lepley. University of Connecticut, Storrs, CT.
(No relevant relationships reported)

Medial posting is a common therapeutic midsole foot orthotic that is used to control excessive pronation movement, and creating a more supinated position of the foot. Consequently, these altered biomechanics may also create more favorable movements at other joints, such as the knee. Knee valgus angle has been identified as a risk factor for lower extremity joint injury, and medial posting may reduce excessive valgus during dynamic tasks, therefore decreasing the risk of injury. **Purpose:** Investigate if medial post orthotics influence knee valgus and performance outcomes during a vertical jump. **Methods:** Thirty healthy participants volunteered (18m/12f; age 24.8 ± 3.1y; height 173.94 ± 8.72cm; mass 73.7 ± 13.2kg). Six maximal vertical jump trials were recorded using electromagnetic 3D biomechanical and force plate assessment. Three trials were performed with bilateral medial posting orthotics, and three without, with the order randomized. Max vertical jump height, jump power, and total valgus range of motion (excursion) during the take-off phase were extracted for each limb and averaged across the three trials for analysis. Paired samples t-tests were performed to assess differences in outcomes between orthotic conditions. Alpha level was set a priori at P ≤ 0.05. **Results:** There were no differences in vertical jump height between the orthotic (46.9 ± 9.0cm) and no orthotic conditions (46.1 ± 8.6cm, t = -0.58, p = 0.56). Jump power also was the same between the orthotic (1219.4 ± 520.9) and no orthotic conditions (1243.5 ± 456.5W, t = 0.35, p = 0.72). Both the left (orthotic: 15.2 ± 7.4°; no orthotic: 18.3 ± 10.5°; t = 2.46, p = 0.02) and right (orthotic: 17.9 ± 8.6°; no orthotic: 19.9 ± 12.4°; t = 1.96, p = 0.05) limbs demonstrated significantly less knee valgus excursion when using the orthotic. **Conclusions:** The medial post orthotic was successful at reducing knee valgus excursion angles during a maximal vertical jump, while also maintaining vertical jump performance, measured via vertical jump height and power. Although medial posting is a common orthotic to correct excessive pronation at the foot, it may also have therapeutic efficacy at knee joint injury prevention during dynamic tasks.

Influence of Holding a Lacrosse Stick on Jump Landing Mechanics

Kylie Calandra, Dr. Matthew Moran. Sacred Heart University, Fairfield, CT.
(No relevant relationships reported)

Female athletes are at an increased risk for anterior cruciate ligament (ACL) injuries by noncontact mechanisms. Close to 60% of all severe injuries sustained during a game are lower extremity strains and knee internal derangements, frequently involving the ACL. No research has been done to investigate the alteration of movement patterns as a result of holding a lacrosse stick. The Landing Error Scoring System (LESS) is a biomechanical movement screen able to detect and quantify these abnormal movement patterns. **PURPOSE**: To determine the effect of holding a lacrosse stick on jump landing mechanics in female collegiate players during a standardized biomechanical screen (LESS). **METHODS**: The LESS was used on 20 collegiate women's lacrosse players (19.7±1.4 yo, 60.8±5.6 kg, 1.66±0.06 m) to examine jump landing mechanics with a lacrosse stick (WS) versus without (WO). Participants jumped forward off a 30-cm box to a spot on the floor 50% of their body height, and performed a maximal vertical jump upon landing. Hi-speed video (240Hz) was recorded in the sagittal and frontal planes. Sixteen biomechanical criteria were measured using video analysis software, and averaged across three trials for each stick condition. The independent variable (holding a lacrosse stick) was counterbalanced, and dependent t-tests were used to compare between LESS scores. **RESULTS**: There was a significant relationship between poor landing mechanics and holding a lacrosse stick reflected in the LESS scores (WS=4.46±0.69, WO=3.16±0.79, p<0.05). At initial contact, knee flexion (WS=27.1°±3.7°, WO=30.7°±3.9°, p<.01), hip flexion (WS=28.8°±3.2°, WO=31.7°±3.1°, p<0.01), and trunk flexion (WS=14.1°±5.7°, WO=17.9°±5.5°, p<0.01) angles were significantly reduced when landing with a stick. Joint flexion displacement, however, was not significantly different (p>0.05). **CONCLUSIONS**: Holding a lacrosse stick significantly changed participant's initial landing position with knees being closer together and an overall more extended posture. Sport dependent variation in arm positioning influences lower extremity movement patterns, demonstrated by the LESS scores. Coaches should consider implementing sport specific upper extremity constraint during ACL prevention programs to increase potential transfer to sport-specific movements.

Mechanical Differences between Adolescents and Adults during Two Landing Phases of a Drop Jump Task

Gavin L. Moir, Shawn N. Munford, Brandon W. Snyder, Shala E. Davis, FACSM. *East Stroudsburg University, East Stroudsburg, PA.* (Sponsor: Shala E. Davis, FACSM)
(No relevant relationships reported)

PURPOSE: To investigate the mechanical differences between the first and second landing phases of a drop jump task performed by adolescent and adult males. **METHODS**: Eleven adolescent basketball players (age: 16.5 ± 0.7 years; height: 1.78 ± 0.07 m; mass: 68.9 ± 8.8 kg) and eleven resistance-trained adults (age: 22.3 ± 1.9 years; height: 1.80 ± 0.10 m; mass: 84.3 ± 9.3 kg) performed two trials of a drop jump from a height of 0.40 m. Force plates (1000 Hz) and an 8-camera 3-D motion analysis system (200 Hz) were used to determine vertical landing velocity (v_{LAND}), the duration of the absorption phase (AT), countermovement depth during absorption phase (CM), normalized peak vertical force during absorption (PF_{NORM}), and the normalized peak extensor moments at the hip (PM_{HIP}), knee (PM_{KNEE}), and ankle (PM_{ANKLE}) joints during absorption.
RESULTS: Adults produced significantly greater v_{LAND} than the adolescents (mean difference [MD]: 0.21 m/s, p=0.004) and v_{LAND} of the second landing was significantly greater than the first (MD: 0.24 m/s, p=0.046). Adolescents produced significantly shorter AT (MD: 0.09 s, p=0.014) and significantly lower CM (MD: 0.16 m, p<0.001) compared to the adults. CM during the second landing was significantly lower than that during the first (MD: 0.08 m, p=0.002). Adolescents produced significantly greater PF_{NORM} during each landing compared to the adults (MD: 1.34 BW, p=0.003) and PF_{NORM} during the second landing was significantly greater than that during the first (MD: 1.88 BW, p<0.001). The adolescents produced significantly greater peak joint moments compared to the adults (MD: 1.48 Nm/kg, p=0.001) and the peak moments during the second landing for both groups were significantly greater than those during the first (MD: 0.65 Nm/kg, p=0.024). PM_{HIP} was significantly greater than PM_{KNEE} (MD: 1.75 - 3.48 Nm/kg, p≤0.001) while PM_{KNEE} was significantly greater than PM_{ANKLE} (MD: 1.73 Nm/kg, p<0.001). The increase in the PM_{ANKLE} between the first and second landing was significantly greater than PM_{HIP} (MD: 1.89 Nm/kg, p=0.003) and PM_{KNEE} (MD: 0.93 Nm/kg, p=0.010).
CONCLUSIONS: The neuromuscular strategy utilized by adolescent males when landing that results in greater forces exerted during shorter absorption phases may predispose them to musculoskeletal injuries.

Alternate Forms Reliability of Reactive Strength Assessments during Depth and Repetitive Countermovement Jumping

Jake Rosburg, Nile Banks, Jordan Preuss, Lara Boman, Talin Louder. *The University of South Dakota, Vermillion, SD.*
(No relevant relationships reported)

Reactive strength assessments are most commonly made using either a depth or repetitive countermovement (RCM) jumping protocol. Reactive strength measures, such as the Coefficient of Reactivity (CoR), Reactive Strength Index (RSI), and Reactive Strength Kinetic (RSK) can be modified for computation using either of the two jumping protocols. Since researchers and practitioners assume comparability of scores across protocols, it is important to assess the extent that reactive strength scores achieved in the depth jump protocol translate to scores achieved in the RCM jumping protocol.
PURPOSE: The purpose of this study was to assess the alternate forms reliability of reactive strength scores achieved in the depth jumping protocol and in the RCM jumping protocol.
METHODS: Thirty-four young adults from the general community and 21 NCAA Division I basketball players performed five RCM jumps and depth jumps from 0.51 m, 0.66 m, and 0.81 m above the laboratory floor. The CoR, RSI, and RSK were computed using tri-axial force platform data and two-dimensional videography. Linear Regressions and intraclass correlation coefficients (ICC) were used to assess the alternate forms reliability of depth jump and RCM reactive strength scores.
RESULTS: Collapsed across sex and sport participation, ICC's comparing reactive strength scores in depth jumping and RCM jumping ranged from 0.71 to 0.77 (RSK), 0.84 to 0.88 (RSI), and -0.01 to -0.05 (CoR). Regressions detected significant associations between RSK (R^2=0.31 - 0.48, p<0.000) and RSI (R^2=0.53 - 0.59, p<0.000) scores in depth jumping versus RCM jumping. Regressions failed to detect significant associations between CoR scores in depth jumping versus RCM jumping (R^2=0.00)
CONCLUSION: RSK and RSI scores in depth jumping explained between 31 and 59% of the variance in reactive strength scores in RCM jumping. These results suggest that scores obtained from the RCM jumping protocols are not necessarily predictive of reactive strength scores in depth jumping. Additionally, these results suggest that the RCM jumping protocol may not be as specific of an assessment of reactive strength in young adults when compared against the depth jumping protocol.

Differences in Joint Mechanics Between Adolescent and Adult Males Performing Countermovement and Drop Jump Tasks

Shawn N. Munford, Brandon W. Snyder, Gavin L. Moir, Shala E. Davis, FACSM. *East Stroudsburg, East Stroudsburg, PA.*
(No relevant relationships reported)

Purpose: To investigate the differences in joint mechanics between adolescent and adult males performing countermovement and drop jump tasks. **Methods:** Eleven adolescent basketball players (age: 16.5 ± 0.7 years; height: 1.78 ± 0.07 m; mass: 68.9 ± 8.8 kg) and eleven resistance-trained adults (age: 22.3 ± 1.9 years; height: 1.80 ± 0.10 m; mass: 84.3 ± 9.3 kg) performed two trials of a countermovement jump (CMJ) and a drop jump from a height of 0.40 m (DJ). Force plates (1000 Hz) and an 8-camera 3-D motion analysis system (200 Hz) were used to determine the following kinetic variables for the hip, knee, and ankle joints during the propulsive phase of each jump: normalized work performed by the moment (JW_{NORM}), normalized power output of the moment (JPO_{NORM}), and normalized joint stiffness (JS_{NORM}). **Results:** The adults produced significantly greater JW_{NORM} across the two jumps (mean difference [MD]: 0.32 J/kg, p=0.014). JW_{NORM} at the knee was greater than that at the hip (MD: 2.09 J/kg, p<0.001) and the ankle (MD: 2.61 J/kg, p<0.001), while JW_{NORM} was greater at the hip compared to the ankle (MD: 0.52 J/kg, p=0.001). The adults performed greater JW_{NORM} at the hip compared to the adolescents (MD: 0.75 J/kg, p=0.005). JPO_{NORM} at the knee was greater than at the hip (MD: 4.49 W/kg, p<0.001) and ankle (MD: 4.32 W/kg, p<0.001) across the two jumps while JPO_{NORM} was significantly greater in DJ compared to CMJ (MD: 0.49 W/kg, p=0.10). The adolescents produced significantly greater JPO_{NORM} at the ankle compared to the adults (MD: 1.35 W/k, p=0.002). The adolescents produced significantly greater JS_{NORM} compared to the adults (MD: 0.021 Nm/kg/deg, p=0.046). Both groups produced significantly greater JS_{NORM} in DJ compared to CMJ (MD: 0.015 Nm/kg/deg, p=0.001) with significant increases in JS_{NORM} at the knee joint from CMJ to DJ (MD: 0.02 Nm/kg/deg, p<0.001). The increase in JS_{NORM} at the hip (MD: 0.025 Nm/kg/deg, p=0.033) and knee (MD: 0.023 Nm/kg/deg, p=0.046) between CMJ and DJ was significantly greater in adolescents compared to adults. **Conclusion:** Adolescent males produce different joint mechanics compared to adults during jumping tasks and rely on a strategy of increasing joint stiffness at the
hip and knee joints when performing DJ. These differences may have implications for musculoskeletal injuries in adolescent males.

Effect of Fatigue on Leg Muscle Activation and Tibial Acceleration during a Jumping Task

Michelle A. Sandrey, Yu-Jen Chang, Krista Meder, Jean L. McCrory, FACSM. *West Virginia University, Morgantown, WV.* (Sponsor: Jean L. McCrory, FACSM)
(No relevant relationships reported)

Lower extremity stress fractures are a common occurrence during load bearing activities of jumping and landing. To detect biomechanical changes during jumping while injured, a fatigue model could be used. **PURPOSE**: To evaluate muscle activation and tibial accelerations in the triceps surae complex, anterior compartment and tibia pre-to-post fatigue following a jumping task. **METHODS**: Thirty active college-aged subjects with and without a previous history of stress fractures were recruited (15 male, 15 female, 21.5±5.04 yrs, ht=173.5±12.7cm, wgt =72.65 16.4±kg) resulting in 177 leg trials for evaluation (control, stress fracture injured and stress fracture contralateral). EMG activity and acceleration of the proximal tibia were recorded pre-to-post fatigue. The EMG protocol consisted of surface electrodes placed on the medial gastrocnemius (MG), soleus (SOL), and tibialis anterior (TA) following a standardized placement protocol. A triaxial accelerometer was attached to the proximal anterior surface of the tibia. Subjects performed a maximal vertical jump on one leg 3 times with arms folded across the chest pre-to-post fatigue. Standing heel raises on a custom built platform at a pace controlled by a metronome until task failure was reached was used for the fatiguing protocol. Legs were tested using a randomized testing order. Pre-to-post fatigue measurements included the linear envelopes of the MG, SOL and TA and peak accelerations (resultant acceleration in take-off and landing). **RESULTS**: There was an interaction for leg and test for TA (P=.050) with a difference between stress fracture and control posttest (P=.05). Decreases in EMG linear envelope following fatigue (P<0.01) were evident for the MG (P<0.01) and TA (P=0.12), but not for the soleus (P=.111). There was a significant difference for tibial acceleration for leg (P=.029) in the stress fracture contralateral leg in comparison to the control leg at takeoff (P=.042). At landing, there was a significant difference for test (P<0.01) as tibial acceleration increased post-test (P<0.01) and leg (P=.019) where there was a difference between stress fracture injured with stress fracture contralateral (P=.014). **CONCLUSIONS**: Attention should be directed to the MG and TA muscles and in providing landing and take-off guidance upon return to activity.

Abstracts were prepared by the authors and printed as submitted.

L5S1 Excursion Reflects Knee Flexion Angle During A Drop Landing Task

Yunae Lee, Ming-Sheng Chan, SM Sigward. *University of Southern California, los angeles, CA.*
(No relevant relationships reported)

Drop landing tasks are used to screen for anterior cruciate ligament (ACL) injury risk. Soft landing with greater knee and hip flexion is considered ACL protective. Greater vertical excursion of the center of mass is thought to improve shock attenuation by reducing ground reaction forces and increasing the contribution of hip extensors. It is not known if vertical excursion of the L5S1 accurately reflects sagittal plane flexion at the knee and/or hip. **Purpose:** To examine the relationship between L5S1 displacement with peak knee and hip flexion during the deceleration phase of a drop landing task. **Methods:** Female soccer players (n=93; 14 ± 2.49 years; 52.9 ± 12.4 kg) performed a drop land (36cm box). Kinematic data was collected (250 Hz) with 8 camera motion system. Peak knee (pkkn) and hip (pkhp) flexion angles were identified during deceleration (contact to minimum L5S1). Total flexion (totflex) was calculated as the sum of pkkn and pkhp. Data were averaged between limbs. Vertical L5S1 excursion (L5S1ex) was calculated as the difference between minimum L5S1 and L5S1 in standing and normalized by standing L5S1. A stepwise linear regression was used to determine which variables best explain L5S1 excursion during a drop land task. **Results:** L5S1ex was positively correlated with pkkn (r=0.95; p<0.00), pkhp (r= 0.74; p<0.00) and totflex (r= 0.892; p<0.00). Of these variables, pkkn was the only predictor of nL5S1ex (r^2= 0.91; p<0.00; prediction equation: L5S1ex=-0.27+(0.005 * pkkn)). **Conclusion:** Vertical L5S1 excursion during a drop land is reflective of knee flexion angle explaining 91% of the variance. When considering the difference between actual pkkn and pkkn calculated with the prediction equation the differences ranged from 0.03-11.37 degrees (average: 3.03 ± 2.37 degrees). L5S1ex may be used as a surrogate for knee flexion angle during ACL risk factor screening with a drop land. Further research is needed to investigate the relationship between L5S1ex and shock attenuation.

Total Knee Flexion vs Normalized L5S1 Excursion

Saggital And Frontal Plane Knee Angles Between Pre-adolescencent Sexes Are Not Different During Jump-landing.

Kenneth C. Holford[1], Michael Torry[1], Adam Jagodinsky[1], Jeff Cowley[2], Steve McCaw[3]. [1]*Illinois State University, Bloomington, IL.* [2]*University of Michigan, Ann Arbor, MI.* [3]*San Fransisco State University, San Fransisco, CA.*
(No relevant relationships reported)

Adolescent and post-adolescent females experience injury to the anterior cruciate ligament (ACL) more frequently than do their male counterparts in similar sports. It has been observed that females tend to land with less knee flexion and greater knee valgus angles than their male peers. These landing patterns are associated to the non-contact ACL injury mechanism.
PURPOSE: The purpose of this study is to examine the knee kinematic landing patterns in youth in the frontal and sagittal planes to determine whether these same kinematic differences exist between pre-adolescent males and female.
METHODS: Thirty-two subjects (16 females and 16 males; aged 6 to 10 yrs) volunteered for participation in the study. They were asked to perform maximal jump and landing motions while being recorded for biomechanical analysis utilizing a 10-camera infrared system (200 Hz; all XYZ coordinates filtered at 20 Hz) and an imbedded force plate (1,000 Hz; filtered at 20 HZ). Values for knee flexion and valgus angles at touchdown and at maximal flexion were extracted from the data and compared between genders with an unpaired *t*-test: alpha ≤ 0 .05.

RESULTS: Valgus angle at initial contact displayed no difference (males: -4.81±7.83°; females: -3.01±8.99°; *p*=0.40). It was found that knee flexion at initial contact was different (males: 16.1±10.5°; females: 20.7±8.10°; *p*=0.05). No differences were observed in valgus ROM (males: 2.75±17.3°; females: 6.68±14.2°; *p*=0.32) nor knee flexion ROM (males: 37.1±19.0°; females: 40.2±10.7°; *p*=0.42).
CONCLUSIONS: These results suggest that the knee kinematic profiles for non-contact ACL injury are not present in pre-adolescent subjects and may develop during maturation.

Mechanics of Countermovement and Drop Jump Tasks Performed by Adolescent and Adult Males

Brandon W. Snyder, Shawn N. Munford, Gavin L. Moir, Shala E. Davis, FACSM. *East Stroudsburg University, East Stroudsburg, PA.*
(No relevant relationships reported)

Purpose: To investigate the mechanical differences between adolescent and adult males performing countermovement and drop jump tasks. **Methods:** Eleven adolescent basketball players (age: 16.5 ± 0.7 years; height: 1.78 ± 0.07 m; mass: 68.9 ± 8.8 kg) and eleven resistance-trained adults (age: 22.3 ± 1.9 years; height: 1.80 ± 0.10 m; mass: 84.3 ± 9.3 kg) performed two trials of a countermovement jump (CMJ) and a drop jump from a height of 0.40 m (DJ). Force plates (1000 Hz) and an 8-camera 3-D motion analysis system (200 Hz) were used to determine the jump height (JH), the duration of the propulsion phase (PT), countermovement depth during the absorption phase (CM), normalized work during the propulsive phase (W_{NORM}), normalized peak power output during the propulsive phase (PO_{NORM}), and normalized vertical stiffness (VS_{NORM}) during each jumping task. **Results:** JH (mean difference: 0.05 m, p<0.001) and PO_{NORM} (mean difference: 2.4 W/kg, p=0.031) were significantly greater during CMJ compared to DJ with no significant differences between the adolescents and adults. PT were significantly greater during CMJ compared to DJ (mean difference: 0.03 s, p=0.033). The adolescents produced significantly shorter PT (mean difference: 0.08 s, p<0.001) and significantly lower CM (mean difference: 0.13 m, p<0.001) than the adults across the jumping tasks. Significantly greater W_{NORM} was performed during the CMJ compared to the DJ task (mean difference: 1.10 J/kg, p<0.001) and the adults performed more work during the propulsive phases of both jumping tasks compared to the adolescents (mean difference: 1.48 J/kg, p<0.001). The adolescents produced significantly greater VS_{NORM} during both jumps compared to the adults (mean difference: 39.6 kN/m/kg, p<0.001). **Conclusion:** Adolescent and adult males use different neuromuscular strategies to attain similar power outputs during jumping tasks with the adolescents producing shorter propulsion times through the modulation of vertical stiffness while the adults generate a greater amount of work over a longer duration.

Patellofemoral Joint Loading During a Variation in Jump-landing Movements

Naghmeh Gheidi, Thomas W. Kernozek, FACSM, Katie L. Hanson, Cheyanne N. Massie. *UWL, La-Crosse, WI.* (Sponsor: Thomas Kernozek, FACSM)
(No relevant relationships reported)

Patellofemoral pain syndrome (PFPS) is common in athletes. Increased patellofemoral joint stress (PFJS) may contribute to PFPS. Few studies have investigated PFJS during jump-landing. PFJS may be different during jump-landing in different directions.
PURPOSE: Examine PFJS during bilateral (B)/unilateral (U) jump-landing and the effect of direction (side (S)/ forward-backward (FB)). **METHODS:** Nineteen males (Age:22.2±1.6yrs.; Height:177.7±8.1cm; Mass:74.5±11.1kg) performed 4 jump-landing variations: bilateral (B) forward-backward (FB), bilateral (B) side (S), unilateral (U) forward-backward (FB), and unilateral (U) side (S). Kinematic and kinetic data were collected. Quadriceps muscle forces (QF) were determined from static optimization. PFJS were estimated using a patellofemoral joint model. A repeated measures multivariate analysis of variance with two within-subjects factors [leg (U/B) and direction (S/FB)] was used to examine differences in knee range of motion (KROM), quadriceps force (QF), and PFJS (α=0.05). **RESULTS:** There were multivariate effects for leg (U/B) (p<.001) and a leg (U/B) by direction (S/FB) interaction (p<.001). No direction (S/FB) main effect (p=.081) occurred. Univariate tests revealed greater KROM (p<.0001) and lower QF and PFJS during B jump-landing (p<.0001). Leg by direction interaction indicated KROM had greater differences between directions (S/FB) during the U jump-landing (p=.012) showing lower KROM during S jump-landing. The interaction also revealed higher QF and PFJS during the B S jump-landing compare to the B FB jump-landing (p<.0001). QF and PFJS were lower during the U S jump-landing compared to the U FB jump-landing (p<.0001). **CONCLUSION:** U jump-landing had greater PFJS than B jump-landing. The effect of direction (S/FB) depended on leg use (U/B). Results may provide insight into both training and rehabilitation efforts in those with PFPS.

Knee Kinematics During a Single-Leg Backwards Jump-Landing With and Without External Load

Colin W. Bond[1], Alexander J. Hron[2], Benjamin C. Noonan[1]. [1]*Sanford Health, Fargo, ND. [2]University of North Dakota, Grand Forks, ND.*
(No relevant relationships reported)

External load may increase the demand on the neuromuscular system to safely control knee motion above its capacity, resulting in knee injury. **PURPOSE:** To assess the influence of external load on knee motion during a backwards single-leg jump-landing. It was hypothesized that external load would increase motion in the frontal plane, but not in the sagittal plane. **METHODS:** Eleven recreationally active participants (23.1 ± 3.3 y, 1.78 ± 0.08 m, 78.2 ± 11.6 kg) performed backwards single-leg jump-landings without (BW) and with (BW10%) external load applied via a weight vest worn around the torso. Participants jumped backwards over a 15 cm hurdle on the dominant leg, landed on the same foot on the force plate, and stabilized. Three trials were completed per condition and averaged for analysis. Frontal and sagittal plane knee angles were identified at initial contact (IC) and peak vertical ground reaction force (vGRF). Effect size (d) was used to evaluate differences in the means between conditions. **RESULTS:** Participants were in greater knee flexion at IC with external load compared to without ($d = 0.40$; BW10% = 42.3° [36.0 - 48.7]; BW = 38.8° [33.4 - 44.2]). During the weight acceptance phase participants extended at the knee in both conditions, but extension was greater with external load than without ($d = 0.53$; BW +10% = 7.9° [0.5 - 15.2]; BW = 2.4° [-4.2 - 8.9]) resulting in similar sagittal plane angles at peak vGRF ($d = 0.20$; BW10% = 34.5° [28.2 - 40.7] BW = 36.4° [30.2 - 42.6]). Participants were in a comparable valgus position at IC ($d = 0.00$; BW10% = 2.2° [-1.1 - 5.4]; BW = 2.1° [-1.3 - 5.5]) and moved similarly towards a varus position during the weight acceptance phase ($d = 0.08$; BW10% = -1.7° [-3.0 - -0.4]; BW = -1.5° [-2.4 - -0.7]), ultimately resulting in comparable valgus positions at peak vGRF ($d = 0.02$; BW10% = 0.5 [-2.1 - 3.0]; BW = 0.6° [-2.4 - 3.6]). **CONCLUSIONS:** Frontal plane knee kinematics were similar between conditions, possibly because the external load was not great enough to exceed the ability to safely control knee motion. Participants landed in greater knee flexion with external load but extended the knee during the weight acceptance phase, possibly due to the unique movement challenges of a backwards jump. This may heighten vertical stiffness, challenge the lower extremity's passive stability, and increase the risk for knee injury.

Trunk Muscle Fatigue and Activation are Associated with Drop Jump Performance

Yasuyuki Uchida[1], Makoto Iguchi[2], Norihiro Shima[3], Yohei Shimokochi[1]. [1]*Osaka University of Health and Sport Sciences, Osaka, Japan. [2]Kansai University of Health Sciences, Osaka, Japan. [3]Tokai Gakuen University, Aichi, Japan.*
(No relevant relationships reported)

Although the importance of core muscles on human motions has been recognized, little is known about the effect of trunk muscle fatigue and activation on drop jump (DJ) performance.
PURPOSE: To examine how trunk muscle fatigue and activation relate to DJ performance.
METHODS: The study included 7 healthy, well-trained males (age 20.8 ± 1.4 years, height 168.4 ± 5.7 cm, weight 67.1 ± 8.0 kg). Subjects held vertical trunk position against a wire with one end attached to the posterior thorax, pulling the trunk posteriorly, with the other end attached to a weight corresponding to 25% of maximal voluntary isometric contraction force. Before and after this fatiguing task, maximum voluntary isometric trunk flexor contraction force (MVIC), and double- and single-leg DJ height (DJH), contact time (CT), and DJ index (DJI; DJH/CT) were measured. Surface electromyography was recorded from the dominant side of the anterior and posterior trunk musculature during DJs. Mean differences before and after the fatiguing task were examined using paired-sample t-tests. Simple linear regression analyses tested the relation of relative changes before and after the fatiguing task in the jump performance index and trunk muscle activation during preactivation, braking, and push off phase of each DJ.
RESULTS: After the fatiguing task, MVIC was significantly decreased to $68.8\pm11.5\%$ ($p<0.01$). DJI (Pre vs. Post fatigue for double- and single-leg DJ: 1.18 ± 0.31 vs. 0.94 ± 0.36, 0.52 ± 0.13 vs. 0.41 ± 0.15) and DJH (Pre vs. Post fatigue for double- and single-leg DJ: 22.12 ± 5.09 cm vs. 20.01 ± 5.24 cm, 13.21 ± 3.04 cm vs. 11.07 ± 3.64 cm) were significantly decreased ($p<0.01$), and CT (0.19 ± 0.02 s vs. 0.22 ± 0.03 s) was significantly extended ($p<0.01$). Regression analyses revealed that greater ensemble trunk muscle preactivation reduction rate was associated with CT lengthening rate in double-leg DJ (R2=0.582, B=-0.257, p=0.046), and DJI reductions rate in single-leg DJ (R2=0.910, B=0.309, p=0.001) and that greater rectus abdominus (R2=0.779, B=0.138, p=0.008) and external oblique activations reduction rate during breaking phase (R2=0.703, B=0.276, p=0.018) were associated with greater DJI reduction rate.

CONCLUSIONS: Trunk muscle fatigue and decreased trunk flexor muscle activation during DJ have negative effects on both double- and single-leg DJ.

Effect of Cognitive Dual Tasks on Lower Extremity Kinematics and Ground Reaction Force during Repeated Tuck Jump Landings

Jae P. Yom, Amber Schnittjer, Janet Simon, Dustin Grooms. *Ohio University, Athens, OH.*
(No relevant relationships reported)

Effect of Cognitive Dual Tasks on Lower Extremity Kinematics and Ground Reaction Forces during Repeated Tuck Jump Landings

Jae P. Yom[†], Amber Schnittjer[†], Janet Simon[†], Dustin Grooms[†]
[†]Ohio University, Athens, OH

Many sports-related injuries occur due to a combination of physical, high joints load during sport-specific maneuvers and cognitive factors, such as keeping other players or the ball in short-term memory. This addition of cognitive challenges can degrade physical performance and increase joint loading. However, previous studies have focused on a single movement and it is unknown how cognitive load influences repeated landing that better simulate the continuous demand of athletic performance. **PURPOSE:** To determine if a cognitive challenge during tuck jumping affect lower extremity landing biomechanics. **METHODS:** Recreational collegiate athletes (N=20, 71.7 ± 11.9kg, 171.1 ± 9.7cm) participated in this study. A baseline: BASE condition of repeated tuck jumps and a cognitive: COG condition of tuck jumps while performing an addition problem from a stream of digits on a computer screen. The tuck jump consisted of 3 sets of 10 seconds repeated double leg vertical tuck jumps. Dominant-side sagittal plane lower extremity angular kinematics and vertical ground reaction forces (VGRF: 1,000 Hz) were compared between the two conditions paired t-tests ($p<.05$). **RESULTS:** COG, compared to the BASE, resulted in increased ankle angle ($30.1\pm1.7°$ and $29.3\pm0.7°$) and decreased knee angle ($20.5\pm0.6°$ and $21.5\pm0.6°$) at initial contact. Also, decreased ankle ($21.8\pm1.4°$ and $22.4\pm1.0°$) and knee ($63.0\pm0.7°$ and $67.9\pm0.9°$) maximum angle occurred. Additionally, COG resulted in an increased ankle ($52.6\pm0.9°$ and $51.6\pm0.9°$), decreased knee ($42.5\pm1.2°$ and $46.4\pm0.8°$) and hip ($31.7\pm1.1°$ and $33.0\pm0.7°$) displacements. No significant differences were found in VGRF between conditions. **CONCLUSION:** We surmised that COG, compared to the BASE, change lower extremity biomechanics that may increase injury risk and knee loading. The more extended knee position at initial contact and reduced sagittal displacement during the COG condition may contribute to increased injury risk when under cognitive load. However, greater ankle displacement during the COG condition may be adaptation strategy to protect the knee under cognitive load.

Effect of External Load on Lower Extremity Stiffness and Time to Stabilization During Jump-Landing

Alexander J. Hron[1], Benjamin C. Noonan[2], Colin W. Bond[2]. [1]*University of North Dakota, Grand Forks, ND. [2]Sanford Health, Fargo, ND.*
(No relevant relationships reported)

External loads similar to common protective athletic equipment may impair the ability to effectively control motion during a jump-landing, increasing non-contact anterior cruciate ligament (ACL) injury risk. **Purpose:** To determine the effect of external load on time to stabilization (TTS) and lower-extremity vertical stiffness (K_{vert}) during backwards single-leg jump-landings. It was hypothesized that both TTS and K_{vert} would be greater in the loaded condition compared to the non-loaded condition. **Methods:** Eleven recreationally active males and females (23.1 ± 3.3 y, 1.78 ± 0.08 m, 78.2 ± 11.5 kg) completed three trials of a backwards single-leg jump-landing on the dominant leg with and without a weight vest on that was adjusted to 10% body weight in a randomized order. Participants jumped backwards off their dominant foot over a 15 cm hurdle, landed on the same foot, and stabilized. Trials were performed on an in-ground force plate and kinematics were quantified using three-dimensional motion capture. TTS was defined as the time required for vertical ground reaction force (vGRF) to stabilize within 5% of the participant's body mass, which was adjusted for external load condition, for one second after landing. K_{vert} was calculated as the relative peak vGRF divided by the change in center of mass vertical position between initial contact and peak vGRF. Effect size (d) was used to assess the magnitude of the standardized difference in the means between conditions. **Results:** Small effects ($d = 0.20$) were demonstrated between conditions for TTS because the participants took slightly longer to stabilize in the loaded condition (1.31 s [0.98 - 1.65]) than in the non-loaded condition (1.21 s [0.88 - 1.55]). Small effects ($d = 0.49$) were also demonstrated between conditions for K_{vert} since the participants had greater stiffness during the weight acceptance period in the loaded condition (0.25 kN m[-1] kg[-1] [0.19 - 0.31]) compared to the non-loaded condition (0.21 kN m[-1] kg[-1] [0.17 - 0.26]). **Conclusion:** Greater TTS and K_{vert} when externally loaded with a weight similar to protective athletic equipment may challenge the neuromuscular system's ability to safely

---

Abstracts were prepared by the authors and printed as submitted.

attenuate ground reaction forces. Although small, these impairments may increase ACL injury risk and be heightened with greater loads, fatigue, and unanticipated movements.

Effects of Increased Gluteus Muscle Activation on Hip and Trunk Kinematics during Single-leg Landing

Yohei Shimokochi[1], Kanae Hosaki[2], Akiko Takiguchi[3], Issei Ogasawara[4]. *[1]Osaka University of Health and Sport Sciences, Sennan-gun, Osaka, Japan. [2]Funabashi Orthopedic Hospital, Funabashi-shi, Chiba, Japan. [3]Tsujimoto Orthopedic Clinic, Amagasaki-shi, Hyogo, Japan. [4]Osaka University, Toyonaka-shi, Osaka, Japan.*

(No relevant relationships reported)

The gluteus maximus (GM) has a triplanar function at the hip joint. It was hypothesized that increased GM activation before and after foot contact (FC) on landing would affect triplanar hip and trunk kinematics and anterior cruciate ligament (ACL) injury risk. **PURPOSE:** To examine how increased GM activation before and after FC affect hip angles and trunk inclination during single-leg landing. **METHODS:** A double-leg drop jump from a 30-cm box, followed by single-leg landing onto a force plate, was performed by 13 males and 15 females in both control (CC) and experimental conditions (EC). In EC, transcutaneous electrical stimulation was applied to increase GM activation immediately before FC and during single-leg landing. Kinetic and kinematic data were collected using a force plate and 3-dimensional electromagnetic motion tracking system, respectively. Hip joint angles and sacrum and thorax inclination angles in space on FC, peak ground reaction force (GRFpk), and peak knee extensor moment (KEMpk) during single-leg landing were calculated. Comparisons were performed using two-way (sex×conditions) repeated measures analysis of variance with a significance level < .05. **RESULTS:** The hip joint exhibited more abduction (EC vs. CC at FC, GRFpk, and KEMpk, respectively: -13.2 ± 7.8° vs. -9.5 ± 6.3°, -8.9 ± 7.7° vs. -4.9 ± 6.8°, -3.3 ± 8.9° vs. -.2 ± 6.5°) and external rotation (-14.8 ± 8.5° vs. -9.8 ± 9.9°, -8.0 ± 3.6° vs. -3.6 ± 9.7°, -6.1 ± 9.7° vs. -1.6 ± 11.2°) at all time points in EC than in CC. The sacrum showed more lateral inclination toward the supporting leg at all time points (14.3 ± 6.4° vs. 11.1 ± 6.4°, 12.1 ± 6.4° vs. 9.0 ± 6.1°, 8.9 ± 7.1° vs. 6.7 ± 6.2°) and more erect position at KEMpk in EC (-1.0 ± 10.6°) than at CC (-4.6 ± 10.5°). No significant differences were observed in thoracic inclination angles. No significant interactions were observed among all variables. **CONCLUSIONS:** Increased GM before and after FC on single-leg landing may have positive effects on frontal and transverse plane hip motion to reduce ACL injury risk. However, excessive GM activation may result in excessive trunk lean toward the supporting leg and more erect position, which increase risk for ACL loading. Thus, appropriate GM activation is necessary to protect the ACL during single-leg landing.

Relationship between Take-Off Force Profiles and Single Leg Hop Distance

Christopher Ballance, Maria Talarico, Daniel Clifton, Michael McNally, James Onate. *The Ohio State University, Columbus, OH.*

(No relevant relationships reported)

The anterior single leg hop for distance test (SLHOP) is a functional performance task that is often used to assess return to play criteria following ACL reconstruction. Clinicians primarily assess SLHOP distance, but the way an individual completes the task may be important when determining return to play status. Recent research has indicated that non-uniformity in vertical ground reaction force (VGRF) profiles may be related to pathomechanics during a vertical jump, but little research has been done to explore the relationship between force profiles and SLHOP distance. **PURPOSE:** To determine the correlation between a force profile ratio and SLHOP distance. **METHODS:** Twenty-three female collegiate soccer players (19.1±1.5 years; 166.9±7.1 cm; 62.6±8.3 kg) performed three SLHOP tests for maximal distance off a tri-axial force plate. The SLHOP was performed on the dominant limb. Ground reaction force (GRF) data were collected during SLHOP take-off phase to produce force-time curves that were used to calculate the ratio between the instantaneous and average force profile between three events. Force profile ratios were calculated between: A) the minimum GRF after initiation of the countermovement and the peak GRF prior to takeoff, and B) the point during the countermovement when body weight is reached and peak GRF. Ratio A and B where calculated in both the vertical (z) and anterior-posterior (y) axes. All forces were normalized to body weight, and SLHOP distances were normalized to leg length (cm/cm). The strength of the association between each of the aforementioned force profile ratios and maximum SLHOP distance were calculated using Pearson correlation coefficients with an alpha level set *a priori* at p<0.05. **RESULTS:** There were no significant correlations between any combination of force profile ratios and SLHOP distance (p-value range: 0.19 to 0.62, r range: -0.11 to -0.26). **CONCLUSION:** Force profile ratios between straight-line

and trace-line distance are not significantly related to average or maximum SLHOP distance. Further research should explore the relationship between other phases within the force-time curve, pathomechanics, and SLHOP distance.

The Relationship Between Side Hop Test Endurance And Energy Absorption

Samantha Price, Chelsey Roe, Haley Reed, Gaelen Athanaze, Jessica Schilling, Kylie Davis, Brian Noehren, FACSM. *University of Kentucky, Lexington, KY.* (Sponsor: Brian Noehren, FACSM)

(No relevant relationships reported)

Many factors are associated with an athlete being able to safely return to sport (RTS). Frontal plane control and endurance in the frontal plane is recognized as important factor in RTS. The ability to absorb energy while fatigued is critical to help dissipate forces and minimize injury risk. Current RTP guidelines do not evaluate fatigue and power absorption. A new 30-second endurance side hop test could provide a means of clinically evaluating this ability. **PURPOSE:** Compare the change in energy absorption over a 30-second side hop test in healthy subjects. **METHODS:** 17 healthy subjects (11 M, ages 22.4 ± 3.14, BMI 22.96 ± 3.06) with no prior lower extremity injuries performed an instrumented single limb lateral hops between two force plates 15.24 cm apart as many times as possible in 30 seconds. Errors were subtracted from total successful hops and included landing between the force plates or putting the non-stance limb down. The change in energy absorption from beginning to the end of the test was also calculated. Pearson product moment correlation was used to evaluate the relationship between the average number of hops to the change energy absorption over 30 seconds. We also assessed the difference in hops between those who maintained versus those who had a reduction in power absorption with an independent samples t test. **RESULTS:**Subjects performed an of 29.4± 6.6 lateral hops over 30 seconds. There was a strong, significant correlation between the number of hops to energy absorption (r=0.68, p= 0.003). There was also a significant difference (p=0.04) in the number of hops between those who maintained energy absorption (32.3± 4.4 J) versus those who did not (26.1± 7.3 J).
CONCLUSIONS: This 30-second side hop endurance test was significantly correlated to energy absorption. Those who performed the best were able to maintain energy absorption throughout the testing protocol. Potentially, the ability to maintain the ability to absorb energy while fatigued may reduce of injury, as these athletes are better able to attenuate loads. Having established the relationship to energy absorption, future studies should evaluate the test's relevance to injury prediction.

Relationship between Single Leg Hop Distance and Descending Phase Force Variables

Maria Talarico, Christopher Ballance, Daniel Clifton, Michael McNally, James Onate. *The Ohio State University, Columbus, OH.*

(No relevant relationships reported)

Anterior single leg hop for distance (SLHOP) is a common functional assessment used to evaluate lower extremity power and dynamic postural stability. Peak force and rate of force development (RFD) have been used to quantify strength and power, but little is known of the relationship between these measures and SLHOP distance. **PURPOSE**: To determine the relationship between vertical and anterior force variables during the descending phase and SLHOP distance. **METHODS**: Twenty-three female collegiate soccer players (19.1±1.5 years; 166.9±7.1 cm; 62.6±8.3 kg) performed SLHOP for maximal distance on their dominant limb, taking off a tri-axial force plate. Kinetic data were collected during the descending phase of the SLHOP to identify peak force in the vertical (Fz) and anterior-posterior (Fy) axes and average rate of force development (RFD), the rate of change in the force-time curve. Two start events were used to calculate RFD: 1) RFDnegative: point of maximum center of mass downward acceleration (subject moving down, acceleration negative) and 2) RFDzero: point when ground reaction force equals body weight (subject moving down, acceleration zero). The RFD end event was peak force (near the lowest point of descending). Forces were normalized to body weight and SLHOP distances were normalized to leg length. A linear regression with best subset selection method was performed to identify which combination of variables were most related to SLHOP distance with an alpha level set a priori at p<0.05. **RESULTS**: Peak Fy (Beta=189.32, 95%CI=133.04, 245.61, p<0.001) and RFDzero in the vertical axis (Beta=-2.94, 95%CI=5.48, -0.40, p=0.03) were significantly related to SLHOP distance (model adjusted R^2=0.69). **CONCLUSION**: Female soccer players who maximized anterior force and minimized vertical RFD during the descending phase of SLHOP achieved greater SLHOP distances. Results suggest maximal SLHOP distance warrants both vertical and anterior force generation. However, these movement strategies may not translate across different jump tasks (i.e. vertical jump, etc.) or different sports. Further research is

warranted to examine the relationship between force and RFD profiles and other jump tasks. Future studies should examine the effect of sex and sport on the relationship between SLHOP distance and force variables.

Evaluation Of The Implementation Of An Academically-integrated Intervention Targeting Obesity-related Health Behaviors In Preschooler-age Children

Christine W. St Laurent, Sarah Burkart, Sofiya Alhassan, FACSM. *University of Massachusetts Amherst, Amherst, MA.* (Sponsor: Sofiya Alhassan, FACSM)
(No relevant relationships reported)

Obesity related health behaviors [ORHBs; physical activity (PA), diet, and sleep] interventions targeting preschool-age children implemented within childcare centers have shown mixed results. The variability of these findings could be related to process evaluation measures, which are frequently not reported. **PURPOSE**: To describe the process evaluation (feasibility, acceptability, and fidelity) outcomes of a 12-week preschool intervention targeting ORHBs that was integrated into early education learning standards (state mandated policies) in preschoolers. **METHODS**: Two preschools (classrooms, n = 7) were randomized to either the 12-week Physical Activity, Diet and Sleep (PADS) intervention or control condition. The PADS program was led by research staff and teachers and included ORHB lessons and activities implemented on four days/week (three days of morning PA, three days of afternoon PA, one day of diet, and one day of sleep). PADS PA intervention intensity was assessed on one randomly selected weekday morning/week with accelerometers. Other process evaluation outcomes were assessed (daily, weekly, and at 12-weeks) using semi-structured questionnaires completed by research staff and teachers. **RESULTS**: Fifty, 33.3, 77.8, and 100.0% of observed lessons were implemented as planned for diet, sleep, morning PA, and afternoon PA, respectively. Only $44.7 \pm 8.6\%$ of the morning PA lessons were spent in moderate-to-vigorous intensity. Among all observed lessons at least 50% of the students participated and the majority of students seemed to enjoy the activities. Teacher encouragement was present in 62.5% (diet) - 72.2% (morning PA) of observed lessons. Greater than 90% of the lessons were perceived as effective and would be used in the future by teachers. **CONCLUSIONS**: This pilot data suggests that integrating ORHBs into education learning standards is feasible and acceptable by preschool teachers and students. PADS PA lessons had the highest levels of implementation, whereas modifications were recommended for some diet and sleep lessons. Implementation of all lessons may also improve with greater teacher encouragement.

Mixed-method Analysis Of An After-school Program To Increase Physical Activity

Kelly R. Rice[1], John Schuna[2], Tim Behrens, FACSM[3]. *[1]Eastern Oregon University, La Grande, OR. [2]Oregon State University, Corvallis, OR. [3]Northern Arizona University, Flagstaff, AZ.* (Sponsor: Tim Behrens, FACSM)
(No relevant relationships reported)

Physical activity (PA) is essential for adolescent health and prevention of chronic diseases. After-school programs and time spent outdoors are important for addressing health behaviors, particularly PA. **PURPOSE**: The purpose of this study was to increase PA through an afterschool program that utilized outdoor resources. **METHODS**: Get Outside - After School Activity Program (GO-ASAP), a 20-wk (2d·wk[-1] for150-180 mins) PA program designed to increase lifestyle PA. Participants (N = 18) were recruited from a local middle school. The Physical Activity Questionnaire for Children (PAQ-C), as well as accelerometers, was used to assess PA. Assessment of social cognitive (SCT) and self-determination (SDT) constructs were measured on a 5-point Likert scale. All assessments were administered pre- and post-intervention. Focus groups were conducted post-intervention to assess self-confidence and enjoyment. **RESULTS**: Participants (male = 11, female = 7) were 12.9 ± 0.9 years of age. Accelerometer-derived PA indicated an increase in MVPA min·hr[-1](2.9 ± 0.8 to 3.9 ± 2.4) but was not significant (p=0.28). Self-reported PA increased from baseline to post (2.06 ± 0.56 to 2.54 ± 0.92; p=0.042). There were no significant changes noted in SCT or SDT constructs. Five themes emerged from focus groups: (1) students liked participating in the GO-ASAP, (2) students learned new skills and activities while exercising outdoors, (3) participation in the GO-ASAP had a positive effect on confidence and self-esteem, (4) Participation in the GO-ASAP had a positive effect on life-long commitments to fitness, and (5) there is a positive interaction between students and GO-ASAP leaders. **CONCLUSIONS**: Results of this pilot project indicated that outdoor-based PA programs might yield small effects in PA. Additional explorations with larger sample sizes are warranted to fully investigate the efficacy of these findings. The need for after school programs involving activities promoting PA into adulthood should be explored.

Changes On Neuroendocrine Parameters (cortisol, Melatonin) And Anxiety Levels After A School-based Exercising And Nutrition Counseling Intervention In School-aged Obese Adolescents From Monterrey méXico.

Marco A. Enriquez Martinez[1], Oswaldo Ceballos Gurrola.[2], Raúl Lomas Acosta[3], José Alberto Valadez Lira.[2], Armando Cocca[2]. *[1]Benemerita Escuela Normal Manuel Avila Camacho., Zacatecas, Mexico. [2]Universidad Autónoma de Nuevo León., San Nicolás de los Garza, Nuevo León., Mexico. [3]Secretaria de Educación Coahuila., Saltillo, Coahuila, Mexico.*
(No relevant relationships reported)

BACKGROUND.
Recent studies point to high prevalences of obesity in adolescent populations worldwide. Its implications derive in various disorders, among which are inflammatory processes, as well as disorders related to sleep-wake, both processes involved in stress situations. There are two neuroendocrine parameters (cortisol and melatonin) two hormones associated with the same sleep-wake process that lead to a certain level of anxiety in obese subjects. Both cortisol and anxiety have been evidenced in various investigations as obesogenic factors. For its part, the practice of physical exercise has been indicated as a factor associated with the increase in melatonin levels, which has anti-inflammatory and recovery functions.**PURPOSE.**
To assess the changes in the levels of neuroendocrine parameters (cortisol, melatonin) and anxiety after an intervention of nutritional counseling and exercise in school age obese adolescents of Monterrey Mexico
METHODS: Experimental study with a sample of 51 adolescents (13 ± 2) randomly assigned in three work groups had participation during 4 months. The control group (CG) did not receive any treatment; experimental group 1 (EG1) participated in a health program composed of 4 weekly sessions of 60 minutes of physical activity; Experimental group 2 (EG2) 4 weekly sessions of 60 minutes of physical activity sessions of nutritional guidance and 2 weekly sessions of light therapy of 45 minutes. The values of cortisol and melatonin were taken in saliva and for anxiety the questionnaire of state anxiety (STAI) was used.
RESULTS: After comparing initial and final values, the results showed significative changes into EG2 increasing melatonin (p > 0.001). Salivary cortisol showed significant decreases into EG1 (p = 0.004) and also into EG2 (p =0.006). Anxiety state showed a significant increase into CG (p<0.001), and significant decreases into EG1 (p< 0.005) and into EG2 (p< 0.001)
CONCLUSIONS:
The School-based Exercising And Nutrition Counseling shows favorable effects in the reduction of cortisol levels y ansiedad, both factors associated with inflammation. The use of light therapy seems to help into the recovery processes increasing secretion of melatonin and recovery after exercise. we suggest analize sleep variables for further studies

Impact of After-School Jump Rope Program on Psychological Outcomes

Jessica Albers. *Minnesota State University Mankato, Mankato, MN.*
(No relevant relationships reported)

As childhood obesity increases and physical activity (PA) in youth populations decreases, it is crucial to implement programs which successfully increase PA while providing positive psychological experiences for growth. After-school program offer opportunities for youth to not only engage in PA but to experience varied types of PA and social interactions which can positively impact their perceptions on PA, exercise, and how they view themselves. **PURPOSE**: The purpose of this study was to explore the impact participating in an after-school jump rope program had on self-perceptions, PA enjoyment, goal orientation, and weekly PA. **METHODS**: Students ages 8-12 years old from two elementary schools (n=28) participated in a 12-week after-school jump rope program that met twice a week for 90 minutes each session. Participants practiced individual and group jump rope skills and learned a team routine that they performed at the end of the 12 weeks. Participants completed pre and post-test measures including Harter's Self Perception Profile, the PA Enjoyment Scale, a combination of the Sport and Classroom Goal Orientation Scale, and the Self-Administered PA Checklist. **RESULTS**: There were no changes in self-perceptions from pre to post-test measures.

Abstracts were prepared by the authors and printed as submitted.

After controlling for pre-test scores, athletic ($F(1, 25)$= 18.577, $p<.001$, η^2 = .426) and scholastic ($F(1, 25)$= 4.462, $p<.05$, η^2 = .151) competence increased for non-minority and decreased for minority participants. There were no significant changes in PA enjoyment. Ego goal orientation decreased among male participants $F(1, 26)$ =5.972, $p<.05$. Weekly physical activity minutes increased from pre to post-test, $F(1, 27)$ =53.115, $p<.001$, η^2 =.663. **CONCLUSIONS**: Participating in the after-school jump rope program did not show consistent increases in assessed psychological variables however there were positive trends in goal orientation, weekly PA, and. Participants were involved in multiple after-school programs which may have influenced the data. Accelerometer data shows that the jump rope program elicited 45.3 minutes of MVPA including an average of 9 minutes of very vigorous PA creating an interval training type program. Further examination of how this type of program impacts self-perceptions is needed.

2822   Board #105   June 1 2:00 PM - 3:30 PM

Cardiorespiratory Fitness Moderate the Prospective Association Between Physical Activity & Cardiometabolic Risk Factors in Children

Turid Skrede[1], Eivind Aadland[1], Lars Bo Andersen[1], Mette Stavnsbo[1], Sigmund Alfred Anderssen[2], Geir Kåre Resaland[1], Ulf Ekelund, FACSM[2]. *[1]Western Norway University of Applied Sciences, Sogndal, Norway. [2]Norwegian School of Sport Sciences, Oslo, Norway.*

(No relevant relationships reported)

Physical activity (PA) and cardiorespiratory fitness (CRF) are independently associated with lower cardiometabolic risk, and may affect risk through different pathways. PA and CRF are two different constructs (behaviour vs trait), and CRF has a genetic component suggesting that some may be predisposed to higher CRF in whom associations between PA and cardiometabolic health might be less pronounced than in those with low CRF. Therefore, CRF might moderate the association between PA and cardiometabolic risk, however, only cross-sectional studies have examined such an influence of CRF on this relationship so far. **PURPOSE**: To examine if CRF moderate the prospective association between PA and cardiometabolic outcomes in 10-year-old children. **METHODS**: In total, 718 children (50.3 % boys) had valid measures of PA measured by accelerometry (GT3X), and CRF assessed by the Andersen intermittent running test, as well as the cardiometabolic outcomes; systolic blood pressure, waist circumference (WC), total cholesterol, high-density lipoprotein, triglycerides, glucose, and insulin. Outcomes were analyzed individually, and as a clustered cardiometabolic risk score (sum of z-scores). PA and cardiometabolic risk factors were measured at baseline and follow-up seven months later. Linear mixed modelling was used to examine the prospective associations between PA exposures and cardiometabolic risk outcomes, including the interaction term ($PA\times CRF$) in the model to assess moderation by CRF. **RESULTS**: CRF modified the association between baseline PA (counts per minute) and between moderate-to-vigorous PA (MVPA) (min/day) with clustered cardiometabolic risk at follow up ($P<0.026$). Moreover, CRF modified the association for PA and MVPA with insulin resistance independent of WC ($P<0.022$). When stratified by CRF level (low/high), PA and MVPA predicted lower insulin resistance [MVPA β-0.119 (95% CI: -0.207, -0.038); P=0.008] and clustered cardiometabolic risk [MVPA β -0.092 (95% CI: -0.166, -0.018); P=0.014] in children with low CRF, but not among their fitter peers ($P>0.323$). **CONSLUSION**: CRF moderate the prospective association between PA and clustered cardiometabolic risk; this moderation was most pronounced for insulin resistance. Our findings suggest that PA may be especially important in children with low CRF.

Physical Activity Influence On Behavior Of Children With ADHD & DBD During Instruction Using Classroom Observation

Jared D. Ramer[1], Catherine L. Davis[2], Stacy L. Frazier[3], David X. Marquez, FACSM[1], Eduardo E. Bustamante, FACSM[1]. *[1]University of Illinois at Chicago, Chicago, IL. [2]Augusta University, Augusta, GA. [3]Florida International University, Miami, FL.* (Sponsor: Dr. Edwardo Bustamante, FACSM)

(No relevant relationships reported)

Evidence suggests physical activity influences children's neurocognitive function and ADHD symptoms. ADHD and Disruptive Behavior Disorder (DBD) are highly comorbid. Extra-curricular physical activity programs may improve academic achievement in ADHD and DBD by increasing academic engagement levels during instruction closer to those of typically developing peers. However, few studies have tested the impact of physical activity on objectively-measured classroom behavior in children with ADHD and/or DBD. **PURPOSE**: To evaluate the impact of physical activity on behavior for children with ADHD and/or DBD using a tool which objectively measures classroom behavior.

METHODS: African American children with ADHD and/or DBD were randomized to a 10-week after-school physical activity program (n=19) or a sedentary control program (n=16). Only 18% had ever received mental health services despite 87% meeting positive or intermediate criteria for ADHD and/or DBD. At posttest, 3 systematic classroom observations were conducted for each student using the BOSS (Shapiro, 2004). For comparison, each BOSS observation also assesses behavior among non-participant classroom peers. ANOVA tested differences in academic engagement and off-task motor (OFT-M) and verbal (OFT-V) behaviors among the physical activity group, control group, and classroom peers. Bivariate correlations tested relationships between program attendance and classroom behavior. **RESULTS**: Omnibus tests revealed differences in OFT-M (F[2,23]=16.9, $p<.001$) and a trend for academic engagement (F[2,23]=2.6, p=.09). Pairwise comparisons revealed that the physical activity and control groups evidenced 52% and 49% more OFT-M (ps<.01), 34% and 33% more OFT-V (ns), and 11% and 15% less academic engagement (ns) than classroom peers. No differences were evident between intervention groups. Large non-significant correlations were found between program attendance and academic engagement in both physical activity (r=.45, p=.08) and control (r=.45, p=.11) groups. **CONCLUSION**: Neither after-school program improved classroom behavior of children with ADHD and/or DBD to levels of classroom peers. Extra-curricular physical activity programs will require greater intentionality to impact classroom behavior in this population.

2824   Board #107   June 1 2:00 PM - 3:30 PM

The Strong Influence of Vigorous Physical Activity on Cardiorespiratory Fitness in Children

Corey A. Selland[1], Jessica R. Meendering[2], Matthew D. Vukovich, FACSM[2]. *[1]Black Hills State University, Spearfish, SD. [2]South Dakota State University, Brookings, SD.* (Sponsor: Matthew D. Vukovich, FACSM)

(No relevant relationships reported)

The influence sedentary time has on cardiorespiratory fitness and health has recently received increased attention. Children become less physically active and more sedentary as they advance through childhood to adulthood, contributing to decrements in cardiorespiratory fitness. **PURPOSE**: The current study examined the relationship among objectively measured cardiorespiratory fitness, physical activity, and sedentary time in children.

METHODS: Participants (n = 35; 15 girls, 20 boys) had cardiorespiratory fitness measured by a maximal treadmill test with VO_2 assessed continuously. Sedentary time and physical activity were objectively assessed by accelerometry for 7 days. Multiple linear regression analyses were performed to identify independent associations of sedentary time, light, moderate, and vigorous physical activity with cardiorespiratory fitness. ANCOVA was used to evaluate whether VO_2peak varied by high/low physical activity/sedentary time groups (high physical activity, low sedentary time; high physical activity, high sedentary time; low physical activity, low sedentary time; low physical activity, high sedentary time). **RESULTS**: VO_2peak was negatively associated with sedentary time and positively associated with light, moderate, and vigorous physical activity (p < 0.05). Further analysis revealed sedentary time (β = -0.03), waist circumference (β = -0.63), and age (β = 2.06) were significant predictors of VO_2peak when not accounting for physical activity in the model. When accounting for physical activity, vigorous physical activity (β = 0.18), waist circumference (β = -0.92), age (β = 2.26), and sex (β = -4.51) were significant predictors of VO_2peak. Lastly, VO_2peak was higher in the low sedentary/high physical activity and high sedentary/high physical activity groups compared to the high sedentary/low physical activity group (p < 0.05). **CONCLUSIONS**: These results suggest cardiorespiratory fitness is predicted by vigorous physical activity, waist circumference, age, and sex but not sedentary time in children. Strategies aimed to promote and improve cardiorespiratory fitness and health in children should emphasize vigorous physical activity.

The Correlations Between Families' SES and Physical Activity Levels of School-aged Children in China

Fan Xiang[1], Cao Zhen-Bo[2], Chen Peijie[2]. *[1]Shanghai Jiao Tong University, Shanghai, China. [2]Shanghai University of Sport, Shanghai, China.*

(No relevant relationships reported)

In recent 30 years, China has made great changes in social and economic. These changes have made a significant impact on health and lifestyle as witnessed by an increased level of physical inactivity among school-aged children. Previous studies have indicated that families' socioeconomic status (SES) can influence children'physical activity (PA), but few studies have explored the correlation between the SES of families and the PA levels of children in China using a large sample survey. **PURPOSE**: To determine the correlation between SES of families and the PA levels of school-aged children in China.

METHODS: Cross-sectional analyses of data from the 2016 Physical Activity and Fitness in China - the Youth Study. Participants were 90,712 primary, junior middle, and junior high school children aged 9-17 years old, recruited from 1204 schools across 32 administrative provinces in the Mainland of China. Participants' moderate-to-vigorous physical activity (MVPA) levels and SES of family were collected via a questionnaire completed by the children and guardians.
RESULTS: Analysis of covariance revealed that 9-11-year-old boys from high SES families spent more minutes per day in MVPA (Mean ±SE: 55.4±1.1) than those who from mid-SES and low SES families (50.1±0.6, 47.9±0.6, P<0.001). Regarding the girls aged 12-14 years, those who from high SES families spent more minutes per day in MVPA (47.9 ±0.8) than those who from mid-SES and low SES families (47.2 ±0.5, 45.2 ±0.4, P<0.001).Logistic regression analysis showed that 9-11-year-old children those who from low SES families were less likely to meet MVPA recommendations (boy: adjusted odds ratio (aOR) =0.74, 95%confidence interval (CI): 0.66-0.83; girls: aOR =0.83, 95%CI: 0.75-0.93) compared with children from high SES families. However, girls in age 15-17 years old who from low SES families were found to be more likely to meet recommendations compared with who from high SES families (aOR =1.31, 95%CI: 1.15-1.48).**CONCLUSIONS**: Overall, the average MVPA minutes per day among Chinese school-aged children is low, and families SES may be considered in the development of PA interventions and policies.

Physical Activity in Latina Caregivers of Children with Developmental Disabilities

Jacqueline Guzman[1], Sandra Magaña[2], Judith S. Rocha[1], Mariana Garcia Torres[1], Miguel Morales[1], David X. Marquez, FACSM[1]. *[1]University of Illinois at Chicago, Chicago, IL. [2]University of Texas at Austin, Austin, TX.* (Sponsor: David X. Marquez, FACSM)

(No relevant relationships reported)

Latina caregivers of children with developmental disabilities (DD) have more chronic health conditions and poorer health compared to both White and Latina caregivers of children without DD. It has been well documented that Latina women, in general, report less than recommended levels of physical activity (PA). A challenge of Latina caregivers is that they focus on caring for the family and the child with DD and take less time to care for themselves which contributes to the low levels of leisure-time PA and exacerbates already existing health disparities in this population. **PURPOSE**: To describe PA levels of Latina caregivers of children with DD and identify if one educational session led to changes in PA. **METHODS**: An 8-week caregiver intervention pilot was conducted with 24 caregivers of children with DD. *Promotoras de Salud,* community health worker (CHW) provided health education. Participants met with CHW in two-hour home visit sessions once a week. One entire session was dedicated to PA, which included the importance and benefits of PA, incorporating PA in everyday routines, and a stretching exercise activity. Participants had a wrist-worn ActiGraph GT3X+ accelerometer for 7 days at baseline and 8 weeks. **RESULTS**: This analysis included accelerometer data from baseline and post-test of 18 caregivers, M_{age}=44.2, all foreign born. The majority of this sample was highly active with a range of 7132 to 19620 steps/day at baseline and 72% and 67% of the participants exceeding 10,000 steps/day at baseline and at post-test, respectively. Participant's average step count significantly decreased at post-test (M=11092, SD=2705) from baseline (M=12055, SD=3247), t(17)=2.10, p=0.025. **CONCLUSIONS**: The present study suggests that Latina caregivers of children with DD are physically active. However, we were not able to identify whether this activity was from leisure-time, occupational or caregiving as we were only able to report on step count from wrist-worn accelerometer data. The program was designed to promote and sustain positive health behaviors, and one 2-hour educational session was not enough to promote PA. PA Interventions for Latina caregivers of children with DD should promote leisure-time PA to address the health disparities in this population.

Weight Status Influences Effectiveness of Need-Supportive Physical Activity Summer Camp in Girls

Megha Vishwanathan, Marlyse Sifre, Sophie Waller, Mika Manninen, Ellen M. Evans, FACSM, Sami Yli-Piipari. *University of Georgia, Athens, GA.*

(No relevant relationships reported)

PURPOSE: Habitual physical activity (PA) is a major factor related to obesity risk. Research has shown PA interventions among adolescents to be moderately successful in the short-term but limited to sustained behavior change. Self-determination theory (SDT) postulates that a psychological need-supportive environment (i.e. one that supports competence, autonomy, and social relatedness) is effective in maintaining volitional motivation which can lead to sustained positive behavioral changes including PA. Although research has supported the central tenets of the SDT, there is limited evidence examining whether a summer camp intervention

can sustain improvements in PA motivation and behavior. This study examined the effectiveness of a 1-week need-supportive summer camp to enhance self-determined PA motivation and behavior at 12-weeks post-camp. **METHODS:** Adolescent girls [*N*=42; *n*=18 overweight or obese girls (OW/OB, >85th percentile); M_{age} = 11.7±1.1] attended a one-week (5 days) camp intentional in need-supportiveness and completed follow-up 12 weeks post-camp. Objective PA was measured via accelerometer. Self-determined PA motivation was assessed using Behavioral Regulations in Exercise Questionnaire-3. **RESULTS:** At baseline, compared to OW/OB, healthy weight girls (HW): a) were similar in PA motivation (18.66±3.52, 19.88±3.59; *p*>.05), b) took more steps/day (12,172±2,103 vs. 7,442±3,737; *p*<.05), and c) engaged in greater moderate-to-vigorous intensity PA (MVPA) (291.7±46.4 vs. 185.4±90.8, *p*<.05). In PA motivation, the repeated measures analysis of variance results showed a significant within-subjects effect (*F*[1,38]=6.83, *p*=.019, η^2=.29). The within-subjects contrast analyses examining the growth trajectories showed a linear and positive growth pattern for OW/OB but a quadratic inverted U-shape for HW. Similarly, the analysis of covariance determined that the camp had a significant between-group effect on PA (steps: *F*[1,19]=15.83,*p*=.001, η^2=.46; MVPA: *F*[1,19]=21.63, *p*>.001, η^2=.52) with OW/OB increasing their PA whereas HW PA remained stable. **CONCLUSIONS:** These findings suggest that the psychological need-supportive summer camp may be more effective in improving and sustaining PA motivation and behavior in OW/OB compared to their healthy weight counterparts.

Safety and Health Outcomes of a Physical Activity Program for Adolescents with Type 1 Diabetes

Garrett I. Ash[1], Kevin L. Joiner[2], Mary Savoye[1], Julien S. Baker[3], James Gerosa[4], Emma Kleck[1], Neha S. Patel[5], Matthew Stults-Kolehmainen[6], Stuart A. Weinzimer[1], Margaret Grey[1]. *[1]Yale University, New Haven, CT. [2]University of Michigan, Ann Arbor, MI. [3]University of the West of Scotland, Lanarkshire, United Kingdom. [4]Southern Connecticut State University, New Haven, CT. [5]Penn State Milton S. Hershey Medical Center, Hershey, PA. [6]Yale New Haven Hospital, New Haven, CT.* (Sponsor: William J. Kraemer, Ph.D., FACSM, FACSM)

(No relevant relationships reported)

Purpose: Evaluate *Bright 1 Bodies (B1B)* intervention for sedentary adolescents with type 1 diabetes (T1D) for safety and health outcomes.
Methods: Eighteen sedentary adolescents with T1D (age 13.7±2.3y, female 67%, Black/Latino 67%, BMI 88±12%'ile, annual income 33% <$20k, 55% <$40k, A1c 9.5±2.3%, 79.9±25.1 mmol·mol[-1]) participated in group exercise classes (35min @ 60-80%HR_{max}) and self-management education 1x·wk[-1] for 12wk. Anthropometrics, glycemic control, brachial blood pressure, fasting lipids, and cardiopulmonary fitness (15m Progressive Aerobic Cardiovascular Endurance Run modified to slower starting speed, MPACER) were compared at baseline and 12wk using repeated measures ANCOVA for intent-to treat (n=18) and per protocol completers (attended ≥8 sessions, n=10).
Results: Blood glucose (BG) dropped from 12.16±4.35 mmol·L[-1] at start of exercise to 9.16±2.94 mmol·L[-1] at completion (p<0.01). Hypoglycemia (BG≤3.89 mmol·L[-1] with signs and/or symptoms) occurred once (0.6%). Average of 8.6±12.1g carbohydrates were required before, during, and/or after exercise. In the total sample (n=18) there were no changes in BMI, A1c, cardiopulmonary fitness, body fat, waist circumference, mean arterial pressure, or lipid profile (p>0.05). In the 10 completers, cardiopulmonary fitness improved (30.0±17.3vs37.1±20.8 MPACER shuttles, p=0.04), LDL increased but within normal ranges (2.23±0.54vs2.52±0.59 mmol·L[-1], p=0.02), and all other variables were unchanged (p>0.05).
Conclusion: B1B was safe for sedentary adolescents with T1D and improved cardiopulmonary fitness among completers. Exercise sessions decreased BG into ADA target range (3.9-10.0 mmol·L[-1]) with low risk of hypoglycemia and minimal need for supplemental carbohydrates (~35 kcals per 35min exercise session). However, overall glycemic control remained poor and BMI overweight, suggesting this at-risk population needs more intensive interventions.

2829   Board #112   June 1 2:00 PM - 3:30 PM

Variability In Implementation Of A Classroom-based Physical Activity Intervention: Implications For Disparities In Pediatric Physical Activity Participation

Lexie R. Beemer, Tiwaloluwa A. Ajibewa, Molly P. O'Sullivan, Matthew R. Nagy, Ben Ransier, Darin Stockdill, U. Sean Vance, Natalie Colabianchi, Rebecca E. Hasson, FACSM. *University of Michigan, Ann Arbor, MI.*

(No relevant relationships reported)

PURPOSE: Disparities in physical activity (PA) participation remain a public health concern with higher rates of inactivity reported in ethnic minority and low-income

youth. When implemented effectively, classroom-based PA interventions may help to reduce these disparities by providing structured PA at school. The purpose of this study was to evaluate the variability in implementation of Interrupting Prolonged Sitting with ACTivity (InPACT), a classroom-based PA intervention, in three economically and racially diverse schools in Southeast Michigan. **METHODS:** Three elementary schools in Michigan, one suburban (school 1: 90% white; 25% on free/reduced lunch), one rural (school 2: 90% white; 50% on free/reduced lunch) and one urban (school 3: 59% black; 74% on free/reduced lunch) participated in this 16-week study. Prior to the start of the intervention, teachers were trained to incorporate 10, 3-minute moderate-to-vigorous physical activity (MVPA) breaks in their classrooms each day. Throughout the intervention, teachers completed surveys to document the number of MVPA breaks completed per day. Direct observation was also used to assess intervention fidelity. **RESULTS:** There was a significant difference in the number of MVPA minutes completed in the classroom per week by school (school 1: 82±11min; school 2: 98±11min; school 3: 50±13min; p=0.04). There was also a significant difference in the percent of students who engaged in MVPA by school (school 1: 92±0.03%; school 2: 84±0.03%; school 3: 77±0.05%, p=0.02). There was a trend towards a significant difference in the number of activity breaks implemented per day (school 1: 5 breaks; school 2: 6 breaks; school 3: 3 activity breaks; p=0.06). **CONCLUSIONS**: Implementation of the InPACT intervention varied by school with school 3, the low-income, ethnically diverse school accumulating significantly fewer minutes of MVPA in the classroom compared to the higher-income, predominantly white schools. Although this intervention was successful in two of our three target schools, tailored intervention strategies are needed to improve implementation in low-income schools to better address disparities in physical activity participation.

2830   Board #113   June 1 2:00 PM - 3:30 PM

Effect Of School-based Physical Activity Programs On Hamstring Flexibility: A Meta-analysis

Sonia Montero-Briceño, Isaura M. Castillo-Hernández. *University of Costa Rica, San José, Costa Rica.* (Sponsor: Ellen M. Evans, FACSM)

(No relevant relationships reported)

PURPOSE: Flexibility is an often neglected but very important physical fitness component that is gaining attention regarding its role in correct posture and the incidence of chronic injuries, especially among children and adolescents.The aim of the study was to examine the chronic effect of school-based physical activity (PA) programs on hamstring flexibility (HFlex) and to evaluate potential moderators of this effect using a meta-analytic approach.
METHODS: A computerized literature search was conducted based on five databases: SPORTDiscus, Google Scholar, PubMed, Dialnet Plus, and MEDLINE. Studies needed to meet the following inclusion criteria to be included in the meta-analysis: 1) a randomized controlled trial design, 2) PA program took place in a school setting 3) published in English or Spanish, and 4) reported descriptive statistics that permitted effect size (ES) calculation. A random-effects model with a within-group design was used to calculate the ES. The moderator effects were analyzed either by one-way analysis of variance of independent groups or by Pearson product-moment correlation coefficients, depending on the variable considered.
RESULTS: From 2006 articles, 13 studies representing 18 ES's and totaling 792 participants (males and females, 10.3 ± 0.5 yo) were included in the analysis. The mean quality score for the studies was 3.4 ± 0.7 (on a scale from 1 to 5). A moderate overall ES of 0.38 ($p \le 0.001$; $CI_{95\%} = 0.22$ to 0.87; z=4.58; Q=13.38; I^2=92.48%) was found suggesting a low-moderate effect of the school-based PA programs to enhance HFlex. Neither a) quality of the studies (r = -0.43, p = 0.87), b) number of intervention sessions (r = -0.16, p = 0.52), nor c) minutes per session (r = -0.03, p = 0.91) were significant moderators. Sex could not be included as a moderator because 78% of the studies did not report the effect on HFlex separately by sex. No bias was found according to Egger's regression analysis (*p=0.80*).
CONCLUSION: School-based PA programs have a significant positive overall effect on children and adolescents' HFlex compared with their control peers. Reporting the effect differentiated by gender and including detailed group demographic data (i.e., experimental and control) is recommended for individual studies.
KEYWORDS: hamstring flexibility, school-based physical activity

Interventions for Increasing Physical Activity in Low-Income, Ethnic Minority Children and Youths: Meta Analysis

Kyungun Kim[1], Seung Ho Chang[2], Jihyun Lee[2], Sukho Lee[3]. *[1]University of Central Missouri, Warrensburg, MO. [2]San Jose State University, San Jose, CA. [3]Texas A&M University-San Antonio, San Antonio, TX.* (Sponsor: Minsoo Kang, FACSM)

(No relevant relationships reported)

Ethnic minority and economically disadvantaged children and youths often show high levels of risk and vulnerability to physical inactivity and health issues. **PURPOSE:**

To provide a better understanding of and examine the effectiveness of interventions to increase physical activity (PA) in children and youths from low-income families and ethnic minorities (LIEM) through a meta-analysis. **METHODS:** We identified relevant studies through August 2017 from PubMed, Medline, CINAHL Plus, SportDiscuss, ERIC, PsychINFO, Scopus, ProQuest, and The Physical Activity Index. The main outcomes were the general PA levels and moderate-to-vigorous- intensity of PA. Inclusion criteria applied were: (a) necessary statistics to compute effect sizes (ES); (b) PA intervention studies; (c) LIEM participants aged 3-12 years; and (d) full-text articles written in English and published in peer-reviewed journals. A random-effects model was used to estimate the ES. Furthermore, moderator analysis was conducted using five moderators: (1) intervention duration (<13, 13-47, or >47 weeks); (2) participant age (<10, 10-12, or >12 years); (3) intervention delivery (teacher, parents, teacher and parents, or specialists), (4) technology (used or not used); and (5) behavioral modification (used or not used). The ES were calculated using the Comprehensive Meta-Analysis 3.0. The ES were computed using Hedges g with 95% CI, and the group difference was examined using the Q-statistic. **RESULTS:** The results indicate that there were small to medium effects of PA interventions on PA (Overall ES = .325, 95% CI = .088, .561). Moderator analysis did not identify any significant differences across groups. However, ES for groups with less than 13 weeks (ES = .527, 95% CI = .163, .891, *p* = .005), participants aged 10-12 (ES = .540, 95% CI = .185, .895, *p* = .003), interventions delivered by specialist (ES = .535, 95% CI = .104, .966, *p* = .015), interventions without technology (ES = .367, 95% CI= .099, .634, *p* = .007), and interventions with behavioral modification (ES = .314, 95% CI = .046, .582, *p* = .022) were significantly different from zero. **CONCLUSION:** The results from this study indicate that interventions targeting increase in PA in LIEM children and youths were somewhat successful with small to medium effects.

Standing Desk Intervention In Elementary School Children: Effects On Physical Activity And Sedentary Behavior

Ann M. Swartz, FACSM, Nathan Tokarek, Chris C. Cho, Nora E. Miller, Hotaka Maeda, Krista Lisdahl, Scott J. Strath, FACSM. *University of Wisconsin-Milwaukee, Milwaukee, WI.*

(No relevant relationships reported)

Movement is very important for the growth and development of children. However, according to NHANES accelerometer data, children aged 6-11years spend almost half of their day sedentary. Therefore, identifying ways to increase physical activity is important to the health of children. **PURPOSE:** To determine the effect of replacing traditional sitting desks with standing desks on total daily sedentary behavior (SB) and physical activity (PA) in elementary school children. **METHODS:** A 9- week within-classroom, controlled design, with teacher allocation to either a traditional seated desk (CON) or a standing desk (INT) was conducted during the first part of the school year. Baseline (September) and post assessments (December) included five consecutive weekdays of waking hour, hip-worn accelerometer (Actigraph GT3x+) assessments. Wilcoxon Rank Sum and Kruskal-Wallis Tests were used to detect significant between group differences (p<0.05) in changes in SB, light-intensity PA (LPA), and moderate-to vigorous-intensity PA (MVPA). **RESULTS:** 22 third (8.5 ±0.7y), 36 third (9.7 ±0.5y) and 41 sixth (11.7 ±0.4y) grade students completed the study and provided complete accelerometer data during the school day. During the intervention, students were exposed to the standing desks in the classrooms (homeroom time) for 19h of the possible 34.4 h per week that students attended school. While both groups showed an increase in percent of homeroom time sedentary and a decrease in PA, changes in SB and PA were significantly less in the INT group than the CON group (SB, p=0.033; LPA, p=0.004; MVPA, p=0.003). Specifically, the INT increased SB by 1.9% and decreased MVPA by 0.1% of wear time, while the CON group increase SB by 6.2% and decreased MVPA by 3.1% of homeroom time. Similar trends in PA, but not SB or sitting, were seen when examining the entire school day. **CONCLUSIONS:** As the school year progresses, there is a tendency for student to increase sitting and decrease PA. The introduction of the standing desk was shown to positively curtail these trends. Therefore, standing desks may be useful in preventing sedentary activity in elementary school classrooms, especially among younger children.

2833   Board #116   June 1 2:00 PM - 3:30 PM

Impact Of Coordinated-bilateral Physical Activities On Attention And Concentration In School-aged Children

Weiyun Chen, Heidi Harris. *University of Michigan, Ann Arbor, MI.*

(No relevant relationships reported)

PURPOSE: This study examined the effects of a 4-week, daily 6-minute coordinated-bilateral physical activity (CBPA) breaks in classroom on attention and concentration in school-aged children. **METHODS**: 116 fifth graders from two elementary schools were assigned to three groups: two intervention groups (n= 60) and one control group (n = 56). Three groups were pre- and post-tested with the d2 Test of Attention, a cancellation test that measures students' performance in attention and concentration.

One intervention group (n = 31) participated in six minutes of daily coordinated-bilateral physical activity (CBPA) classroom break for four weeks. Another intervention group (n = 29), the Fitbit Only (Fitbit-O), wore Fitbits per day, five school days per week for four weeks without CBPA breaks. Processing Speed, Focused Attention, Concentration Performance, Attention Span, and Accuracy were used as parameters of attention performance for data analysis. The d2 Test had high test-retest reliability coefficients for all parameters, ranging from .95 to .98. A 2 × 3 ANOVA repeated measures were conducted, followed by the post hoc comparisons. **RESULTS**: The repeated measure ANOVA revealed a significant interaction between time × treatment in processing speed ($F_2 = 3.372$, $p = .038$, $= 0.058$), focused attention ($F_2 = 4.37$, $p = .015$, $= 0.074$), concentration performance ($F_2 13.53$, $p = .000$, $= 0.197$), and attention span ($F_2 = 8.04$, $p = .001$, $= 0.128$), but not in accuracy. Subsequently, the post hoc comparisons indicated that the CBPA group showed significant increases in processing speed ($F_1 = 6.876$, $p = .010$), focused attention ($F_1 = 10.688$, $p = .002$), concentration performance ($F_1 = 26.46$, $p = .000$), and attention span ($F_1 = 14.090$, $p = .000$) over the control, but not in accuracy. The CBPA group also showed significant improvement in concentration performance ($F_1 = 24.162$, $p = .000$) and attention span ($F_1 = 6.891$, $p = .011$), compared to the Fitbit-O. No significant changes in all five attention parameters were found between the Fitbit-O and the control. **CONCLUSIONS**: Engaging students in daily, highly-focused, coordinated-bilateral activities is an effective strategy to improve attention and concentration in school-aged children.

2834   Board #117   June 1 2:00 PM - 3:30 PM

The Impact Of Stand-biased Desks On After-school Physical Activity Behaviors In Children

Nathan R. Tokarek, Chi C. Cho, Hotaka Maeda, Scott J. Strath, FACSM, Nora E. Miller, Ann M. Swartz, FACSM. *University of Wisconsin - Milwaukee, Milwaukee, WI.* (Sponsor: Ann M Swartz, FACSM)

(No relevant relationships reported)

PURPOSE: To assess changes in after-school time spent performing sedentary behavior (SB), light-intensity physical activity (LPA), and moderate- to vigorous-intensity physical activity (MVPA) among elementary school children in response to the introduction of stand-biased desks in the classroom. **METHODS:** Thirty-one 6th grade participants were assigned by their teacher to either a traditional (TD) (n=16) or stand-biased (SBD) (n=15) desk. After-school PA and SB were measured using accelerometry on four consecutive weekdays at baseline (prior to introduction of the stand-biased desks), and again following 9-weeks of exposure to either a TD or SBD in the classroom. After-school weather conditions and sport participation were recorded during both measurement periods using National Oceanic and Atmospheric Administration (NOAA) data and the Youth Activity Profile Questionnaire (YAP), respectively. Wilcoxon Rank Sum Tests were used to detect significant differences (p<0.10) in changes in after-school SB and PA between groups. **RESULTS:** No significant between group differences were found during the after-school period in pre-post changes in time spent performing SB (p=0.770), LPA (p=0.740), vigorous-intensity PA (VPA) (p=0.599), or MVPA (p=0.470). Significant between group differences in the median change in proportion of time spent performing moderate-intensity PA (MPA) (SBD: -1.4%; TD: -0.2%, p=0.093) were detected, with the SBD group experiencing a decrease of 4.3 minutes/after-school period relative to a 0.1 minute increase among TD participants. Coinciding with a change in PA, it was found that the average after-school temperature decreased from 60.0 °F at pre to 11.4 °F at post, while daylight also decreased by 81 minutes during the after-school period. Further, after-school sport participation between groups also changed from pre-post, with TD experiencing an increase of two after-school sport participants, while SBD experienced a decrease in after-school sport participation of two participants. **CONCLUSION:** Stand-biased desks did not have a negative impact on children's after-school PA and SB. Instead, seasonal variation and the structure of children's after-school schedule may have a greater influence on after-school activity than a mild classroom-based stand-biased desk intervention.

2835   Board #118   June 1 2:00 PM - 3:30 PM

Evaluation of Physical Activity and Flexibility Metrics in Children with Congenital Heart Diseases or Obesity Attending a Golf Camp

Christopher Kist, Amanda Gier, Nicole Weisner, Seth Gray, Bob Siegel, Clifford Chin. *Cincinnati Children's Hospital, Cincinnati, OH.*

(No relevant relationships reported)

PURPOSE: The purpose of this study is to evaluate the effects of a 5-week summer golf camp on cardiovascular fitness and flexibility in youth with obesity and/or congenital heart disease.
METHODS: Twenty-six youth, ages 8 to 13, were recruited for the First Tee golf camp sponsored by the Children's Heart Association. Twelve patients had congenital heart disease and 14 patients were obese. The camp consisted of a 3-day SCRATCH

---

golf training program followed by 5 weeks of golf sessions. Golf sessions were 90 minutes long, offered twice weekly, for a total of 13 sessions. Informed consent/assent was obtained for all participants. Pre and post-camp flexibility measurements were assessed via the back saver sit-and-reach test. Subjects completed the PACER test to assess aerobic capacity before and after the completion of camp.
RESULTS: Mean age of participants was 11 years old. Pre and post-test data from the PACER test was obtained from 22 (85%) participants (14 boys, 8 girls). There were significant improvements in PACER scores from baseline (p < 0.0001). 21 (95%) participants improved PACER scores by the conclusion of camp. PRE PACER lap score was (10.0 ± 5.6). POST PACER lap score was (13.3 ± 7.0). Pre and post-test sit and reach data was obtained from 25 of the 26 (96%) camp participants (17 boys, 8 girls). There were significant improvements in right and left leg sit and reach scores for both girls and boys (right side, p < 0.0001; left side, p < 0.0001). Right side PRE sit and reach was (9.7 ± 2.3) compared to POST = (11.3 ± 2.1). Left side PRE sit and reach was (9.5 ± 2.9) compared to POST = (11.4 ± 2.4).
CONCLUSIONS: Youth with congenital heart disease and/or obesity show significant improvements in flexibility and cardiorespiratory fitness after attending golf camp. Camp appears to offer health benefits in addition to learning about golf and may promote children to be outside and active. There is limited research on the effects of participating in a golf camp in pediatric congenital heart disease and obese populations; further studies may identify additional health benefits.

The Association Of Blood Lipids With Selected Other CVD Risk Factors In Michigan Adolescents

Ashlyn Jendro[1], Breanne R. Carlson[2], Erich J. Petushek[3], Karin A. Pfeiffer, FACSM[3], Joseph J. Carlson[3]. [1]*Northern Michigan University, Marquette, MI.* [2]*Michigan State University Extension, East Lansing, MI.* [3]*Michigan State University, East Lansing, MI.* (Sponsor: Karin Pfeiffer, FACSM)

(No relevant relationships reported)

Cardiovascular disease (CVD) is the leading cause of death in adults in the United States. A concern in U.S. children is the increasing rates of CVD risk factors (obesity, dyslipidemia and low cardiorespiratory fitness) which tend to track into adulthood and are related to premature morbidity and mortality. Specifically, high levels of low-density lipoprotein (LDL), total cholesterol and blood pressure, alongside low levels of high-density lipoprotein (HDL) and cardiorespiratory fitness, have been identified as risk factors for CVD. **PURPOSE:** To identify the association of several CVD risk factors from a pediatric population participating in (S)Partners for Health. **METHODS:** This cross-sectional study included 248 (151 female, 97 male), 9-13 year old students in 2008-2013, from Michigan, who participated in baseline measures for the (S)Partners for Health. Pearson correlations were used to evaluate if LDL, HDL or total cholesterol were directly associated with body weight, percent body fat, waist circumference, body mass index (BMI), mean arterial pressure (MAP) and aerobic performance (20-meter PACER scores). **RESULTS:** There were significant, but weak, correlations among HDL, LDL, total cholesterol and body weight, body fat, waist circumference and BMI (Table 1). **CONCLUSION:** The weak associations between lipid indicators and CVD risk factors measured in (S)Partners for Health align with previous research. Future studies should investigate the modifiability of these variables and use factor analytic or profiling techniques to address the various measurement properties of this extensive CVD risk assessment battery to improve efficiency.

Table 1: Correlation of lipid indicators and other CVD risk factors					
	Body Weight	Body Fat	Waist Circumference	BMI	20-meter Pacer Score	MAP
HDL	-0.268**	-0.292**	-0.264**	-0.239**	0.107	-0.032
LDL	0.305**	0.330**	0.309**	0.334**	-0.151*	0.232**
Total Chol.	0.226**	0.265**	0.241**	0.268**	-0.132*	0.219**
** p<0.01 * p<0.05

Changes in Physical Activity Enjoyment following HIIT Training in Adolescents

Elizabeth K. Bailey, Christine Tassitino, Lexi Byrd, Brianna Marino, Taylor McMaster, Bre'anna Warren, Megan Farrell, Stephen P. Bailey, FACSM. *Elon University, Elon, NC.* (Sponsor: Stephen P. Bailey, FACSM)

(No relevant relationships reported)

Pleasurable experiences with exercise appear to be important in the development of positive lifelong physical activity habits in adolescents. High-intensity interval training (HIIT) has been described as being a more pleasurable experience then traditional exercise training. **PURPOSE:** The purpose of this investigation was to describe the impact of HIIT training on enjoyment of physical activity, cardiovascular fitness,

and body composition in male and female adolescents. **METHODS:** Thirteen (6 male, 7 female; Age=12.8$\pm$0.7 years) adolescents completed an 8 week HIIT training program. HIIT training consisted of two 30 minutes sessions a week (5 min warm up, 20 minute stimulus, 5 min cool down). During the stimulus period, subjects completed twenty 30 sec "on", 30 sec "off" intervals. The initial "on" workload was set to be equivalent to 90% of maximal workload recorded during the VO_2max test, while the "off" workload was set to be equivalent to 50% of maximal workload. Intensities were adjusted during each session so that RPE during the last 5 intervals was equivalent to at least 9 out of 10 on the Borg RPE scale. Enjoyment of physical activity (Physical Activity Enjoyment Scale, PACES), VO_2max and body composition were assessed before and after the training program. **RESULTS:** Response to the PACES improved 23% following HIIT training (Pre=52$\pm$3, Post=64$\pm$3; p=0.01). Similarly, VO_2max (18%) (Pre=26.7$\pm$2.0 ml·kg^{-1}·min^{-1}, Post=31.6$\pm$2.7 ml·kg^{-1}·min^{-1}; p=0.002) and maximal workload (58%) (Pre=144$\pm$7 W, Post=228$\pm$18 ml·kg^{-1}·min^{-1}; p=0.001) increased as a result of HIIT. In contrast, body fat (Pre=46.6$\pm$2.5%, Post=44.9$\pm$2.4%; p=0.001) was reduced following HIIT. **CONCLUSION:** The results of this investigation indicate that HIIT training elicits a more positive perception of exercise and beneficial adaptations in cardiovascular fitness and body composition. HIIT training appears to be a good option to develop positive lifelong physical activity habits in adolescents.

Effects Of A Weight Bearing Exercise Program On Bone Mineral Density Of Adolescent Female Athletes

Kayla Daniel[1], Kelsey Conrad[2], Jaqueline Buell[2], Julie Young[1], Lihong Huang[1], Anastasia Fischer, FACSM[1]. [1]*Nationwide Children's Hospital, Columbus, OH.* [2]*Ohio State University, Columbus, OH.* (Sponsor: Anastasia Fischer, FACSM)
(No relevant relationships reported)

PURPOSE: Bone Mineral Density (BMD) is a modifiable target of the Female Athlete Triad for intervention. Low BMD can be screened, prevented, and treated. In female adolescents, low BMD is associated with increased risk of fracture and development of osteoporosis. Weight bearing exercise interventions are proven to elicit a substantial bone mineral accrual advantage in childhood. The purpose of this study was to evaluate for a change in BMD in female adolescent athletes after a weight bearing physical activity intervention designed to optimize BMD and bone architecture.
METHODS: : A convenience sample of 19 female high school athletes completed a Dual Energy X-Ray Absorptiometry (DEXA) scan and resting metabolic rate (RMR) as well as eating and activity questionnaires. Girls participated in a one hour program designed to improve BMD twice per week completing 16 sessions in 8-12 weeks. Following the program, girls completed a second DEXA scan. 12 months after the program, girls completed a third DEXA scan. Total Body Less Head (TBLH), lumbar spine, and Total Fat Free Mass (TFFM) were recorded. Energy availability (EA) was calculated using estimated energy intake from eating questionnaire and energy needs were estimated using the activity questionnaire added to their RMR. Girls were diagnosed with decreased EA if they consumed <30kcal/kg FFM per day. Repeated measures ANOVAs were run to examine differences between BMD between three time points.
RESULTS: Average age at the beginning of the study was 16.31±1.19. Fourteen girls were tested immediately after the exercise program and 8 one year after the program. There were no differences in TBLH, lumbar spine or TFFM (p=.22, p=.23, p=.29 respectively) over the program. Girls with decreased EA did not accrue BMD significantly differently than those with adequate EA.
CONCLUSIONS: BMD did not increase following a weight bearing exercise program in adolescent female athletes. EA did not affect accrual of BMD during this short time in this research cohort.

2839 Board #122 June 1 2:00 PM - 3:30 PM

Objectively Measured Physical Activity in Parent-Child Dyads Exercising Together in Five Activities.

Patrick Filanowski[1], Noelle Merchant[1], Ronald J. Iannotti[2], Sarah M. Camhi[1], Jessica A. Whiteley[1], Laurie Milliken, FACSM[1]. [1]*University of Massachusetts Boston, Boston, MA.* [2]*CDM Group, Inc., Bethesda, MD.* (Sponsor: Laurie Milliken, FACSM)
(No relevant relationships reported)

PURPOSE: To objectively measure and compare the intensity of 5 physical activities completed by parent-child dyads.
METHODS: Thirteen children (C) (6.6 ± 1.8 yrs) and their parents (P) (37.1 ± 7.5 yrs) participated in physical activity (PA) sessions. Each parent-child dyad completed 5 different PAs in random order [brisk walking (BRISK), jumping games (JG), dancing (D), body-weight exercises (BWE), and tag games (TG)] together for 8 minutes each. Minutes of PA for each participant was measured using Actigraph GT9X accelerometers worn at right hip. Time spent in moderate (%MPA) and vigorous (%VPA) PA were estimated using validated cut points for appropriate age ranges.

Independent t-tests were used to compare PA between P and C. A repeated measures ANOVA was used to compare PA across 5 different PAs, separately for P and C. Alpha was set at p < 0.05.
RESULTS: [P versus C]: C had more %VPA than P during BRISK (mean difference: 15.8 ± 23.1), JG (21.2 ± 0.1), D (16.2 ± 12.0), and TG (24.7 ± 7.6). P had more %MPA than C during BRISK (mean difference: 22.2 ± 4.9), JG (10.8 ± 3.1), and TG (12.3 ± 0.5). [Brisk walking]: BRISK (68.1 ± 18.8) resulted in more time spent in %MPA for P when compared to JG (28.2 ± 9.6), BWE (31.0 ± 8.8), D (39.7 ± 19.3), and TG (41.7 ± 10.3). C had more %MPA during BRISK (45.9 ± 23.7) than JG (17.4 ± 6.5). [Jumping games]: P had more %VPA in JG (29.4 ± 9.6) when compared to BRISK (00.0 ± 00.0), BWE (13.3 ± 6.3), D (5.3 ± 4.6), and TG (4.5 ± 5.3). C had more %VPA during JG (50.6 ± 9.5) than BRISK (15.8 ± 23.1), BWE (30.9 ± 12.6), D (21.5 ± 16.6), and TG (29.2 ± 12.9). [Body-weight exercises]: P had more %VPA during BWE (13.3 ± 6.3) when compared to BRISK (00.0 ± 00.0), D (5.3 ± 4.6), and TG (4.5 ± 5.3) and C had more %MPA during BWE (22.7 ± 9.6) than JG (17.4 ± 6.5). [Dancing]: P had more %VPA (5.3 ± 4.6) than BRISK (00.0 ± 00.0) (p < 0.05). [Tag Games]: P had more %MPA during TG (41.7 ± 10.3) when compared to JG (28.2 ± 9.6) and BWE (31.0 ± 8.8). C had more %MPA during TG (29.4 ± 9.8) than JG (17.4 ± 6.5). p < 0.05 for all comparisons mentioned.
CONCLUSIONS: C spent significantly more time in VPA during all 5 PAs when compared to P. However, P spent significantly more time in MPA during BRISK, JG, and TG than C. For both P and C, JG had the most VPA when compared to the other PAs. These findings can be used to plan future PA interventions for P and C exercising together.

2840 Board #123 June 1 2:00 PM - 3:30 PM

The Contribution Of A Community-Based Gym And Aquatics Program To Physical Activity In Children

Mark R. Scudder, Neil P. Sharma, Sharon E. Taverno Ross, John M. Jakicic, FACSM. *University of Pittsburgh, Pittsburgh, PA.*
(No relevant relationships reported)

PURPOSE: To compare physical activity in children accumulated from gym and aquatic instruction during a 2-hour community-based physical activity program.
METHODS: The community-based program consisted of a summer weekday program and a fall Saturday program, with each program including both a gym and aquatics component. Each program served approximately 60-85 boys and girls 3-13 years of age. Observations were conducted over 10-12 sessions for each program to quantify the amount of physical activity engagement. Observations included use of the System for Observing Fitness Instruction Time (SOFIT) to quantify children's physical activity (e.g., sedentary vs. 'very active') and the context of the program (e.g., skill practice vs. free play). SOFIT observations were made by two trained observers, and the inter-rater reliability was greater than 90%. Physical activity and context variables were subjected to linear mixed model analyses, with type of instruction entered as a fixed factor, and multiple observations of the same age or skill group entered as a repeated factor.
RESULTS: Gym and aquatic instruction each contributed approximately 25 min of moderate-to-vigorous physical activity, with the proportion of time spent in moderate-to-vigorous physical activity not statistically different during aquatic vs. gym sessions (53.4% vs. 49.0%, $p = .09$). Compared to the gym session, however, the aquatic session resulted in less time sitting (4.8% vs. 17.2%) and more time 'very active' (25.1% vs. 13.9%, $p<.001$), as well as higher estimated energy expenditure (0.087 vs. 0.079 kcal/kg/min, $p<.001$). Compared with the gym, children spent less time in management contexts (i.e., breaks and transitions; 15.9% vs. 30.2%, $p<.001$) and more time in free play (10.7% vs. 0.7%, $p<.001$) during the aquatic sessions. **CONCLUSIONS:** The results suggest that these types of programs can be effective at engaging children in physical activity during out-of-school time, with the data from the aquatic sessions of particular interest. Additional research is needed to examine whether these results are consistent across different community-based programs and with varying skill level of program instructors, and whether the physical activity achieved with these programs provides health-related benefits in children.

2841 Board #124 June 1 2:00 PM - 3:30 PM

Physical Activity Enjoyment in Different Physical Activities in Parent-Child Dyads When They Exercise Together

Noelle Merchant[1], Patrick Filanowski[1], Ronald J. Iannotti[2], Sarah M. Camhi[1], Jessica A. Whiteley[1], Laurie Milliken, FACSM[1]. [1]*University of Massachusetts Boston, Boston, MA.* [2]*CDM Group, Inc., Bethesda, MD.* (Sponsor: Laurie Milliken, FACSM)
(No relevant relationships reported)

PURPOSE: To objectively measure and compare the enjoyment of 5 physical activities designed for parent-child dyads.
METHODS: Thirteen parent-child dyads (parents mean age = 37.1 ± 7.5 yrs, children mean age = 6.6 ± 1.8 yrs) participated in physical activity (PA) sessions facilitated by trained research assistants. The 6-point Visual Analog Scale (VAS), with 1 meaning 'like it very much' and 6 meaning 'don't like it at all', was used to assess

participants' enjoyment of each PA during the PA sessions. Each parent child dyad completed 5 different PA's together (brisk walking, jumping games, dancing, body-weight exercises, and tag games) in random order for 8 minutes each. Immediately after completion of each of the 5 PA's, research assistants provided the VAS to the parent and child, independently, and asked them to indicate their enjoyment rating of the preceding PA. A Mann-Whitney U test was used to compare enjoyment of the 5 different PA's between parents and children, with a significance level set at p < 0.05. Friedman tests were used to compare the differences in enjoyment of the activities separately for parents and children. Post hoc analyses with Wilcoxon signed-rank tests were conducted with Bonferroni corrections applied, resulting in a significance level set at p < 0.0125 to compensate for multiple comparisons.
RESULTS: Parent's enjoyment was significantly higher for dancing compared to children's (parents mean = 1.46 ± 0.78, children's mean = 3.00 ± 1.58, U = 34.5, p = 0.007). When comparing PA's performed by parents, parents enjoyed tag games (mean = 1.31 ± 0.48) significantly more than brisk walking (mean = 2.38 ± 1.21, Z = -2.547, p = 0.011) and body-weight exercises (mean = 2.77 ± 1.36, Z = -2.859, p = 0.004). When comparing activities performed by children, children enjoyed tag games (mean = 1.23 ± 0.59) significantly more than dancing (mean = 3.00 ± 1.58, Z = -2.825, p = 0.005).
CONCLUSION: Both parents and children enjoyed tag games the most, when compared to the other 5 PA's. These results could aid future PA programming and interventions when recommending activities for families to complete together. Future studies should investigate if varying enjoyment levels of parent-child dyads could impact the likelihood that they would exercise together where enjoyment levels are not matched.

2842   Board #125   June 1 2:00 PM - 3:30 PM

Effects Of An Educational, Nutritional And Recreational Camp Intervention In Health Parameters In Overweight Children

Carmen Silvia Grubert Campbell[1], Suliane Beatriz Rauber[1], Henrique Lima Ribeiro[1], Isabella Reis Praça[1], Joyce Bomfim Vicente[1], Geiziane Melo[1], Zelia Vargas dos Reis[1], Valeria Pedrosa[1], Pablo Cidelino[1], Daniel Fernandes Barbosa[1], Eric Vale[1], Alisson Luiz Aquino da Silva[1], Herbert Gustavo Simões[2]. [1]Catholic University of Brasilia, Taguatinga, Brazil. [2]Catholic University of Brasilia, Águas Claras, Brazil.
(No relevant relationships reported)

PURPOSE: To investigate the impact of a Health Educational Program for Children (HEPchild) composed by 5 days of Camp Kids (KIDS) and 12-weeks of follow-up (FOU) on the Physical Activity Level (PAL), Sedentary Behavior (SB), Anthropometric data and Food Intake (FI) in overweight children. **METHODS:** Twelve children attended the HEPchild program which consisted of pre assessments, KIDS and 12 weeks of FOU. The PAL, SB and FI were assessed throughout questionnaires. **RESULTS:** The anthropometric were reduced (p<0.05) after KIDS which was maintained at the 12 weeks of FOU. After the FOU, children increased (p<0.05) their mean level of physical activity by 344 METs/week. In addition 25% of the children became more active (> 1500 and <3000METs/week) after FOU in comparison to pre KIDS. On the other hand, the amount of sedentary children (<600METs/week) decreased by 15% and the insufficiently active (600 at 1500METs per week) increased by 15%. The PAL leisure time increased significantly throughout the weekdays (26.0%) and the weekends (14.1%) after FOU comparing to pre KIDS. The SB showed a significant reduction in 177.14 and 41.43 minutes along the weekdays and the weekends respectively. Before KIDS, the consumption of sugars and candies were out of control (100% inadequate), and, after the intervention, 58.4% started to consume these foods in a balanced way. In addition, the body fat, triceptal and subscapular skinfolds, waist circumference and waist-to-height ratio decreased significantly after KIDS and the results maintained after FOU in comparison to pre KIDS. In addition, it was observed a significant reduction in body fat, triceps and subscapular skinfolds, waist circumference and waist-to-height ratio after KIDS which was maintained after FOU in comparison to pre KIDS. **CONCLUSION:** The HEPchild (5-days KIDS camp + 12 weeks of FOU) contributed to increase the PAL and to reduce the SB and anthropometric data in overweight children.

Six-month Sustained Improvement In Motor Proficiency In Youth After A 24-week Home-based Intervention

Daniela A. Rubin, FACSM[1], Kathleen S. Wilson[1], Debra J. Rose[1], Marilyn Dumont-Driscoll[2]. [1]California State University Fullerton, Fullerton, CA. [2]University of Florida Gainesville, Gainesville, FL.
(No relevant relationships reported)

PURPOSE: Motor proficiency and physical activity (PA) levels are below average in youth with Prader-Willi syndrome (PWS), a rare neurodevelopmental disorder causing motor, behavioral, and medical challenges. This study aimed to determine if participation in a 24-week parent-led PA intervention led to sustained improvement in gross motor proficiency (MP) in youth with and without PWS.
METHODS: Participants included 107 youth ages 8-16 with PWS or without PWS but categorized as obese, assigned to an intervention group or to a wait-list control group. After serving as controls, the wait-listed group received the intervention. Follow-up assessments were then conducted six months post intervention. The home-based PA program included playground and interactive console games scheduled 4 days a week. Training and program materials were provided to families at baseline to guide implementation of the program. Gross MP (Bruininks-Oseretsky Test of Motor Proficiency body coordination and strength and agility subtests) was obtained at baseline (pre), after 24 weeks of participating in the intervention (post) and at 6-month FU. Scale scores are reported (Mean ± SE). Intent-to-treat analyses were conducted.
RESULTS: All youth demonstrated improved upper-limb coordination, bilateral coordination, balance, running speed and agility, and muscular strength at post (p<0.04 for all). At FU all youth maintained improvements in bilateral coordination (pre= 9.3±0.4, post=12.0±0.5, FU=11.6±0.6) and speed and agility (pre=9.2±0.4, post=10.8±, FU=11.4±0.5), p<0.05. At FU all youth maintained improvements in upper-limb coordination (pre=10.7±0.5, post=12.2±0.6, FU=12.1±0.8) balance (pre=8.1±0.3, post=9.3±0.4, FU=9.2±0.5) and strength (pre=8.0±0.3, post=9.0±0.4, FU=9.0±0.5), but the FU scores for these tests showed a slight decrease such that they were no longer significantly different from baseline (p<0.05).
CONCLUSIONS: This parent-led game-based PA program resulted in immediate positive changes in gross MP in youth with and without PWS with improvements maintained for six months post intervention. Participation in a PA routine emphasizing motor skill development at home shows promise in leading to sustained improvements in MP in obese youth and in youth with PWS.

Are Graded Task-based Interventions The New Remedy For Unfit Overweight And Obese Female Adolescents?

Emmanuel Bonney, Gillian Ferguson, Bouwien Smits-Engelsman. *University of Cape Town, Cape Town, South Africa.*
(No relevant relationships reported)

Promotion of physical activity and fitness in adolescent girls who are physically unfit and have less opportunity to practice remains a challenge, particularly in low income communities. It is therefore critical to identify new methods for increasing fitness in this population.
Purpose: To determine the efficacy of two graded task-based interventions in improving neuromotor fitness among adolescent girls.
Methods: Fifty-six female adolescents (14.4±0.9years) classified as overweight or obesity participated in the study. Participants were randomly allocated to receive either the graded Wii exercises or task-based functional exercise and attended weekly 45min exercise sessions for 14 weeks. During the training period, the participants received supervised exercise training that was systematically graded with simple objects such as sandbags and plastic bottles over 14 sessions. Outcome measures included motor competence, lower extremity muscular strength (both isometric and functional strength), aerobic and anaerobic fitness. Data on enjoyment and ratings of perceived exertion were collected for each session. A repeated measure ANOVA was used to analyse the data with significance level set *apriori* at p<0.05.
Results: At the end of the intervention, it was observed that both groups had significant improvement in motor competence [F(1,54)=0.465,p=0.001], lower extremity muscular strength (isometric strength) [F(1,54)=592.470,p=0.001], lower extremity muscular strength (functional strength) [F(1,54)=15.993, p=0.001], aerobic [F(1,54)=5.586, p=0.022] and anaerobic fitness [F(1,54)=45.792,p=0.001]. Though the two interventions were equally considered to be enjoyable by the participants, there was no difference in outcomes for the two groups.
Conclusions: The two graded task-based interventions may be useful for increasing neuromotor fitness in this population. People working with girls in this age group could implement either of the two depending available resources. We recommend the adoption of these interventions for physical education and/or fitness promotion programmes among girls in low income settings.

The Effect of Education on Perceived Risk of Diabetes in Traditional-Age College Students

Heather E. Webb, Shannon Strawn, Mikaela Boham, Liana Davis. *Texas A&M Corpus Christi, Corpus Christi, TX.*

(No relevant relationships reported)

Type II diabetes is a concern in the United States, and risk factors that contribute to this disease are largely mediated by lifestyle interventions. Identification of those at high risk for type II diabetes and implementation of risk reduction behaviors may prevent onset of the disease. **PURPOSE:** To investigate the effect education on the perceived risk of type II diabetes and intent to adopt healthier lifestyles in traditional-age college students. **METHODS:** 29 participants provided demographic information, physical activity level, anthropometric measures, and a blood sample, as well as completing the Risk Perception Survey-Developing Diabetes (RPS-DD), perceived risk of diabetes visual-analogue scale (PRD-VAS), and the diabetes risk calculator (DRC), with 17 of these participants also providing information on their intent to change fitness behaviors. **RESULTS:** RMANOVAs assessed changes across time in the RPS-DD and PRD-VAS. Kendall's tau-B correlations were conducted to examine relationships between the abovementioned variables. Data analysis revealed six participants at high risk for prediabetes and 12 with at least one risk factor for metabolic syndrome. RPS-DD risk and RPS-DD knowledge scores did not change, but analysis of the PRD-VAS indicated a significant change across time ($p = 0.01$). The DRC did not correlate with prediabetes or metabolic syndrome. Significant interactions between prediabetes status and perceived risk ($p = 0.04$), but not between prediabetes risk and intent to adopt healthier lifestyle ($p = 0.42$) were shown, and between metabolic syndrome and prediabetes risk ($p = 0.03$), as well as criteria for both diseases, excluding HbA1c ($p = 0.15$). **CONCLUSIONS:** Students in this study possessed many risk factors for developing type II diabetes. Those at high risk for such diseases demonstrated an understanding of their risk, but did not express an intent to modify their lifestyle behaviors. Further, the noninvasive prediabetes and diabetes risk calculator did not consistently identify these diseases in this population. Research should be dedicated to determining how to change perceived risk of developing type II diabetes, methods of promoting healthier lifestyles, and development of a validated noninvasive instrument for use among traditional-age college students.

2846   Board #129   June 1 2:00 PM - 3:30 PM

Associations between Chinese College Students' Social Cognitive Beliefs, Physical Activity, and Health: Sex Differences

Jichao Liu[1], Nan Zeng[1], Kun Tao[2], Qingwen Peng[2], Xianxiong Li[3], Shanying Xiong[4], Zachary Pope[1], Zan Gao, FACSM[1]. [1]*University of Minnesota, Minneapolis, MN.* [2]*Huaihua University, Huaihua, China.* [3]*Hunan Normal University, Changsha, China.* [4]*Shenzhen Polytechnic University, Shenzhen, China.* (Sponsor: Zan Gao, FACSM)

(No relevant relationships reported)

PURPOSE: Use of a theoretical framework can offer implications for physical activity (PA) intervention. College students represent a population which might benefit from theoretically-grounded PA interventions. This study investigated the associations among Chinese college students' Social Cognitive Theory-based beliefs, PA levels, and relevant health outcomes while also examining if sex were present for any outcome. **METHODS**: In June of 2017, 220 college students (115 females; $M_{age} = 20.29 \pm 2.37$) were recruited from a South Central Chinese University. Students' PA-related Social Cognitive beliefs (i.e., self-efficacy, enjoyment, family support, friends support, and environment) were assessed using a validated questionnaire. One-week PA levels were recorded via ActiGraph Link accelerometers. Finally, body fat percentage and objective health status were evaluated using the InBody 230 Monitor whereas cardiovascular fitness was assessed via the 3-Minute Step Test. **RESULTS**: Correlation analyses indicated both self-efficacy and environment factors were significantly related to family/friends' support and enjoyment (r range: 0.11 - 0.48, $p < 0.05$), and that friends' support were highly related to family support ($p < 0.01$). Interestingly, regression analyses revealed self-efficacy to negatively predict average MVPA per day ($\beta = -0.21$, $p < 0.01$) but, as expected, that a lower body fat percentage was predictive of improved objective health ($\beta = -0.17$, $p < 0.05$). Finally, significant sex differences were observed for average MVPA per day, $F(1, 213) = 22.2$, $p < 0.01$, $\eta^2 = 0.09$, PA self-efficacy $F(1, 217)=26.5$, $p < 0.01$, $\eta^2 = 0.11$, and PA enjoyment $F(1, 217) = 3.9$, $p = 0.05$, $\eta^2 = 0.02$, wherein males demonstrated higher values for all three outcomes. No other sex differences were observed. **CONCLUSIONS**: Findings suggest that male and female Chinese college students differ with regard to MVPA per day in addition to PA-related self-efficacy and enjoyment. As self-efficacy and enjoyment are predictive of long-term PA participation, PA interventions among college students, particularly females, are needed targeting these Social Cognitive beliefs to improve various health outcomes such as body fat percentage and cardiovascular fitness.

2847   Board #130   June 1 2:00 PM - 3:30 PM

Use And Acceptance Of Sit-to-stand Workstations In The College Classroom

Jeremy A. Steeves, Colby Beach. *Maryville College, Maryville, TN.* (Sponsor: David R. Bassett, FACSM)

(No relevant relationships reported)

PURPOSE: To evaluate the impact and acceptance of portable sit to stand workstations in a college class. METHODS: This 10-week pilot study used a non-randomized two-group pre-post comparison design. Half of the students (n=7) had access to sit to stand workstations (STS) during one course (two 75-min class meetings per week). The other half (n=7) retained usual sitting desks (SIT) in all classes. All participants completed questionnaires at baseline, at the end of week 2, and week 10, which captured participant characteristics including age, sex, classroom engagement, and focus. A 7-day log was used to capture classroom sitting and standing at these three time points. After week 10, STS participants were asked about the acceptability of the sit to stand workstations and changes in perceived classroom engagement and focused attention. Mann Whitney U tests compared STS and SIT groups for classroom sitting, and classroom focus. Within the STS group, paired t-tests compared classroom focus between the traditional seated position and the non-traditional standing position. In addition, changes in classroom posture in the class with the sit to stand workstation and acceptability of the sit to stand workstations are reported. RESULTS: At baseline, fourteen students (21.9±1.9 yrs) reported sitting for 89.7% of all their classes (142.4 min/day). Despite no differences in overall classroom based sitting between the groups, the STS group trended towards increased classroom focus when standing compared to the SIT group (week 2: 3.7±0.8 vs 2.8±0.8; p=0.067, and week 10: 4.1±0.7 vs 3.4±0.5; p=0.058). When the STS group had access to the sit-to-stand workstations, sitting time decreased by almost 60% from 74 min/class at baseline to 43 and 44 min/class in weeks 2 and 10, respectively. Students reported that the sit to stand workstations were easy to use, enjoyed having the choice to sit or stand in class, and that engagement and focused attention was improved with the sit to stand workstations compared to traditional sitting. CONCLUSION: Providing college students with access to sit to stand workstations in some classes may reduce sitting, and help them focus.

2848   Board #131   June 1 2:00 PM - 3:30 PM

Examining the Relationships between Physical Activity Participation and Sleep Quality in Chinese College Students

Nan Zeng[1], Kun Tao[2], Qingwen Peng[2], Shanying Xiong[3], Xianxiong Li[4], Zan Gao, 55455, FACSM[1]. [1]*University of Minnesota, Minneapolis, MN.* [2]*Huaihua University, Huaihua, China.* [3]*Shenzhen Polytechnic University, Shenzhen, China.* [4]*Hunan Normal University, Changsha, China.* (Sponsor: Zan Gao, FACSM)

(No relevant relationships reported)

Purpose: Sleep quality and physical activity (PA) participation are two crucial factors that help individuals maintain a healthy lifestyle. However, evidence regarding associations between sleep and PA in young adults remains unclear. The purpose of this study was to determine the relationships between Chinese college students' objectively-measured daily PA and sleep. **Methods:** A total of 220 college students (115 females, $X_{age} = 20.29 \pm 2.37$, $X_{BMI} = 20.67 \pm 3.12$) were recruited from a university in South Central China. Participants wore a wrist accelerometer (ActiGraph GT9X Link) for 7 consecutive days. Participants' PA was defined by Troiano Adult (2008)'s cut points as follows: sedentary behavior (SB, 0-99 counts per minute [CPM]), light PA (LPA, 100-2019 CPM), moderate to vigorous PA (MVPA, 2020 and above CPM) (Troiano, 2008), while total sleep time (TST, mins/night) and sleep efficiency (SE%, the number of mins in bed/number of mins of sleep periods) were calculated from the same monitors. **Results:** Descriptive statistics indicated that participants spent 77.53% (SD = ± 10.03), 12.12% (SD = ± 2.68), 10.35% (SD = ± 2.73) of their time in SB, LPA, and MVPA, while TST and SE were 341.67 mins (SD = ± 80.65) and 84.12% (SD = ± 4.79), respectively. Correlation analyses revealed there was no significant relationship among SE, LPA, and MVPA (all p > 0.05). However, a significant positive relationship between SE and TST (p < 0.01, r = .31) was observed. Notably, there was an inverse relationship between TST and MVPA (p < 0.05, r = -.16), and between SE and SB (p < 0.05, r = -.16). Although multiple regression suggested the overall model was statistically significant [F (3, 219) = 5.72, p < 0.05, η² = 0.12] when age, gender, and BMI were controlled, SB did not appear to be an ideal predictor of SE. **Conclusion:** Accelerometry-determined daily PA was not related to sleep efficiency, suggesting higher PA participation does not necessarily improve sleep quality in the short-term. Notably, daily increases in MVPA may result in a reduction in TST. Nevertheless, decreased SB may lead to improvement in sleep efficiency. As low PA and low sleep quality are linked to adverse health outcomes, more long-term research with larger diverse samples examining how daily PA impact sleep is warranted.

2849   Board #132   June 1 2:00 PM - 3:30 PM

Research of the Perceived Exertion Scale of Physical Activity Intensity for Chinese Preschool Children

Qu Sha, Luo Dong mei, Yao Tian cong. *Beijing Sport University, Beijing, China.*
(No relevant relationships reported)

PURPOSE: In previous studies, a variety of scales were used to evaluate physical activity intensity among children, such as the Children's Effort Rating Table and OMNI Scale of Perceived Exertion scale. However, most of the Perceived Exertion Scales are only applicable to children over six years old. Therefore, it is necessary to design a Perceived Exertion Scale of Physical Activity Intensity for Chinese Preschool Children (PESPAI).
METHODS:The draft scale was designed according to the children's Perceived Exertion Scales and the Observer Evaluation Scale of Physical Activity Intensity for Preschool Children of our previous research. A Zephyr monitor and an ActiGraph triaxial accelerometer were used to measure physical activity of 116 children. The children completed the PESPAI. The revision of the scale was based on the heart rate, Count value and children's feedback. Finally, the reliability and validity of the final scale were analyzed by SPSS Statistics 13.0.**RESULTS**: The PESPAI utilizes cartoon images for the items and contains 6 options. Each option includes a children's cartoon image, a ribbon and description language. Some children questioned the image of gender and minority characteristics. Thus, the revision of the scale was based on that. There was very significant difference between each option index ($P<.01$). It is indicated that the PESPAI can reflect the changes of different activity intensity of preschool children. There was a strong correlation between the scale scores in the first test and second test ($r=.842,P<.01$), indicating that the scale has high reliability. The scale scores of preschool children had a moderate correlation with heart rate only during high intensity activity. It is indicated that the correlation between scale scores and objective indexes is related to the physical activity intensity. When all the data were analyzed, it was found that there was a strong correlation between the scale scores and heart rate($r=.604, P<.01$), indicating that the scale has good validity.
CONCLUSIONS: The PESPAI utilizes cartoon images for the items and contains 6 options. The PESPAI has good reliability and validity, which indicates that the scale can be used to evaluate the preschool children's physical activity intensity. The scale is more applicable to evaluate high intensity physical activity.

Effect of Physical Activity Over 1-Week on Peak Expiratory Flow in Asthmatic Children

Alexandra B. Ptacek, Gina M. Besenyi, Craig A. Harms, FACSM. *Kansas State University, Manhattan, KS.* (Sponsor: Craig A. Harms, FACSM)
(No relevant relationships reported)

PURPOSE: Asthma is the most common chronic respiratory disease among children in the US, and may be a barrier to physical activity due to breathlessness and chest tightness. The purpose of this study was to determine if airway function was influenced by moderate to vigorous physical activity (MVPA) in asthmatic children over one week. It was hypothesized that as minutes of MVPA increased, peak expiratory flow (PEF) would also increase. **METHODS**: 45 children (6-13 yrs old), who were physician diagnosed with asthma, participated in a five-day asthma camp whose purpose was to improve child knowledge and management of their disease while providing a safe environment for normal summer camp activities. PEF as a measure of airway function was taken by a respiratory therapist for each child daily via a spirometer in the morning (0800). In asthmatic patients, PEF has been reported to correlate with forced expiratory volume in 1-sec (FEV_1). Objective MVPA was recorded daily with hip-worn Actigraph GT3X accelerometers from 0845-1125 and 1445-1625 at 5s epochs. Minutes of MVPA were calculated using validated child cut-points. Pearson correlations were used to examine relationships between minutes of MVPA and PEF across the week and by age group (young (Y) 6-9 yrs; older (O) 10-13 yrs). Repeated measures ANOVA was used to determine differences in daily mean PEF percent change and minutes of MVPA, controlling for short-relief medication use. **RESULTS**: Data from 37 asthmatic children were analyzed (boys: 58.5%) and divided among age groups (Y=50%; O=50%). Over the week, MVPA was 73.3 + 34.2 min/day. Pearson correlation coefficients were nonsignificant for PEF and minutes of MVPA across the week for total sample (r=-0.11, p=0.55) and by age group (6-9 years, r=0.10, p=0.72; 10-13 years, r=-0.28, p=0.25). PEF was not different (p=0.17) from baseline across time. **CONCLUSIONS**: These results suggest that airway function is not influenced by MVPA in asthmatic children over the course of a weeklong asthma camp. Future research should incorporate a longer intervention period and a larger sample.

2851   Board #134   June 1 2:00 PM - 3:30 PM

Are Latino Preschool Children Meeting Recommendations Related To The 5-2-1-0 Message?

Neil P. Sharma, Sharon E. Taverno Ross, Bethany B. Gibbs, Patricia I. Documét. *University of Pittsburgh, Pittsburgh, PA.* (Sponsor: Dr. Russell Pate, FACSM)
(No relevant relationships reported)

PURPOSE: Almost 17% of Latino preschool children are obese, which is far higher than their racial/ethnic counterparts. To address the key behaviors associated with childhood obesity, the 5-2-1-0 message was developed (>= 5 servings of fruits and vegtables [F/V], <= 2 hours of recreational screen time, >= 1 hour of physical activity [PA], and zero sugary drinks per day). In this study, we examined baseline data from ANDALE Pittsburgh, a culturally-tailored obesity prevention program, to determine whether or not Latino preschool children were meeting recommendations from the 5-2-1-0 message.
METHODS: N=51 parents (33.5±6.1 years) with preschool-aged children (3.5±1.2 years, 59% female) were recruited from community venues in Southwestern Pennsylvania. Screen time (parent survey; n=51), F/V and sugary beverage consumption (food screener; n=51), and PA (accelerometry; n=22) were assessed. For analysis, we used PA guidelines from the Institute of Medicine (IOM) recommendations for preschool children (>= 15 min/hour of total daily physical activity). Sociodemographic and home factors related to the 5-2-1-0 message were assessed via parent survey. A trained researcher measured child height and weight to calculate body mass index and percentiles. We calculated descriptive statistics [mean (SD) and frequencies (n)] in SPSS version 25.0.
RESULTS:Most parents were Mexican (63%), stay-at-home caregivers (71%), completed high school or less (55%), and had low acculturation (86%). On average, children consumed 2.25± 1.44 servings/day of F/V, consumed 15.5± 26 kcals/day from sugary drinks, accumulated 12.9± 2.9 min/hr of total PA, watched 98.7± 74.2 min/day of screen time, and 46% were overweight or obese. Only 6% of children met the F/V recommendation, 54% met screen time recommendations, 27% met the IOM PA recommendations, and 58% met the sugary drinks guideline.
CONCLUSIONS: In this community sample of Latino preschool children, nearly half were overweight/obese and few were meeting recommendations from the 5-2-1-0 message; this suggests our sample is comparable or worse off than the general U.S. preschool population for these key behaviors. Efforts are needed to effectively intervene and improve 5-2-1-0 behaviors associated with excessive weight gain in Latino preschool children.

A Multi-level Analysis Of The Effects Of Epoch Length On Children'S Physical Activity Pattern

Han Chen. *Valdosta State University, Valdosta, GA.*
(No relevant relationships reported)

A Multi-Level Analysis of the Effects of Epoch Length on Children's Physical Activity Pattern
Purpose: Using the new generation ActiGraph GT3X+ accelerometer, the study examined the effects of different epoch lengths on children's moderate to vigorous physical activity (MVPA) generated by five different cut points while monitoring them during activity classes. The study also tested the moderating effects of physical activity (PA) level on the relationship between epoch length and MVPA.
Methods: The participants included both third ($n = 28$) and fourth grade ($n = 35$) students. Students in third grade participated in a Sports, Play, and Active Recreation for Kids (SPARK PE) class while the fourth graders were engaged in an active video game (AVG) class. Data were downloaded using 1s, 5s, 10s, 15s, 30s, and 60s epoch lengths. MVPA was determined by five different cut points. Multi-level analyses were conducted to test the effects of level 1 (i.e., epoch length) and level 2 (i.e., gender, body mass index [BMI], and class content) variables on MVPA. The study also examined the moderating effects of level 2 variables on the relationship between epoch length and MVPA.
Results: When lower cut points suggested by Freedson (2005), Evenson (2008), and Pulsford (2011) were used, MVPA increased, followed by the increase of epoch lengths. This positive relationship between epoch length and MVPA was stronger when the PA level was higher. When MVPA was determined by higher cut points suggested by Puyau (2002) and Mattocks (2007), epoch length was found to negatively relate to MVPA, and this relationship was stronger when the PA level was lower.
Conclusions: Different epoch lengths generate various MVPA levels, and the relationship between epoch length and MVPA is moderated by PA levels.

2853   Board #136   June 1 2:00 PM - 3:30 PM

The Development And Testing Of A Direct Observation Protocol For Children's Free-play Activity

Melanna F. Cox, Gregory J. Petrucci, Jr, Brittany R. Masteller, John R. Sirard. *University of Massachusetts Amherst, Amherst, MA.*

(No relevant relationships reported)

Traditional real-time direct observation (DO) systems have been used for decades to assess children's free-living physical activity (PA). Using video-taped DO would overcome several methodological issues and allow for more precise assessments of behaviors. **PURPOSE**: To develop and test a novel video-based DO system for children's free-play activity.
METHODS: Following iterative DO system development (The Observer XT, Noldus), 28 children (age=8.4±1.5 years) participated in a 30-minute indoor free-play session. The participants were recorded using a GoPro camera and wore an accelerometer on the hip (AG-H) and non-dominant wrist (AG-W). Researchers coded videos for the main Whole-Body Movement and four modifiers: 1) Locomotion, 2) Limb Movement, 3) Activity Type, and 4) MET value. For intrarater reliability, percent agreement was calculated from six randomly selected videos, using duplicate entries by an expert coder one-week apart. For inter-rater reliability, three videos were used to calculate percent agreement between entries from trained, novice coders (n=6) and the expert coder. To assess construct validity, time spent in activity intensity categories from expert-coded DO MET values were compared with accelerometer estimates using Wilcoxon Rank-Sum tests.
RESULTS: Percent agreement for intra-rater reliability was above 80% except for Locomotion (47%; video 4, 26%; video 3) and Limb Movement, and MET value (19%, 78%, respectively; video 3). Across all variables, percent agreement for inter-rater reliability ranged widely from 12%-96%, 0-100%, and 36%-97% for videos 1, 2 and 3, respectively. Mean estimated time spent in PA intensity categories from AG-H overestimated sedentary (SED; p=0.008), moderate (MPA; p<0.001), and moderate-to-vigorous PA (MVPA; p=0.017) and underestimated light, (LPA; p< 0.001). The AG-W underestimated SED (p=0.03) and LPA (p<0.001) but overestimated MPA (p<0.001) and MVPA (p<0.001).
CONCLUSIONS: The current DO system is feasible for observing detailed changes in children's free-play activity. However, refinement to the system must be made to improve reliability before it is adopted as a criterion measure for free-play activity in children. Supported by: University of Massachusetts Amherst Commonwealth Honors College

Associations Of Physical Activity And Screen Time With Obesity In Chinese Children And Adolescents

Zheng Zhu[1], Shengxia Ma[1], Yang Bai[2], Yan Tang[1], Jie Zhuang[1], Yang Liu[1], Peijie Chen[1], Zhen-Bo Cao[1]. *[1]Shanghai University of Sport, Shanghai, China. [2]University of Vermont, Burlington, VT.*

(No relevant relationships reported)

Associations of Physical Activity and Screen Time with obesity in Chinese Children and Adolescents
Zheng Zhu[1,2], Shengxia Ma[1],Yang Bai[3], Yan Tang[1,2], Jie Zhuang[1,2], Yang Liu[1,2] , Peijie Chen[1,2],Zhen-Bo Cao[1,2]
1. Shanghai University of Sport, Shanghai, China
2. Shanghai Research Center for Physical Fitness and Health of Children and Adolescents, Shanghai, China
3. University of Vermont, Burlington, VT
PURPOSE: The objective of this study was to examine the associations of physical activity and screen time with obesity in Chinese children and adolescents.
METHODS: We conducted cross-sectional analyses of 33,399 participants (boys:48.9%, age:12.5±2.5 yr, weight:48.1±14.9 kg, height:154.6±13.8 cm, Body mass index:19.7±3.9 kg/m^2) who completed height and weight measurement and physical activity and sedentary behavior questionnaire (including screen time and time spent in doing homework after school). Based on the criteria set by Working Group on Obesity in China, the participants were categorized into either obesity or not using the body mass index. The associations of physical activity and screen time with weight status were examined, through multiple logistic regressions, after controlling for gender, age and time spent in doing homework.
Results: The children and adolescents who did not meet the recommendation of at least 60 min/day of moderate to vigorous physical activity (MVPA) had 1.21 times the odds of being obese compared to those meeting the guideline (95% confidence interval [CI] of Odds Ratio:1.10-1.33), after adjusting gender, age, time spent in doing homework and screen time. The children and adolescents who did not meet the screen time recommendation of ≤2h/day had 1.16 times the odds of being obese compared to those meeting guideline (95% CI of Odds Ratio: 1.07-1.26) after adjusting gender, age, time spent in doing homework and MVPA. In joint association analysis, children

and adolescents who did not meet physical activity nor screen time guidelines had 0.45 times higher odds of being obese than children and adolescents who met both guidelines (95% CI of Odds Ratio: 1.27-1.66).
CONCLUSION: The results demonstrated that MVPA and screen time are independently but also jointly associated with obesity in Chinese children and adolescents.

Teaching Styles in Physical Education: The Effects on Physical Activity Levels of Middle School Students with Different Motivation Types

Yongju Hwang[1], Jooyeon Jin[2]. *[1]University of Wisconsin-La crosse, Onalaska, WI. [2]University of Seoul, Seoul, Korea, Republic of.*

(No relevant relationships reported)

PURPOSE: Self-determination theory (SDT) has been widely investigated as a powerful theoretical framework to understand and change an individual's physical activity behavior in different settings (Deci & Ryan, 1985; De Meyer et al., 2016). However, there is a limited understanding on how entire SDT explains objectively measured moderate to vigorous physical activity (MVPA) levels of adolescents in physical education lessons. To examine if physical educators' teaching style influences student needs that affect student motivation, which in turn predict objectively measured student MVPA levels (i.e., a serial mediator model).
METHODS: A total of 313 students from three middle schools in Wisconsin completed Learning Climate Questionnaire modified from Williams and Deci (1996), Psychological Need Scale and Need Frustration Scale adopted from Chen et al. (2015), and Physical Education Questionnaire modified from (Aelterman et al., 2012) to assess perceptions of autonomy-supportive teaching, experience of need satisfaction and need frustration, and motivational outcomes, respectively. After a week of the survey administration, participants' MVPA levels were recorded using a GT3X+ accelerometer for four consecutive physical education lessons. PROCESS, a regression-based computational procedure program designed for mediation analyses in SPSS, was used to examine the mediating relationships.
RESULTS: Bootstrapping with 10000 samples showed that autonomous teaching behavior significantly influence MVPA levels through relatedness satisfaction and intrinsic motivation (b = .79; 95% CI: .29 - 1.35), autonomous teaching behavior significantly influence MVPA levels through competence satisfaction and intrinsic motivation (b = 1.17; 95% CI: .69 - 1.77), and autonomous teaching behavior significantly influence MVPA levels through competence satisfaction and identified regulation (b = 1.33; 95% CI: .83 - 1.99). In addition, bootstrapping with 10000 samples revealed that controlling teaching behavior significantly affects MVPA levels through autonomy frustration and amotivation (b = -.49; 95% CI: -1.03 - -.08).
CONCLUSIONS: The findings indicates that an autonomy-supportive teaching style may promote MVPA levels of middle school students during physical education lessons.

Relationships of Physical Activity and Academic Achievement in the College Student Attending a Two-Year Institution

Gwendolyn Plucar, David Barrett. *Southwest Minnesota State University, Bloomington, MN.*

(No relevant relationships reported)

PURPOSE: Physical activity is directly related to a healthy body along with a healthy mind. The relationship between physical activity and academic activity has been studied for decades. Researchers have focused on the effects on K-12 students. Academic performance in college students has been linked with: cognition, sleep, mental health, self-efficacy, diet, and stress. Depression and anxiety tendencies tend to have the highest prevalence of mental health issues in college students. All factors that have been shown to improve with exercise. This study will determine a correlation between organized and leisurely forms of physical activity and academic achievement in college students.
METHODS: Three hundred ninety-nine students, enrolled in classes at Normandale Community College completed a wellness questionnaire. Student participation was voluntary and responses were anonymous. The survey asked students to self- report factors related to: age, GPA, physical activity, sleep, diet, and GRIT (Duckworth's 8-item GRIT scale, a validated measure of Growth, Resilience, Intuition, and Tenacity). Correlation and Regression models were assessed in version 20 of SPSS.
RESULTS: Significant correlations were found between the response variable, GPA, and predictor variables of GRIT Score, students ages 17 and under, and occurrence of eating breakfast. GPA = 2.728 + (GRIT Score * .196) + (Age under 17 * .328) + (Breakfast all of the time * .197) + (Breakfast most of the time * .148). No significant differences were found between physical activity and GPA. The statistical significance for GRIT score and eating breakfast all the time had a p value < 0.001, age 17 and under p-value= 0.01, and eating breakfast most of the time p-value= 0.009.

CONCLUSIONS: This study found statistically significant correlations with GRIT score, age related GRIT score, and breakfast frequency. Results related to physical activity may have been related to social desirability responses. GRIT related to age is likely related to the required academic achievement of Post-Secondary Education Option students. Gender identification was not included in the survey to protect anonymity. Gender identification may change the correlation factors that were found.

Changes In Student Perceptions of Interdisciplinary Collaboration After Community Health Fair Volunteer Experiences

Mary C. Stenson, Mark Glen, Nicole Lang, Julie Strelow. *College of St. Benedict/ St. John's University, Saint Joseph, MN.*
(No relevant relationships reported)

PURPOSE The purpose of this study was to identify student perceptions of interdisciplinary collaboration in healthcare professions before and after community health fair experiences. **METHODS** Three community health fairs provided an opportunity to introduce pre-healthcare students to interdisciplinary collaboration. A descriptive, mixed-methods design was used with an interdisciplinary convenience sample of pre-healthcare college students who identified as exercise science, Integrative Health Science, nursing, and nutrition majors. Surveys were conducted before and after the health fairs using a 7 item scale developed by Gallagher et al. (2010) and open-ended questions developed by the researchers that measured the impact of the collaborative experience. **RESULTS** A significant increase was observed in knowledge of community agencies that can provide optimum care ($\Delta 0.67$; t=-4.51; p=<0.000), knowledge of the value of an interdisciplinary healthcare team ($\Delta 0.85$; t=-7.17; p<0.000), knowledge of strengths and skills of other disciplines ($\Delta 0.69$; t=-5.95; p<0.000), and experience working with healthcare teams ($\Delta 0.97$; t=-5.43; p<0.000). Students more strongly agreed that other members of the healthcare team are important to their work after the health fair experiences than before ($\Delta 0.15$; t=-2.87; p<0.000). No significant change was found in attitudes towards the importance of communication between team members ($\Delta 0.03$; t=-1.00; p=0.32) or learning from other professionals ($\Delta 0.08$; t=-1.93; p=0.06). In open ended responses students indicated that they were motivated to learn about other healthcare disciplines to improve patient/client care and they experienced challenges in applying the professional values they perceive as important. **CONCLUSION** Students increased their knowledge of the value of an interdisciplinary healthcare team. Students recognized the importance of interdisciplinary collaboration, but engaged in collaboration to varying degrees. The health fairs provided an intentional, foundational experience to support development as future healthcare professionals and effective members of interdisciplinary teams. Using skills in a real-world setting helped students recognize their strengths and areas where their interdisciplinary teamwork skills may need improvement.

2858   Board #141   June 1 2:00 PM - 3:30 PM

Who Are the Undergraduate Equestrians in the Intercollegiate Horseshows Association, and What Are Their Lifestyle Habits?

Jessie Bitler, Helen Battisti, Shelby Yeager, Diane DellaValle. *Marywood University, Scranton, PA.*
(No relevant relationships reported)

Purpose: Given there is little available research on equestrian athletes, and none about the members of the Intercollegiate Horse Shows Association (IHSA), the purpose of this cross-sectional study was to describe demographic characteristics and lifestyle habits of undergraduate student members of the IHSA.
Method: Participants included 528 undergraduate student members from the eight zones of the IHSA (Age 20.30 ± 1.43 years, 96 % female, 91.7 % white). Participants completed an online survey including demographic characteristics, academics, years of riding experience, sleep, physical activity, fruit and vegetable intake, and alcohol (ETOH) and tobacco use. Body Mass Index (BMI) was calculated based on self-reported height and weight. Participants were divided into two groups (less experience and more experience) based on the sample median of 12 years of riding experience. Independent-samples t test and Chi-Square test of independence were used to assess differences between years of riding experience for characteristics and lifestyle habits.
Results: Participants reported 11.7 ± 4.5 years of riding experience, 55.7 % did not own their own horse and 64.8 % rode English. Mean GPA of participants was 3.4 ± 0.4 and 46.4 % reported majoring in math, science and animal sciences. There were no significant differences found between riding experience groups and BMI (23.2 ± 3.7 kg/m^2), alcohol consumption (34.3 reported none, 46.6 % reported < 1 serving ETOH per day), cigarette smoking (98.1 % non-smokers), fruit consumption (83.6 % reported 1-3 servings/day), vegetable consumption (82.8 % reported 1-3 servings/day), and hours of sleep per night (84.6 % reported 6-8 h/night). There were also no significant differences in physical activity within sport (44.1 % reported 30-60 min/day), vigorous physical activity outside of sport (59.2 % reported 0-30 min/day), and light activity outside of sport (64.8 % reported 15-60 min/day).

Conclusion: There were no differences between riding experience groups and demographics or lifestyle habits in this representative sample of undergraduate members of the IHSA. Given that this study is the first description of nutrition and physical activity habits of this understudied population, it opens the door to further research in this highly-trained group of equestrian athletes.

F-58   Free Communication/Poster - **Physical Activity and Cancer**

Mid-term Effectiveness Of An Unsupervised Exercise Prescription Program In Breast Cancer Survivors

Gabriele Mascherini, Benedetta Tosi, Leonardo Osti, Giorgio Galanti. *University of Florence, Florence, Italy.*
(No relevant relationships reported)

Purpose The efficacy of physical exercise prescription as therapy in breast cancer survivors is largely documented in literature. Unsupervised exercise produces short-term improvements in physical fitness of breast cancer survivors, but regarding the mid-term effectiveness only few studies are available. The purpose of this study was to assess the effects of an unsupervised exercise prescription program on body composition, physical fitness and Health Related Quality of Life of breast cancer survivors. **Methods** Forty-two (average age 52.0 ± 10.1 years) women were enrolled. Assessments performed at baseline and after 6 months of exercise prescription: - body composition (anthropometric parameters and bioimpedance analysis); - physical fitness: aerobic capacity by Six-Minute Walk Test (6 MWT), limbs strength by Hand Grip Test and Chair Stand Test, flexibility by Sit and Reach Test; TOGLIERE PRESSIONI - Health Related Quality of Life (SF-36). Statistical analysis was conducted by Student's t-tests and multiple regression. **Results** Body composition improvements: - BMI (T0=27.3 ± 4.2; T5=26.1 ± 3.9 kg/m^2; p<0,001); - waist circumference (T0=90.2 ± 10.8; T5=85.3 ± 9.8 cm; p<0,001); - extracellular water (T0=17.5 ± 1.9; T5=16.8 ± 1.9 L; p<0,01); - fat mass (T0=25.0 ± 8.1; T5=22.6 ± 7.2 kg; p<0,001). Physical fitness improvements: - 6 MWT (T0=518.6 ± 133.0; T5=584.8 ± 97.2 m; p<0,001); - Hand Grip (T0=24.3 ± 4.8; T5=26.5 ± 4.5 kg; p<0,01); - Chair Test (T0=14.5 ± 3.8; T5=18.3 ± 4.3 repetitions; p<0,001); - Sit and Reach (T0=2.6 ± 9.3; T5=8.5 ± 7.1 cm; p<0,001). Health Related Quality of Life improvements: - Physical Functioning (T0=72.7 ± 24.6; T5=83.7 ± 17.1 %; p<0,001); - General Health (T0=64.7 ± 20.4; T5=69.1 ± 18.9%; p<0,001); - Social Functioning (T0=60.5 ± 24.5; T5=67.6 ± 22.9%; p<0,05); - Mental Health (T0=63.4 ± 14.8; T5=67.3 ± 12.5%; p<0,05). The percentage change in fat mass has been associated with adjuvant cancer therapy (intercept= -0,016; b=8,629; p<0,05). **Conclusions** An unsupervised exercise prescription program improves body composition, physical fitness and Health Related Quality of Life in breast cancer survivors. Longer term follow-up studies to establish the real capacity of this program to induce long-term changes in lifestyle are needed.

2860   Board #143   June 1 2:00 PM - 3:30 PM

The Effects of Smart Watch Intervention on Breast Cancer Survivors' Biomarkers and Health Outcomes

Nan Zeng[1], Chunyuan Han[2], Ning Liao[3], Zan Gao, FACSM[1]. *[1]University of Minnesota, Minneapolis, MN. [2]South China University of Technology, Guangzhou, China. [3]Guangdong People's General Hospital, Guangzhou, China.* (Sponsor: Zan Gao, FACSM)
(No relevant relationships reported)

PURPOSE: Adverse health outcomes are often seen among breast cancer survivors (BCS), with physical activity (PA) a possible solution in disease management. To date, little research has examined how smart watches might promote BCS' health-related outcomes. This study assessed the effectiveness of a smart watches PA intervention on biomarkers and functional fitness in Chinese BCS.
METHODS: Thirty-three BCS ($\bar{X}_{age} = 44.7 \pm 7.1$, $\bar{X}_{BMI} = 21.7 \pm 2.5$) were recruited from Southern region of China. All patients received a Xiaomi smart watch to track their PA behaviors (e.g., steps, *calories burned*, etc.). An individually-tailored exercise prescription (e.g., increasing step counts by $\geq 2,000$ steps/day to reach a daily step counts $\geq 9,000$ steps) was delivered to each patient based on their smart watch data collected via online server every month. Patients' biomarkers triglycerides (TG), high-density lipoprotein (HDL), low-density lipoprotein (LDL), blood glucose (BG), carcinoembryonic antigen (CA), and functional fitness: leg strength and endurance (LSE; 30-second chair stand test); upper body strength and endurance (UBSE; 30-second arm curl test); lower body flexibility (LBF; chair sit and reach test);

shoulder range of motion (SRM; measured by back scratch test); aerobic endurance (AE; 2-minute step test); and mobility and balance (MB; up and go test), were assessed at baseline and 12-months.
RESULTS: Dependent t-tests revealed no significant mean differences in TC, HDL, LDL, and CA from pre- to post-test (all $p > 0.05$). However, significantly change in BG was observed ($p < 0.05$, Cohen's $d = 0.38$) at 12-months. Moreover, functional fitness LBF ($p < 0.05$, Cohen's $d = -0.55$) and MB ($p < 0.01$, Cohen's $d = 0.67$) significantly improved after the intervention. Notably, patients' AE ($M_{dif} = -92.26$, $p < 0.01$, Cohen's $d = -1.26$) demonstrated the greatest improvements among all outcomes.
CONCLUSIONS: A 12-month smart watch-based PA intervention may promote improved biomarkers and functional fitness among Chinese BCS. Such innovative PA intervention has important implications in promoting disease prevention and management in this population. Larger samples with randomized clinical trials are warranted.

Changes in Sedentary Time and Physical Activity of Cancer Survivors Participating in an Exercise Program
Sarah Greterman. *Concordia College, Moorhead, MN.*
(No relevant relationships reported)

Purpose: The purpose of this investigation was to examine changes in sedentary time (SED) and physical activity (PA) of cancer survivors participating in a post-treatment, 12 week, group exercise program.
Methods: Forty-seven cancer survivors volunteered to wear armband activity monitors for seven consecutive days over three different time points of the group exercise program: weeks 1, 6 (midpoint), and 12 (endpoint). A repeated measures ANOVA with mixed model framework and time varying covariate compared time spent in SED, LIT, MOD, and VIG between weeks 1, 6, and 12 was used to analyze the data.
Results: Of the 47 recruited, 15 participants (age = 55.20 ± 13.85) completed week 1 (Group A), 19 participants (, age = 52.17 ± 11.71) completed weeks 1 and 6 (Group B), and 12 participants (; age = 53.08 ± 11.01) completed weeks 1, 6 and 12 (Group C). Participants averaged > 17 hr•day^{-1} of non-sleep activity monitor wear time with no significant differences in wear time (p = 0.05, F = 4.48). Minimal VIG PA resulted in combining MOD and VIG activity into one moderate-vigorous PA group (MVPA). Group C engaged in more PA compared to Groups A and B, but there were no statistically significant differences between Groups A and C (p = 0.24, F = 1.47) during week 1 or between groups B and C during both week 1 (p = 0.54, F = 0.39) and week 6 (p = 0.33, F = 0.98). For Group C, total PA based on wear time increased slightly from weeks 1 to 6 and decreased from weeks 6 to 12, but there were no statistically significant changes over all three time points (p = 0.12, F = 1.83). All three groups averaged more than 40 min•day^{-1} of MVPA. Group C engaged in less SED time compared to Groups A and B, but there were no statistically significant differences between groups A and C (p = 0.64, F = 0.22) or between groups B and C (p = 0.42, F = 0.67). For Group C, SED time was lower at both week 6 and week 12 compared to week 1, but week 12 was slightly higher than week 6. There was a statistically significant difference in change in SED time from weeks 1 to 6 (p = 0.03, t = 2.79) and weeks 6 to 12 (p = 0.03, t = -2.85), but not weeks 1 to 12 (p = 0.9997, t = 0.03).
Conclusion: The fact that participants exceeded the 150 min•week^{-1} CDC recommendation of PA and SED time declined from week 1 to week 12 is promising.

Effect Of Self-control Exercise Practice Dose On Lymphocyte Subsets Of Lung Cancer Patients
Jibing Wang[1], Weimo Zhu, FACSM[2], Renwei Wang[3], Jiaying Lang[1], Ruirui Xing[3], Shuhao Quan[3]. *[1]Tongji University, Shanghai, China. [2]University of Illinois at Urbana-Champaign, Urbana, IL. [3]Shanghai University of Sport, Shanghai, China.*
(No relevant relationships reported)

PURPOSE: Self-Control Exercise (SCE), known also as Guolin Qigong, is a mind-body exercise being used in China for cancer survival for more than 40 years. This study was to examine the dose of SCE on lymphocyte subsets of lung cancer patients and the possible mechanisms.
METHODS:33 lung cancer patients (9 males & 24 females; M±SD: Age in yr: 60.24 ± 6.14; Cancer survival yr: 1.67 ± 0.69) were recruited from the Shanghai Cancer Club. All the patients were diagnosed pathologically. The patients began to learn SCE for 3 weeks and then performed 24-week SCE at their will. Cancer history was surveyed, physical activity including SCE was recorded during the intervention. The lymphocyte surface antigen CD3/CD4/CD8/CD28/CD(16+56)/CD19/CD4CD25 were examined by direct immunofluorescence staining and flow cytometry. Pearson correlation coefficient were computed to determine the correlations between the change of lymphocyte surface antigen and the SCE duration (minutes) per week.
RESULTS: The mean SCE practice was 80.91 ± 44.68 minutes per day with a range from 30 to 180minutes per day. It was found that CD4$^+$ increased significantly ($p<0.01$), CD4$^+$CD25$^+$ declined significantly ($p<0.05$) respectively after 24 weeks.

CD3$^+$, CD8$^+$, CD(16+56)$^+$ and CD19$^+$ showed no statistical difference before and after intervention . The change of CD8$^+$CD28$^+$ is moderately correlated with SCE duration per week ($r=0.552$, $p<0.01$).
CONCLUSIONS: SCE intervention improved the cellular immune function of lung cancer patients and is correlated with the duration of the practice.

An Investigation Of Physical Activity And Cardiorespiratory Fitness In Childhood Cancer Survivors.
David Mizrahi[1], Claire E. Wakefield[1], Joanna E. Fardell[1], David Simar[1], Ann Maguire[2], Gill Hubbard[3], James McBride[4], Penelope Field[4], Richard J. Cohn[4]. *[1]University of New South Wales, Sydney, Australia. [2]The Children's Hospital at Westmead, Sydney, Australia. [3]University of Stirling, Inverness, United Kingdom. [4]Sydney Children's Hospital, Sydney, Australia.*
(No relevant relationships reported)

Purpose: Survivors of childhood cancer experience an increasing incidence of late sequelae with age, with the effect on health likely compounded by limited physical activity and low cardiorespiratory fitness (CRF). This study aimed to determine survivors' physical activity levels and to objectively measure CRF, compared with controls.
Methods: *Stage 1:* We collected physical activity data from parents of survivors aged 7-18 years, ≥5 years after diagnosis, from 11 Australian and New Zealand hospitals as well as from age-matched controls using the International Physical Activity Questionnaire. We compared moderate-vigorous physical activity levels with American Cancer Society guidelines (≥300 min/week). *Stage 2:* We then assessed CRF in survivors aged 8-18 years, ≥1 year after treatment completion, by cardiopulmonary exercise test using the Bruce Protocol, 6-minute walk test (6MWT), and self-reported fitness (International Fitness Scale).
Results: *Stage 1:* 192 parents of survivors (mean age=12.9 ± 2.3 years) and 111 parents of control children (mean age=12.3 ± 2.7 years) participated. Parents reported child survivors to participate in more physical activity than controls (248.4 ± 217.6 vs 184.8 ± 213.6 min/week, p=0.036), with 31% of child survivors meeting physical activity guidelines, compared with 22.7% of controls (p=0.011). *Stage 2:* To date, 11/42 survivors (mean age=10.7 ± 6.2 years) and 10/42 controls (mean age=10.6 ± 1.1 years) have completed comprehensive CRF assessments. Survivors appear to have similar CRF compared with controls in terms of VO2max (43.1 vs 46.8ml/kg/min, p=0.31; 47th vs 60th percentile, p=0.41) and 6MWT distance (737m vs 690m, p=0.07; 85th vs 78th percentile, p=0.43). Preliminary data suggest little difference in self-reported CRF (p=0.98) and overall fitness (p=0.07).
Conclusion: Only one-third of young survivors of childhood cancer are meeting American Cancer Society's physical activity guidelines. Preliminary data indicate similar fitness levels between survivors and age-matched controls. However, considering the increasing risk of late-effects during aging in survivors, regularly assessing physical activity and CRF provides clinicians with vital information to monitor and encourage survivors to mitigate risks by adopting a healthy lifestyle long-term.

Association Between Cancer Screening and Physical Activity in Cancer Survivors
Katlynn M. Mathis. *Pennsylvania State University, State College, PA.*
(No relevant relationships reported)

PURPOSE: To determine if cancer survivors who adhere to cancer screening guidelines are more likely to be physically active.
METHODS: A Health Risk Factor Questionnaire was mailed to cancer survivors in Central Pennsylvania who were identified by the PA Cancer Registry in 2017. The survey addressed physical activity levels and participation in regular cancer screenings for breast, cervical, and colorectal cancers. Physical activity levels were categorized as meeting ACSM guidelines for aerobic training, resistance training, or both Adherence to cancer screening guidelines was determined for colorectal, cervical, and breast cancer as put forth by the American Cancer Society, which included a colonoscopy, PAP smear, and mammogram, respectively. Odds ratios were calculated for aerobic, resistance, and combined physical activity levels in people who adhered to cancer screening guideline or not.
RESULTS: Among cancer survivors in Central PA, those who met colorectal cancer screening guidelines are more likely to meet aerobic training guidelines (OR=0.369; 95% CI=0.165 to 0.826) and those that met cervical cancer were more likely to meet aerobic and resistance training guidelines combined (OR=0.255; 95% CI=0.094 to 0.691). No other results were significant.
CONCLUSIONS: Cancer survivors who adhere to colorectal cancer screening guidelines are more likely to meet ACSM guidelines for aerobic exercise and those that adhere to cervical cancer screening are more likely to meet ACSM guidelines for

both aerobic and resistance exercise. Physical activity is an important part of cancer prevention and should be further addressed in a high risk population such as cancer survivors in Central PA.

Neuropathy And Fine-motor-function In Survivors Of Childhood Acute Lymphoblastic Leukemia: A Report From St. Jude Life

Robyn E. Partin, Carrie R. Howell, Ching-Hon Pui, Hiroto Inaba, Heather Chambliss, FACSM, Leslie L. Robison, Melissa M. Hudson, Kirsten K. Ness. *St. Jude Children's Research Hospital, Memphis, TN.*
(No relevant relationships reported)

Up to 40% of survivors of childhood acute lymphoblastic leukemia (ALL) have persistent neuropathy, which interferes with general mobility and walking. Neuropathy may also interfere with fine motor skills, which potentially impacts activities of daily living and quality of life (QOL). These relationships have not been investigated in long-term survivors of childhood ALL. **PURPOSE**: To evaluate associations between peripheral neuropathy, fine motor skills, and QOL in adult survivors of childhood ALL. **METHODS**: Adult survivors of childhood ALL (N=365, 52% male; age 6.8±4.5 years at diagnosis and 28.6±5.9 years at evaluation) were evaluated using the modified total neuropathy score (mTNS), physical performance test (PPT), and Medical Outcomes Study Short Form Survey (SF-36). Neuropathy was defined as a total score ≥4 on the mTNS. Participants were identified as having fine motor impairments according to timed writing and eating PPT tasks (> 10 seconds). Vincristine and cranial radiation doses from childhood cancer treatment, abstracted from medical records, were included as covariates in logistic regression models. **RESULTS**: 39.7% of ALL survivors had neuropathy (N=145) and 44.1% had fine motor impairments (N=161). Survivors with neuropathy received a mean cumulative dose of vincristine of 47.4 mg/m2; those without neuropathy had a mean cumulative dose of 31.5 mg/m2 (p<0.001). Neuropathy was significantly associated with fine motor impairments (Odds ratio (OR): 1.5, 95% confidence interval (CI): 1.01-2.39), after controlling for current age, sex, and cranial radiation. Fine motor impairments were associated with a 2.20-fold (95% CI: 1.07-4.52) risk of a physical component summary T-score <40 on the SF-36. **CONCLUSIONS**: Adult survivors of childhood ALL with neuropathy are at higher risk for fine motor impairment. In addition, survivors with fine motor impairment are at increased risk for reporting poor physical quality of life. Interventions designed to address loss of fine motor function may improve quality of life in this vulnerable population.

Analysis of Cancer Survivor's Accessibility to Exclusively Tailored Exercise Programs in Nebraska

Ava T. Coughlin, Roderick T. Bartee, Kate A. Heelan, FACSM, Paul R. Burger. *University of Nebraska at Kearney, Kearney, NE.*
(No relevant relationships reported)

Exercise has been shown to be an effective way to reduce acute and latent side effects associated with cancer treatment, as well as improve cancer survivor's quality of life. In Nebraska, more than 50% of the state's population lives within two metropolitan areas which poses concern of accessibility to exercise programs for rural residents. **Purpose:** The purpose of this investigation is to examine cancer survivor's accessibility to exercise facilities (EF) and exercise programs designed exclusively for cancer survivors (EPCS) in Nebraska, USA. **Methods:** Geographic Information Science (GIScience) was utilized to construct a spatial database consisting of: cancer patient survivors, EF, and identified EPCS, all geocoded from street addresses. Network analyses were performed to assess distance and travel time to both the nearest EF and EPCS. The U.S. Census Bureau's Core Based Statistical Area (CBSA) definitions for 2013 were used to categorize counties as part of a Metropolitan Statistical Area (MSA) or Micropolitan Statistical Area (mSA) and the balance, rural. **Results:** Multi-level geocoding of cancer survivors achieved a 99.9% match rate with 90.6% successfully geocoded to either a point or street address. Fifty-nine percent of survivors reside in a county classified as an MSA, 19% are in an mSA, and 22% are rural. Survivors living in an MSA had a mean distance of 3.2 ± 5.4 miles (2.0 ± 4.1 minutes) away from the nearest EF and a mean distance of 15.9 ± 28.8 miles (10.9 ± 22.4 minutes) away from the nearest EPCS. Survivors living in an mSA had a mean distance of 6.5 ± 8.6 miles (4.4 ± 6.4 minutes) from the nearest EF and a mean distance of 157.2 ± 122.4 miles (114.9 ± 91.9 minutes) to the nearest EPCS. Similar to mSA, rural survivors had a mean distance of 25.8 ± 20.1 miles (19.3 ± 15.4 minutes) from the nearest exercise facility while having a mean distance of 168.4 ± 124.5 miles (118.8 ± 84.5 minutes) from an EPCS. **Conclusion**: Exercise facilities are accessible to cancer survivors throughout Nebraska, however, EPCS are not located within a reasonable distance to rural survivors to facilitate participation. On-line and prescript EPCS programs and trainings should be developed and shared with rural and mSA exercise facilities to increase accessibility.

Adherence To Lifestyle Recommendations Regarding Physical Activity, Diet, Smoking And BMI in Cancer Survivors

Renate M. Winkels[1], Wayne Foo[1], Joachim Wiskemann[1], Joel E. Segel[2], Scherezade Mama[2], Kathryn H. Schmitz, FACSM[1]. *[1]Penn State Cancer Institute, Hershey, PA. [2]Penn State University, State College, PA.* (Sponsor: Kathryn Schmitz, FACSM)
(No relevant relationships reported)

Purpose: Assess adherence to lifestyle recommendations for physical activity, diet, smoking and BMI in cancer survivors in Central Pennsylvania.
Methods: A survey on health-related lifestyle factors was send to cancer survivors in Central Pennsylvania (PA) facilitated by the PA Cancer Registry in 2017. The survey included questions on current BMI, smoking status, physical activity level, and diet. From this, we assessed adherence to the WCRF/AICR recommendations for cancer prevention, as they are also recommended for cancer survivors. Respondents were assigned 1 point for each of the following recommendation they adhered to: BMI between 20-25 kg/m², currently not smoking, consumption of 5 or more servings of fruits/vegetables per day and being physically active at least 30 minutes/day (maximum score 4 points).
Results: The response rate to the survey was ~27%, and varied from 23% (lung) to 30% (breast). The average age of the respondents was 66 years. The overall score for adherence was 1.6 points which was largely driven by the high adherence to the recommendation not to smoke; adherence to the other guidelines was significantly lower. Survivors who adhered to the recommendation on physical activity had a similar score for the other lifestyle recommendations (1.1 out of 3) compared to 1.0 of 3 for survivors who did not adhere to the recommendation on physical activity.

	Total	Breast	Colorectal	Gynecologic	Lung	Prostate
n	585	144	107	131	81	122
Sufficiently active	47%	49%	42%	48%	35%	54%
BMI 20-25	20%	25%	22%	15%	26%	13%
At least 5 servings f/v	0%	0%	0%	0%	0%	0%
Not smoking	91%	93%	92%	94%	82%	93%
Average score	1.6	1.7	1.6	1.6	1.4	1.6

Conclusion: In this survey among cancer survivors in central PA, adherence to lifestyle recommendations was low for all types of cancer. Response rate was 27%; possibly, cancer survivors who were higher educated and more health-conscious were more likely to respond. Thus, the adherence to lifestyle recommendations among cancer survivors in central PA may even be lower than what is presented here.

Cardiorespiratory Fitness and Cancer In Women

Baruch Vainshelbom[1], Stephen M. LoRusso[1], Ivan Mulligan[1], Stephen Baker[1], Patricia Fitzgerald[1], Kristofer Wisniewski[1], Jonathan Myers, FACSM[2]. *[1]Saint Francis University, Loretto, PA. [2]VA Palo Alto Health Care System/ Stanford University, Palo Alto, CA.*
(No relevant relationships reported)

The preventive role of cardiorespiratory fitness (CRF) in cancer is not well established among women. **PURPOSE**: The current study sought to evaluate the association between CRF, cancer incidence and cancer mortality in women. **METHODS**: Maximal exercise testing was performed in pilot cohort of 184 women (59.3±15.2 years) free from malignancy at baseline who were followed for a mean of 12±6.9 years. Multivariate Cox hazard analyses were conducted for all-type cancer incidence and cancer mortality. Population Attributable Risks (PAR) and Number Needed to Treat (NNT) were determined for low CRF (<5 METs). **RESULTS**: During the follow-up, 11.4% were diagnosed with cancer and 3.2% died from cancer. CRF was inversely associated with cancer outcomes. For every 1 MET higher CRF there was a 19% reduction in cancer incidence [Hazard Ratio (HR) 0.81, 95% Confidence Intervals (CI) (0.68 to 0.96), p=0.016)] and 38% reduction in cancer mortality [HR 0.62, 95%CI (0.42 to 0.92), p=0.017]. The PARs% and NNT of low CRF was 12.3% and 16.6% and 5 and 8 for cancer incidence and cancer mortality, respectively. **CONCLUSIONS**: Higher CRF is associated with lower risk for cancer incidence and cancer mortality in women, suggesting the possible protective benefits for cancer prevention. Eliminating low CRF as a risk factor would potentially prevent considerable cancer morbidity and mortality and reduce the associated societal-economic burden. Achieving CRF of ≥5 METs could be cost-effective for public health and may play an important role in primary cancer prevention programs. Future large cohorts should ascertain these findings.

2869   Board #152   June 1 2:00 PM - 3:30 PM
The Effect of Radiation Therapy on Cancer Patients Participating in Structured Exercise

Amber M. Huang[1], Cynthia Villalobos[1], Justin C. Brown[2], J. Mark VanNess[1], Jeremy P. McConnell[1], Paul D. Vosti[3], Courtney D. Jensen[1]. [1]*University of the Pacific, Stockton, CA.* [2]*Harvard University, Cambridge, MA.* [3]*St. Joseph's Medical Center, Stockton, CA.* (Sponsor: Kathryn H. Schmitz, FACSM)

(No relevant relationships reported)

Radiation therapy was first attempted as a treatment for cancer in 1896. Since then, it has become a common modality, and the survival rate among diagnosed patients has increased drastically. While radiation can prolong life expectancy, it can be deleterious to the patients' health. Exercise has consistently demonstrated improvement in anthropometric, cardiometabolic, and functional capacities of cancer survivors, but data concerning the effect of radiation on exercise outcomes are limited. **PURPOSE:** To evaluate the effect of radiation therapy on exercise outcomes in cancer survivors. **METHODS:** Patients participated in a 10-week exercise intervention involving aerobic, resistance, and flexibility training. There were 59 patients who had never used radiation (NR), 63 who had complete radiotherapy (HR), 18 currently undergoing treatment (CR),and 17 who failed to report their status. We analyzed differences among the three radiation exposure groups (NR, HR, and CR) in baseline characteristics, exercise adherence, and improvement in several parameters of health and function using chi-square and multivariate tests; post-hoc analyses tested specific group differences. **RESULTS:** There were no baseline differences between groups in age, health history, body composition, cardiovascular parameters, fatigue, insomnia, or depression. Patients in the NR group performed better on the five times sit-to-stand test than HR patients ($p=0.013$) and better on sit-and-reach ($p=0.037$) and functional reach ($p=0.059$) than CR patients. There were no differences in program completion based on use of radiation ($p=0.404$). Although there were no baseline differences in the six-minute walk ($p=0.987$), CR patients improved more than HR patients ($p=0.038$) and NR patients ($p=0.051$). There were no baseline differences in systolic blood pressure ($p=0.957$) but CR patients experienced greater reductions than patients in the HR group ($p=0.011$) and NR group ($p=0.035$). **CONCLUSION:** Exercise may be an effective way to mitigate some of the health consequences associated with radiation therapy. In our sample, exercise improved blood pressure and six minute walk more in patients who were currently undergoing treatment; however, our low retention rate may create potential bias and fail to accurately characterize expected results.

Effect of an Exercise Program on Fitness and Motivation Outcomes in Overweight Breast Cancer Survivors

Rita Musanti[1], Damion Martins[2], Dean Padavan[2], Adam Kahn[2]. [1]*Rutgers, New Brunswick, NJ.* [2]*Atlantic Sports Health Institute, Morristown, NJ.*

(No relevant relationships reported)

Background/Purpose. Overweight breast cancer survivors are at high risk of recurrence and mortality. Exercise can mitigate these outcomes, but this subset of survivors dropout from exercise programs at a high rate. We tested the Breast Cancer Healthy Lifestyle Intervention Study (BCHLIS) which incorporates evidence-based components to enhance physical fitness and intrinsic motivation(IM). **Theoretical Framework**. Self-determination theory (SDT) and exercise theory informed BCHLIS. We focused evidence-based components of the program on the psychological needs of autonomy (A), competence (C), and relatedness(R). Theoretically, if these are met then IM increases. **Methods.** A descriptive study that used a convenience sample of 14 breast cancer survivors. BCHLIS include individualized aerobic, resistance and flexibility exercise which was delivered for 24 weeks, 12 supervised and 12 in the community. Variables measured included : VO_2max, grip, balance and body composition. Psychological needs and motivation were measured with Basic Psychological Needs for Exercise Scale (BPNES)and Behavioral Regulation of Exercise Questionnaire-2 (BREQ-2), at 0, 3 and 9 months. Descriptive statistics, ANOVA for repeated measures, and bivariate correlation were used to analyze the data. **Results.** 14 women were enrolled, 9 women completed all survey data, 6 women completed both survey and fitness assessments, 5 women dropped out for various reasons: 1 disease related, others personal. Results included significant weight decrease ($p = .023$), increase in Met/hrs/week ($p = .04$), right hand grip strength ($p = .022$), balance ($p = .037$); and clinically relevant increase in VO_2max. Psychological needs satisfaction was noted at 3 months for A, C, and R. Motivation was observed to be maintained in 7/8 survivors, but retained a greater extrinsic than intrinsic source. **Conclusions & Implications**. Participation in BCHLIS resulted in increased physical activity, improved body composition and fitness profile. Motivation was maintained during the program, however a shift to more intrinsic motivation was not realized indicating that exercise programing may require external support beyond the 24 week time frame in overweight breast cancer survivors.

Chemotherapy and the Exercising Cancer Survivor

Samantha R. Gayla[1], Cynthia Villalobos[1], Justin C. Brown[2], J. Mark VanNess[1], Paul D. Vosti[3], Courtney D. Jensen[1]. [1]*University of the Pacific, Stockton, CA.* [2]*Harvard University, Cambridge, MA.* [3]*St. Joseph's Medical Center, Stockton, CA.* (Sponsor: Kathryn H. Schmitz, FACSM)

(No relevant relationships reported)

Advancements in treatment, such as chemotherapy, have improved survival rates among cancer patients. Today, approximately 67% of patients are at least five-year survivors; however, the combination of cancer and its care often affects the quality of those years. Patients commonly experience psychological symptoms, losses in physical function, and deterioration of cardiovascular health. Exercise ameliorates many of these consequences, but the effect of chemotherapy on exercise outcomes requires further exploration. **PURPOSE:** To evaluate the effects of chemotherapy on exercising cancer survivors. **METHODS**: We enrolled cancer survivors in a comprehensive 10-week exercise program; 40 patients had never received chemotherapy (NC), 80 had a history of chemotherapy (HC), 24 were currently undergoing treatment (CC), and 13 failed to report status. During a pre-exercise evaluation, we gathered demographic, morphological, psychological, cardiovascular, and functional data. Following the intervention, we repeated all assessments. We compared baseline data and analyzed pre-to-post differences in the three exposure groups (NC, HC, and CC) using chi-square and multivariate tests; post-hoc analyses measured specific group differences. **RESULTS:** Patients in the NC group were older ($p=0.013$), weighed more ($p=0.054$), and had a higher body mass index ($p=0.067$); obesity affected 56.7% of NC patients, 39.1% of HC patients, and 19.0% of CC patients ($p=0.026$). The NC group also had a higher incidence of hyperlipidemia ($p=0.058$) and worse performances in the six-minute walk ($p=0.019$), timed up-and-go ($p=0.002$), chair stand ($p=0.043$), and epic lift ($p=0.029$). There were no group differences in exercise adherence ($p=0.414$). NC patients improved the least in arm curls ($p=0.022$) and improved the most in VO_2 max ($p=0.037$) and systolic blood pressure ($p=0.064$). **CONCLUSION:** Patients who had used chemotherapy in the past or were currently undergoing treatment were younger than those with no history of use; age may explain the differences noted. Our results indicate chemotherapy is not a barrier for exercise participation; as long as it is tolerated, exercise should be encouraged throughout cancer survivorship. While chemotherapy did not affect attrition, our low retention rate overall limits the strength of these findings.

Self-Reported Physical Activity at Breast Cancer Diagnosis is Associated with Greater Physical Activity During Chemotherapy

Chad W. Wagoner, Allison M. Deal, Seul K. Choi, Jordan T. Lee, Hyman B. Muss, Kirsten A. Nyrop. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

(No relevant relationships reported)

PURPOSE: Examine the associations among self-reported physical activity levels at breast cancer diagnosis to physical activity levels during chemotherapy. **METHODS:** Prior to beginning chemotherapy, patients were approached by research staff to participate in a walking intervention. 100 early stage (I-III) breast cancer patients participated in the intervention, and were asked to walk 150 minutes per week during chemotherapy. Patient characteristics and physical activity levels were assessed via questionnaire at baseline. Physical activity during treatment was monitored via weekly step totals obtained from a Fitbit Zip and uploaded directly into research computers. A linear regression analysis of self-reported physical activity prior to chemotherapy with mean Fitbit steps per week during chemotherapy was conducted. **RESULTS:** Breast cancer patients (age 48 ± 8 years) who reported higher self-reported walking minutes/week at baseline (79.9 ± 16.7; $p < 0.0001$) and a history of self-reported vigorous physical activity (55% vs 45%; $p < 0.01$) at baseline exhibited greater weekly Fitbit step totals during chemotherapy. **CONCLUSIONS:** In this sample, early stage breast cancer patients with a history of greater physical activity prior to chemotherapy are more apt to remain physically active during chemotherapy. Funding: Breast Cancer Research Foundation, New York, NY.

Time-Course of Muscle Performance Recovery of Hodgkin's Lymphoma Survivors After a Resistance Exercise Session: A Preliminary Study

Sandro N. Chaves, Filipe Dinato de Lima, Ritielli de Oliveira Valeriano, Ricardo Jacó de Oliveira. *University of Brasília, Brasília, Brazil.*

(No relevant relationships reported)

Cancer survivors experience several disabling long-term side effects promoted by the cancer treatment and the pathology. Although the American College of Sports Medicine recommend the practice of strength training to cancer survivors similarly to healthy subjects, these recommendations are based on a restricted literature. Cancer survivors may require a longer recovery between sessions due to physiological impairments.**PURPOSE**: To assess the time-course of muscle performance recovery after a resistance exercise session in Hodgkin's Lymphoma survivors. **METHODS**: Four Hodgkin's Lymphoma survivors (age: 28.00 ± 8.16; height: 1.71 ± 0.06m; weight: 68.38 ± 9.83kg) participated in this study. The volunteers attended to the laboratory in four consecutive days. On the first visit, the isokinetic knee extension peak torque was assessed and the volunteers performed an exercise session composed by six sets of ten repetitions at 60º/s and 120-sec rest interval. On the following visits, the peak torque was assessed to determine muscle recover time-course. Repeated measures one-way ANOVA was used to analyze data.
RESULTS: There was no significant time effect (F = 0.036; p = 0.990) for peak torque. There was no difference between pre (178.55 ± 56.87 N.m), 24 hours (178.97 ± 58.54 N.m), 48 hours 177.90 ± 52.09 N.m) and 72 hours (179.75 ± 59.65 N.m).
CONCLUSIONS: Hodgkin's Lymphoma survivors recover muscle strength production capacity 24 hours after a resistance exercise session and do not require longer rests between training sessions.

Objectively Quantified Doses of Activity and Inactivity and Subjective Well-Being in Breast Cancer Survivors

Amanda Hickey[1], Richard Viskochil[2], Patty Freedson, FACSM[2], Barry Braun, FACSM[3]. *[1]Keene State College, Keene, NH. [2]University of Massachusetts, Amherst, MA. [3]Colorado State University, Fort Collins, CO.*

(No relevant relationships reported)

Introduction: Physically active breast cancer (BC) survivors have higher quality of life (QOL) compared to those who are sedentary. However, exercise programs may introduce compensatory responses to total daily physical activity (PA) and sedentary time (ST) that could undermine the expected benefits of exercise training. The primary aim of this study was to evaluate changes in daily PA and ST following the implementation of an exercise training program in BC survivors. A secondary aim was to examine the relationship between PA/ST and fatigue/QOL.
Methods: 12 postmenopausal BC survivors wore an ActiGraph GT3X monitor on the right hip for 7 consecutive days and completed the EORTC QOL questionnaire and Piper Fatigue Scale prior to and during the final week of a supervised 12-wk exercise training program (45-60 min/day, 2-4 days/wk). The activity data were categorized using the Freedson 1998 cut-points and are presented as a percentage of wear-time spent in each intensity category. **Results:** The table presents PA, ST, perceived fatigue and QOL scores.

	ST (%)	Light (%)	MVPA (%)	Piper Fatigue Score	EORTC QOL Score
Baseline	77.2 (6.41)	17.6 (4.95)	5.2 (3.94)	80.6 (40.40)	5.7 (0.69)
Post-Intervention	71.8* (8.38)	22.7* (6.75)	5.5 (3.29)	66.1* (31.87)	5.9* (0.96)

Note: Data are presented as mean (SD); * indicates significant change from baseline (p<0.05)
By post-intervention these women replaced ST with light intensity activity. The EORTC score was significantly correlated with ST at baseline (R^2=0.33, p=0.05), but this relationship was not significant at post-intervention. There were no significant relationships found between the Piper Fatigue Score and ST.
Discussion: These findings suggest participants did not reduce PA or increase ST during the exercise program. It has been reported that exercise training may lead to compensatory declines in habitual PA and/or increases in ST but our results do not support this. It is possible that as BC survivors increase purposeful exercise, they are able to substitute low levels of PA for ST. The relationship found between QOL and ST suggests that reductions in ST could be a potential target for interventions that aim to improve QOL in BC survivors.

Effects of a Lifestyle Intervention on Select Social Cognitive Outcomes in Prostate Cancer Patients Undergoing Androgen Deprivation Therapy

Brian C. Focht, FACSM[1], Alexander R. Lucas[2], Elizabeth Grainger[1], Christina Simpson[1], Ciaran M. Fairman[1], Jennifer M. Thomas-Ahner[1], Jessica Bowman[1], Victoria R. DeScenza[1], Zachary L. Chaplow[1], Steven K. Clinton[1]. *[1]The Ohio State University, Columbus, OH. [2]Wake Forest University, Winston Salem, NC.*

(No relevant relationships reported)

Social cognitive theory (SCT) variables are well-established determinants of lifestyle behavior change. Although exercise consistently improves clinically relevant outcomes in prostate cancer (PCa) patients undergoing androgen deprivation therapy (ADT), knowledge of the effects of lifestyle interventions promoting concomitant change in both exercise and dietary (EX+D) behavior upon key SCT outcomes remains limited. **PURPOSE**: The purpose of the single-blind, randomized controlled Individualized Diet and Exercise Adherence-Pilot (IDEA-P) trial is to evaluate the preliminary efficacy of a combined exercise and dietary (EX+D) intervention, implementing a group-mediated cognitive behavioral (GMCB) approach, relative to standard of care (SC) treatment among PCa patients undergoing ADT. In the current study, we evaluated the effects of the EX+D intervention on select SCT outcomes at the end of the intensive phase of the intervention. **METHODS**: A total of 32 PCa patients (*M* age = 65 years) on ADT were randomly assigned to the EX+D (n = 16) or SC (n = 16) interventions. Measures of select SCT outcomes were obtained at baseline and 2-month follow-up assessments. **RESULTS**: Results of intention to treat ANCOVA analysis of residualized change scores yielded a significant treatment main effect for (p<0.01) for self-regulatory self-efficacy and satisfaction with physical function. Post hoc analysis revealed that the intensive phase of the EX+D intervention resulted in superior improvements in self-regulatory self-efficacy (*d* = .55) and stair climb (*d* = 1.20) performance relative to the SC intervention at 2 months. **CONCLUSIONS**: Findings from the IDEA-P trial suggest that the intensive phase of the EX+D intervention, implementing a GMCB approach designed to promote adoption and adherence to lifestyle behavior change, resulted in superior changes in select SCT outcomes relative to SC approach. These results underscore the utility of a GMCB-based EX+D intervention for promoting meaningful improvement in key SCT outcomes among PCa patients undergoing ADT. Changes in Quality of Life of Cancer Survivors Participating in a Group Exercise Program

Sarah Greterman. *Concordia College, Moorhead, MN.*

(No relevant relationships reported)

Purpose: The purpose of this study was to evaluate the overall quality of life (QOL) of cancer survivors participating in the LIVESTRONG® at the YMCA 12-week group exercise program using the Functional Assessment Cancer Therapy – General (FACT-G).
Methods: Thirty-seven cancer survivors, representing a variety of cancer and treatment backgrounds, volunteered to complete the (FACT-G) QOL questionnaire at three different time points of the LIVESTRONG® at the YMCA Program: weeks 1, 6 (midpoint), and 12 (endpoint). The FACT-G includes questions related to social (SWB), emotional (EWB), functional (FWB), and physical well-being (PWB). Repeated measures ANOVA with mixed model framework was used to determine significance differences at weeks 1, 6, and 12. Post-hoc paired t-tests with Tukey-Kramer correction were conducted if significant differences were found.
Results: Of the 37 recruited, 7 participants (age = 55.20±13.85) completed week 1 (Group A), 12 participants (age = 52.17±11.71) completed weeks 1 and 6 (Group B), and 11 participants (age = 53.08±11.01) completed weeks 1, 6 and 12 (Group C). There were no statistically significant differences between total FACT-G score or between each subscale between Groups A and C or Groups B and C at the end of week 1, nor between Groups B and C at the end of week 6. For Group C, there were no statistically significant changes in three of the four subscales: SWB (F = 0.09, p = 0.916), EWB (F = 1.14, p = 0.345), or FWB (F = 0.40, p = 0.679) at all three time points. PWB was the only subscale to show statistically significant changes over the three time points (F = 5.09, p = 0.02). Changes in PWB were statistically significant between weeks 1 and 6 (t = -3.14, p = 0.017), but there was insufficient evidence to suggest any statistically significant differences between weeks 1 and 12 (t = -2.05, p = 0.131) or weeks 6 and 12 (t = 0.28, p = 0.514).
Conclusion: Perceived QOL plays a significant role in life satisfaction, engagement in physical activity, and physical, psychological, emotional, and social well-being. Although little significant differences were observed, the fact that PWB improved may suggest participation in the program has a positive impact on increasing energy levels, reducing pain, and improving ability to meet physical needs.

Abstracts were prepared by the authors and printed as submitted.

Age, Mobility Performance, and Physical Activity in Prostate Cancer Patients Undergoing Prolonged Androgen Deprivation Therapy

Victoria R. DeScenza[1], Brian C. Focht, FACSM[1], Alexander R. Lucas[2], Elizabeth Grainger[1], Christina Simpson[1], Ciaran M. Fairman[1], Jennifer M. Thomas-Ahner[1], Jessica Bowman[1], Zachary L. Chaplow[1], Steven K. Clinton[1]. *[1]The Ohio State University, Columbus, OH. [2]Wake Forest University, Winston Salem, NC.* (Sponsor: Brian C. Focht, FACSM)
(No relevant relationships reported)

Androgen deprivation therapy (ADT) is a foundation of treatment for men with prostate cancer (PCa). However, ADT is accompanied by adverse effects that increase risk of functional decline. Although some clinical observations suggest that ADT may have a greater impact upon functional status among aged men, empirical evidence addressing age-related differences in the trajectory of adverse effects of prolonged ADT remains limited. **PURPOSE**: The purpose of the present pilot study was to explore differences in change in mobility performance and physical activity (PA) across 6 months among 3 different age cohorts of PCa patients undergoing ADT. **METHODS**: A total of 44 PC patients undergoing prolonged ADT (> 6 months of treatment) were classified into 1 of 3 age cohorts: 55-64 (n=13); 65-74 (n=19); and 75+ years of age (n=12). Measures of mobility performance (400M Walk) and objectively-determined PA were obtained from men at baseline and 6 month follow-up assessments. **RESULTS**: Results of 3 (Age) x 2 (Time) ANOVA analysis demonstrated a significant Age main effect for mobility performance ($p < .05$) while the Age main effect for PA approached significance ($p < .06$). Post hoc analysis revealed patients in the youngest group had more favorable mobility performance relative to the middle ($d = -.71$) or oldest ($d = -1.04$) age groups and patients in the oldest group were accruing less objectively-determined PA relative to the middle ($d = .65$) or youngest ($d = .92$) age groups. However, the Age x Time interaction was not significant for mobility performance ($p < .38$) or PA ($p < .28$) indicating no differences in the trajectory of change were observed for either outcome as a function of age across time. **CONCLUSIONS**: This study provides some of the first preliminary evidence examining potential age-related differences in the trajectory of change in physical function and PA in PCa patients on ADT. Findings revealed that although well-established, anticipated age differences in mobility performance and PA were observed, no age-related differences in the trajectory of change in functional decline or PA emerged among PCa patients undergoing prolonged ADT.

Aquatic Exercise Training Program Outcomes on Quality Of Life and Lower Limb Lymphedema: Pilot Study

Andrée Dionne[1], Tarik Azlag[1], Sandra Morales[1], Serge Goulet[2], Mario Leone[3], Alain Steve Comtois[1]. *[1]University of Quebec in Montreal, Montreal, QC, Canada. [2]University of Sherbrooke, Montreal, QC, Canada. [3]University of Quebec in Chicoutimi, Chicoutimi, QC, Canada.*
(No relevant relationships reported)

Lower limb lymphedema (LLL) has a negative impact on many aspects of daily living, including household chores, physical activity, and psychological well-being. Patients with LLL that are not properly managed may become progressively worse and lead to an increases impairment of physical functional capacity and decline in the quality of life. **PURPOSE**: To determine whether patients with LLL can benefit from water immersion exercise to improve quality of life and control-diminish limb volume. **METHODS**: A total of 7 female participants affected by bilateral (n=4) or unilateral (n=3) LLL were included in this pilot study. Patients had primary or secondary LLL as complications of melanoma or gynecological cancers. Water immersion interval training exercise was conducted over a 6-week period (12 sessions of 45 minutes) and consisted of yoga exercises, aqua-jogging, pedaling on a water stationary bike and muscular training on a step and a trampoline. Outcome measures were taken before (pre) and after (post) the exercise program using the quality of life for limb lymphedema questionnaire (LYMQOL), 6 min walk test, handgrip strength test, bioelectrical impedance spectroscopy (BIS) and lower limb circumferences. **RESULTS**: Pre vs post lower limb circumference volumes remained stable, while BIS measurements increased significantly ($R_o = 204.8 \pm 58.5$ vs 220.9 ± 68.3 ohm, p=0.04) indicating a reduction in the extracellular fluid compartment. The distance covered in the 6 min walk test (458.4 ± 117.0 vs 520.0 ± 126.0 meter, p=0.04) and the sum of right and left handgrip strength (32.6 ± 5.6 vs 38.0 ± 10.8 kg, p=0.003) were significantly improved and so did the emotion score (2.1 ± 0.7 vs 1.6 ± 0.6, p=0.03) and overall quality of life (7.09 ± 1.8 vs 8.1 ± 0.8, p=0.05). **CONCLUSIONS**: Water immersion exercise training allowed patients with lower limb lymphedema to lower the extracellular fluid volume, increases physical fitness, and quality of life outcomes.

The Importance of Adiposity to the Cancer Patient Initiating Exercise

Alexia Amo[1], Cynthia Villalobos[1], Justin C. Brown[2], Paul D. Vosti[3], Courtney D. Jensen[1]. *[1]University of the Pacific, Stockton, CA. [2]Harvard University, Cambridge, MA. [3]St. Joseph's Hospital, Stockton, CA.* (Sponsor: Kathryn H. Schmitz, FACSM)
(No relevant relationships reported)

Each year, more than 600,000 adults are diagnosed with an obesity-associated cancer. Maintenance of a healthy body weight may reduce the likelihood of developing these cancers, slow the deterioration of health, and lower the risk of recurrence. Exercise is a commonly prescribed method of weight management in cancer survivors, but data are limited regarding the individualized benefits experienced by obese versus non-obese patients. **PURPOSE:** To compare the effects of exercise on obese and non-obese cancer survivors. **METHODS:** We enrolled 157 patients in a 10-week exercise program. At baseline, we determined anthropometric and cardiovascular profiles, psychological wellbeing, and physical functioning. Follow-up data were collected on subjects who completed the program (n=58). Obesity was defined by a body mass index ≥ 30 kg/m^2. Cardiovascular variables were blood pressure and heart rate. Wellbeing was assessed with questionnaires evaluating fatigue, insomnia, and depression. Physical function was measured with 13 tests of strength, coordination, aerobic capacity, and flexibility. Independent-samples t tests compared baseline characteristics and changes in outcome measurements of obese and non-obese patients. **RESULTS:** At baseline, obese (40%) and non-obese (60%) patients were similar with the exception that obese patients performed poorer in the six-minute walk (p<0.001) and timed up-and-go (p=0.012) while they were stronger in push (p=0.017) and pull (p=0.040) assessments. Retention rate did not differ by obesity status (p=0.853). From baseline to follow-up, patients improved in wellbeing and most functional tests, but there were no differences in improvement between obese and non-obese patients in any component of their cardiovascular profile, psychological health, or physical functioning (p>0.190). **CONCLUSION:** Obese and non-obese cancer survivors have similar profiles at baseline and generally improve with exercise. Exercise may be more critical to obese patients, not due to cardiovascular, psychological, or functional changes, but because of the risk of recurrence associated with excess adiposity. Our findings reiterate the importance of exercise to the cancer survivor, regardless of body composition, but there is potential for bias owing to the high dropout rate found in our study.

Cancer Stage Does Not Affect Fatigue or VO$_{2peak}$ Improvements Following an Exercise-Based Cancer Rehabilitation Program

Daniel Y.K. Shackelford[1], Jessica M. Brown[1], Brent M. Peterson[2], Reid Hayward[3]. *[1]Carroll University, Waukesha, WI. [2]Biola University, La Mirada, CA. [3]University of Northern Colorado, Greeley, CO.*
(No relevant relationships reported)

INTRO: Cancer stage reflects the severity and extent of the disease, with stage IV reflecting advanced cancer and poorer prognosis. Exercise has been shown to improve a number of psychological and physiological variables in cancer survivors, such as cancer-related fatigue (CRF) and cardiovascular fitness (VO$_{2peak}$). However, the effect of stage on these improvements is unknown. **PURPOSE:** To examine whether diagnosed cancer stage affects or modifies improvements in CRF and VO$_{2peak}$. **METHODS:** A total of 384 cancer survivors (57 ± 12 years of age) completed initial assessments of CRF and VO$_{2peak}$ via the Piper Fatigue Scale and the University of Northern Colorado Cancer Rehabilitation Institute's cancer-specific treadmill protocol, respectively. Participants were divided into four groups based on diagnosed cancer stage (I, II, III, and IV). Survivors completed supervised, one-on-one exercise sessions three days per week, 60 minutes per day for 12 weeks. The intervention consisted of individualized and progressive cardiovascular, whole-body strength, balance, and flexibility training. Participants' CRF and VO$_{2peak}$ were reassessed following the intervention. **RESULTS:** Collectively, pre-to-post assessments demonstrated significant overall improvements in CRF (-25%) and VO$_{2peak}$ (11%) across all stages (p<0.01). No significant differences in CRF (p=0.92) or VO$_{2peak}$ (p=0.44) improvements occurred between the stages. When evaluating individual cancer stage CRF, significant improvements (p<0.01) were observed with each stage (I, -32%; II, -27%; III, -29%; IV, -29%). Similarly, significant improvements in VO$_{2peak}$ (p<0.01) occurred with each cancer stage (I, 16%; II, 14%; III, 12%, IV, 11%). **CONCLUSION:** Exercise-based cancer rehabilitation during and following cancer treatment has been shown to have positive effects on CRF and VO$_{2peak}$, but the effect of stage diagnosis on these improvements has been unclear. We observed no significant differences in improvement of CRF and VO$_{2peak}$ between cancer stages, and all stages experienced significant benefits following a 12-week cancer rehabilitation program. These results suggest that reductions in CRF and improved cardiovascular function are possible in all cancer patients, regardless of cancer stage.

Recruitment Strategies for Cluster Randomized Controlled Trials Targeting Workplace Sedentary Behavior- a Retrospective Review

Sarah L. Mullane[1], Sarah A. Rydell[2], Miranda L. Larouche[1], Meynard John L. Toledo[1], Linda H. Feltes[3], Brenna Vuong[4], Noe C. Crespo[5], Mark A. Pereira[2], Matthew P. Buman, FACSM[1]. *[1]Arizona State University, Phoenix, AZ. [2]University of Minnesota, Minneapolis, MN. [3]Minnesota Department of Health, Minneapolis, MN. [4]Fairview Health Services, St Paul, MN. [5]San Diego State University, San Diego, CA.* (Sponsor: Matthew P. Buman, FACSM)

(No relevant relationships reported)

Increased demand for sedentary behavior reduction in workplace environments has led to the planning of large-scale interventions implemented at the group level in the form of cluster randomized controlled trials (RCTs). To date, limited evidence is available regarding cluster RCT recruitment strategies. **PURPOSE**: The purpose of this paper is to provide a review of recruitment strategies employed in a large cluster RCT targeting a reduction in workplace sedentary behavior. **METHODS**: Recruitment yields ([N enrolled/N screened] x 100) were calculated. Mean (±SD) and median worksite sizes were calculated at each recruitment step. The percentage of participants who progressed to each recruitment step (of the total N screened per worksite) was calculated to determine the mean percentage of a worksite successfully randomized. Recruitment barriers and modifications were recorded by the research team. A survey was completed by a subset of non-participants (N = 57) and thematic analyses conducted to examine reasons for non-participation, positive impacts and negative experiences. **RESULTS**: Cluster recruitment yield was 43% (24 worksites enrolled/56 screened). Individual recruitment yield was 49% (641 employees enrolled/1317 screened). On average, 52 ± 16% of the worksite was successfully randomized. Eighteen modifications were developed to overcome participant-related, context-related and research-related barriers. **CONCLUSIONS**: Researchers should plan to screen at least 200% of the intended number of worksites and they should target worksites that are approximately double the size of the intended cluster size to avoid loss of statistical power or timeline extensions. Acknowledging temporal fluctuations in worksite-specific workloads, providing options throughout the recruitment process, and adopting a participant-centered approach may facilitate cluster RCT success.

2882   Board #165   June 1 2:00 PM - 3:30 PM

Validation Of Two Physical Activity And Sedentary Behavior Questionnaires In Orthopedic Trauma Patients

William G. Veitch[1], Rachel E.D. Climie[2], Belinda J. Gabbe[1], David W. Dunstan[2], Neville Owen[2], Christina L. Ekegren[1]. *[1]Monash University, Melbourne, Australia. [2]Baker Heart and Diabetes Institute, Melbourne, Australia.*

(No relevant relationships reported)

Orthopedic trauma can be a catalyst for substantially reduced physical activity and increased sedentary behavior that can persist post-recovery. While objective measures (e.g. accelerometry) provide rigorous approaches to assessing physical activity and sedentary behavior, they may be inappropriate for studies with some patient groups. Self-report measures provide potential alternatives, however, their validity must be established. **PURPOSE**: To determine, in orthopedic trauma patients, the agreement and concordance of physical activity and sedentary behavior data from two self-report measures, the International Physical Activity Questionnaire (IPAQ) and the domain-specific sitting questions from the Australian Diabetes, Obesity and Lifestyle General Questionnaire 3 (AusDiab3), with data derived from objective measures. **METHODS**: 64 patients with isolated upper- or lower-limb fractures wore two activity monitors (ActiGraph, ActivPAL) for 10 days, from 2-weeks post-surgery. Participants then completed the IPAQ and AusDiab3 questionnaires relating to the previous 7 days of objective monitoring. Bland-Altman plots, Lin's Concordance Correlation Coefficients (LCCCs) and weighted kappa statistics were used to assess agreement and concordance across several physical activity and sedentary behavior variables. **RESULTS**: The IPAQ overestimated objectively-assessed overall physical activity (median METmins: 550 vs.0) and underestimated median daily sitting time (8.00 vs.10.59 hrs). The AusDiab3 questionnaire underestimated median daily sitting time to a lesser degree than the IPAQ (9.21 vs.10.53hr/day). There was moderate concordance between IPAQ-reported and objectively-derived overall physical activity (ρ=0.431,

p<0.001), weak concordance between IPAQ-reported and objectively derived sitting time (ρ=0.384, p<0.001) and moderate concordance between AusDiab3-reported and objectively measured sitting time (ρ=0.551, p<0.001).
CONCLUSIONS: There was disagreement and discordance between the IPAQ and Ausdiab3 questionnaire and objectively derived data, suggesting that these measures cannot be used interchangeably in orthopedic trauma patients. Modifications could be made in order to more specifically address the activity characteristics of this population.

Informing Workplace Sedentary Behavior Interventions Through Momentary Affective States And Email-based Prompts.

Meynard John L. Toledo, Sarah L. Mullane, Sayali S. Phatak, 85004, Marios Hadjimichael, Eric B. Hekler, Matthew P. Buman. *Arizona State University, Phoenix, AZ.* (Sponsor: Matthew P Buman, FACSM)

(No relevant relationships reported)

PURPOSE: The study aimed to (a) examine the effect of momentary affective states on workplace sedentary behavior (WSB); and (b) test the proximal effects of email-based prompts on WSB. **METHODS:** Office workers with sit-stand desks were recruited in a two-part 20-workday study. In part A, participants completed ecological momentary assessments (EMA; at 3 random times/day) of affective states. Each EMA response was matched with behavioral outcomes (i.e., time spent sedentary, standing, or moving proceeding each EMA response). Part B involved a micro-randomized prompt-based trial. Prompt delivery was randomized to be sent (ST) or not sent (NST) to all participants (probability of 0.5), at eight decision points per day between 9am and 5pm. Half of the prompts encouraged standing and the other half encouraged moving. An activPAL device was used continuously through the 20 days to measure WSB. Multilevel models were used to examine the associations of workplace behaviors and affective states. General estimating equations were used to examine the likelihood of a response to a prompt (i.e., transition from sitting to standing/moving) over the proceeding 5 and 30 min intervals. All models were adjusted for age, gender, race, and job type. **RESULTS:** Participants (N = 18; 56% females) who completed part A contributed 493 EMA responses (27.4±13.3 EMA responses/participant). When examining momentary relationships, individuals sat less (b[SE]= -3.9[1.8], p=.02) and stood more (b[SE]= 3.5[1.6], p=.02) in the hour following higher than usual energy and sat less (b[SE]= -2.8[1.4], p=.04) and moved more (b[SE]= 1.2[0.4], p<.01) following higher than usual intentions to stand/move. Among participants (N = 15; 67% female; age = 50.9 ± 9.5yrs) who completed part B, 1147 decision points occurred when seated. Participants were 42% more likely to transition from sitting to standing within 5 mins when a prompt was sent (OR[95%CI] = 1.4[1.1, 1.8], p<.01). Stand prompts were 25% more likely to elicit a transition (OR[95%CI] = 1.6[1.2, 2.0], p<.01) than move prompts (OR[95%CI] = 1.3[1.0, 1.7], p<.05).
CONCLUSIONS: Prompts may be an effective complementary strategy to encourage sit-stand desks use. Information regarding context (i.e., affective states and intentions) may complement these findings in developing just-in-time interventions.

2884   Board #167   June 1 2:00 PM - 3:30 PM

Impact of 3-Month Changes in Sedentary Time and Light-Intensity Physical Activity on Subjective Sleep Quality

Miranda L. Larouche[1], Meynard John L. Toledo[1], Sarah L. Mullane[1], Kristina Hasanaj[1], Sarah A. Rydell[2], Mark A. Pereira[2], Matthew P. Buman, FACSM[1]. *[1]Arizona State University, Phoenix, AZ. [2]University of Minnesota, Minneapolis, MN.* (Sponsor: Matthew Buman, FACSM)

(No relevant relationships reported)

Regular moderate-vigorous physical activity (MVPA) has been shown to improve sleep quality. However, little is known about whether reducing sedentary time (i.e., replacing sitting with standing) or increasing light-intensity physical activity (LPA) may also improve sleep.
PURPOSE: To examine whether 3-month changes in objectively measured sedentary time and LPA are associated with subjective sleep quality.
METHODS: Participants (N=632, 72.3% female, 71.2% white, 44.6 ± 11.2 years of age) were recruited from 24 worksites in the Phoenix and Minneapolis regions to participate in the multi-component cluster randomized controlled trial 'Stand & Move at Work,' to reduce sitting and increase LPA in the workplace. Participants wore an activPAL accelerometer continuously for seven consecutive days to assess sedentary (i.e., sitting/lying down) and LPA (stepping at < 100 steps/min) behaviors. Daily logs were used to separate data into work and non-work hours and behaviors were standardized to 8hr workdays. The Pittsburgh Sleep Quality Index (PSQI) was administered concurrently with the activPAL at baseline and at 3 months to assess

subjective sleep quality (lower scores = better sleep quality). Mixed-effects regression models adjusted for worksite clustering and age, gender, race, job type, body mass index (BMI), and MVPA. **RESULTS:** Participants spent 333.1 ± 78.0 min/8hr workday and 30.7 ± 14.8 min/8hr workday in sedentary and LPA behaviors at baseline, respectively. Overall, sedentary time was reduced by 33.6 ± 13.6 min/8hr workday and LPA was increased by 0.1 ± 0.9 min/8hr workday. Increases in LPA were associated with 3-month improvements in PSQI sleep latency (b[se]= -.009 [.20], p=.025). No other changes in sedentary or LPA behaviors were associated with PSQI changes.
CONCLUSION: Workplace interventions targeting reductions in sedentary behavior may be effective for improving sleep onset, but not other aspects of sleep quality. Future interventions should examine longer term follow-up periods, assess sleep objectively, and incorporate interventions that target sedentary time and LPA both during and outside of work hours.

2885 Board #168 June 1 2:00 PM - 3:30 PM
Patterns of Sedentary Behavior in Pregnant Women

Anya Odabasic, Meghan Baruth, Rebecca A. Schlaff, Samantha J. Deere. *Saginaw Valley State University, University Center, MI.*
(No relevant relationships reported)

Previous research indicates that women become more sedentary during pregnancy. However, very few studies have objectively measured sedentary behaviors in this population. **PURPOSE:** To quantify objectively measured sedentary behaviors, including patterns of sedentary behaviors, in a sample of pregnant women. **METHODS**: Participants included pregnant women enrolled in a behavioral nutrition and physical activity intervention. Participants wore an Actigraph accelerometer during all waking hours for seven consecutive days. The total volume of sedentary behaviors was quantified (% of day), as was the amount of time spent sedentary according to time of day (morning [6am-12pm], afternoon [12pm-6pm], evening [6pm-12am]) and type of day (weekday, weekend). Surveys were administered to assess demographic characteristics. Descriptive statistics calculated the percentage of time spent sedentary, in addition to the percentage of type and time of day spent sedentary. **RESULTS:** On average, the participants (n=41) were 28.0±4.4 years of age, 17.8 ±2.3 weeks gestation, and had a pre-pregnancy body mass index (BMI) of 27.0 ±7.5. The majority of the sample were Caucasian (82.5%), married (68.3%), and had some college education (72.3%). Overall, participants spent 59.1% of waking hours sedentary. When looking at type of day, participants were sedentary 60.2% of the day on weekdays, and 55.6% of the day on weekend days. When looking at time of day, participants were sedentary 57.7% of time during morning hours, 58.6% during afternoon hours, and 61.3% during evening hours. **CONCLUSION:** Results indicate that pregnant women spend a majority of their day engaged in sedentary behaviors. When looking at type and time of day, the data indicate that our sample was more sedentary on weekdays and during evening hours. Given the benefits of regular physical activity during pregnancy for both the mother and baby, and the high rates of sedentary behaviors, interventions aimed at decreasing sedentary time during pregnancy are needed. Replacing sedentary behaviors with even light activity may be a first step in successfully decreasing the total volume of sedentary behavior.

2886 Board #169 June 1 2:00 PM - 3:30 PM
Associations Between Sedentary Behavior And Metabolic Syndrome Are Mediated By Cardiorespiratory Fitness But Not Mvpa

Katrina Taylor[1], Megan C. Nelson[2], Chantal A. Vella, FACSM[2].
[1]*Eastern Washington University, Cheney, WA.* [2]*University of Idaho, Moscow, ID.*
(No relevant relationships reported)

Sedentary behavior is negatively associated with individual metabolic syndrome (MetS) risk factors in young adults but little research has investigated these associations using a clustered risk score. **PURPOSE:** To determine whether sedentary behavior is associated with a clustered MetS score independent of moderate-to-vigorous physical activity (MVPA) and cardiorespiratory fitness (VO_2peak) in young adults. **METHODS:** 146 participants (age 22.0±3.7 years, BMI 25.0±3.9 kg.m^{-2}, VO_2peak 43.9±8.5 ml.kg.min^{-1}) volunteered for the study. Total minutes and bouts of sedentary behavior (<150 counts/minute) and MVPA (≥2,690 counts/minute) were measured by an accelerometer worn during waking hours for 7 consecutive days. MetS risk factors measured were waist circumference, blood pressure, and fasting glucose, triglycerides and high-density lipoprotein cholesterol. VO_2peak was measured using an incremental treadmill test to exhaustion. Confirmatory factor analysis (CFA) was used to construct a model for MetS and individual indicator variables. Structural equation modeling (SEM) was used to determine the associations among sedentary behavior, VO_2peak, MVPA and MetS. Goodness-of-fit indices were used to assess model fit for CFA and standardized estimates with an alpha level of 0.05 were used for SEM models. **RESULTS:** The clustered score was a valid model of MetS (χ^2=12.9, p=.12;

CFI=.93; RMSEA=.07). On average, participants engaged in 503.4±87.4 minutes/week of sedentary behavior and 190.9±145.2 minutes/week of MVPA in 10-minute bouts. Total sedentary behavior was significantly and positively associated with MetS (β=.24, p=.03). This association was independent of MVPA (β=.23, p=.04) but mediated by relative VO_2peak (β=.25, p=.29). Similarly, sedentary behavior in bouts of 10, 20, 30, and 60-minutes or longer were all significantly and positively associated with MetS independent of MVPA (β range .23 to .29, p<.05) but not VO_2peak (β range .16 to .25, p>.05). **CONCLUSIONS:** Our findings suggest sedentary behavior is associated with clustered metabolic risk in young adults, independent of MVPA, and that bouts of 20 minutes or longer may have the greatest impact on MetS risk. Additionally, fitness may play an important role in attenuating the effects of sedentary behavior on MetS in this population.

Adapting Sedentary Video Games to Require Physical Activity

Christen J. Mendonca, Jillian L. Hawkins, Sinclair A. Smith. *Drexel University, Philadelphia, PA.* (Sponsor: Dr. Stella Volpe, FACSM)
(No relevant relationships reported)

Approximately $117 billion in annual healthcare costs are associated with physical inactivity. The Pew Research Center reports that about 49% of American adults play video games (VG). Adapting traditionally sedentary VG controls to require physical activity using low-cost devices may increase opportunities to adhere to physical activity guidelines. **Purpose:** To determine the effects of adapting sedentary VG to require physical activity on exercise intensity, perceived exertion, enjoyment, and VG performance. **Methods:** Six women and nine men 19 to 52 years of age played PAC-MAN Championship Edition DX+ (NAMCO) in three conditions: sedentary play (SED), standing active play using gestures recognized by a motion sensor (AVG-G), and standing active play using buttons (AVG-B). Each participant started with SED and the two adapted conditions were counterbalanced. Exercise intensity was assessed by recording continuous heart rate using a chest strap monitor. Ratings of perceived exertion (RPE) were reported using the Borg 6 to 20 scale. Enjoyment was reported using an abbreviated Physical Activity Enjoyment Scale. VG performance was represented by the in-game score. Repeated measures ANOVA tests were used to compare heart rate, RPE, enjoyment, and VG performance across conditions. **Results:** There was a significant effect of game condition on heart rate, percent of age predicted heart rate maximum (APHRM), RPE, and VG performance (p < 0.001). Enjoyment was not significantly different across conditions (p = 0.216). Post hoc analysis indicated that AVG-G and AVG-B elicited a higher mean (±SD) heart rate (108±16 and 97±15 BPM), percent of APHRM (58±10 and 51±9%), and RPE (13±2 and 12±2) versus SED (72±13 BPM, 39±8% APHRM, 7±1 RPE). Participant VG performance was lower during AVG-G and AVG-B (51.75±28.07 and 68.84±35.52 arbitrary units) versus SED (202.11±91.08 arbitrary units). **Conclusion:** These results suggest that the majority of participants achieved and sustained moderate to vigorous physical activity during adapted sedentary VG for at least 10 minutes. Enjoyment did not suffer as a result of active play despite lower VG performance.

Impact of HealtheSteps Lifestyle Prescription Program on Healthful Eating and Sedentary Time in At-Risk Adults

Dawn P. Gill[1], Wendy Blunt[1], Roseanne W. Pulford[1], Adam Gavarkovs[2], Narlon C. Boa Sorte Silva[1], Cassandra Bartol[1], P Karen Simmavong[1], Ashleigh De Cruz[1], Guangyong Zou[1], Robert J. Petrella, FACSM[1]. [1]*Western University, London, ON, Canada.* [2]*Harvard University, Cambridge, MA.*
(No relevant relationships reported)

Chronic diseases (CDs) account for two-thirds of deaths worldwide. Physical inactivity and unhealthy eating are key risk factors contributing to the global CD burden. **PURPOSE:** 1) To determine whether a 6-month lifestyle prescription program [Health*e*Steps (H*e*S)] can improve healthy eating and decrease sedentary time in adults at-risk for CD; 2) To explore long-term maintenance of these behaviours. **METHODS:** Pragmatic randomized controlled trial of adults with ≥1 CD risk factor (metabolic syndrome or type 2 diabetes; body mass index >25 kg/m²; exercise <150 min/wk; sit ≥3 hr/d; eat <8 servings of fruit and vegetables/d) from 5 primary care settings in Ontario, Canada. Individuals (N = 118; mean age 57 (SD=12) years; 76% female) were randomized to intervention (H*e*S) or comparator (wait-list; WL). From baseline (V0) to 6 mo. (V1), H*e*S included 4 bimonthly coaching sessions (lifestyle prescriptions; strategies to achieve goals) and access to *e*Health technologies (phone coaching; social network; apps; website). From V1 to 12 mo. (V2), participants only had access to *e*Health technologies; from V2 to 18 mo. (V3), access included only publically available technologies. We examined *within* and *between* group differences in mean healthful eating (Starting the Conversation, STC; score 0-16, lower=better) using linear mixed models (LMM) adjusted for age, sex and site (covariates). Quantile

regression was used to examine *between* group differences at V1 in median sitting time (International Physical Activity Questionnaire; min/d, typical wk day), adjusted for baseline and covariates. A log-transformation was applied and changes in sitting time *within* H*e*S were examined via a LMM. **RESULTS:** By V1, H*e*S improved healthful eating more than WL [mean change in STC score (95% CI), p-value for difference: [H*e*S: -1.84 (-2.56, -1.13); WL: -0.35 (-1.03, 0.34); p=0.002] and maintained these improvements to V2 (p<0.001) and V3 (p=0.002). By V1, H*e*S decreased sitting time more than WL [difference between groups in median change (95% CI), p-value: -66.16 (-117.68, -14.64) min/d; p=0.01] and maintained decreased sitting time in the long-term (V2: p=0.002; V3: p=0.04).

CONCLUSION: Compared to usual care, H*e*S improved healthful eating and decreased sitting time in at-risk adults over 6 months, with strong potential for long-term sustainability.

2889   Board #172   June 1 2:00 PM - 3:30 PM

Reproducibility Of Free-living Physical Activity/ sedentary Behaviors In College Undergraduates

Justin M. Moreng, Jesse A. Goodrich, Jeffrey C. Higdon, Marissa Holliday, Miguel A. Rueda, Sourav Podder, Theresa D. Hernandez, Matthew B. McQueen, Kenneth P. Wright Jr., William C. Byrnes, FACSM. *University of Colorado- Boulder, Boulder, CO.* (Sponsor: William C. Byrnes, FACSM)
(No relevant relationships reported)

PURPOSE: To determine the reproducibility of free-living physical activity/sedentary behaviors in college undergraduates. **METHODS:** Twice during an academic semester, 20 college students wore activPAL and Actiwatch monitors for seven consecutive days. Subjects were instructed to wear the devices at all times. These devices were worn according to manufacturer's instructions. Sleep and non-wear time were determined via the Actiwatch; waking physical activity and inactivity parameters were determined with the activPAL. The weekly means of these parameters were compared via paired t-tests and used to determine the typical error (TE) and coefficient of variation (CV). **RESULTS:** For the following waking day parameters, there were no significant differences between weeks one and two, so the average of both weeks are reported as the mean ± SD together with the TE and CV: total number of steps (9647.0 ± 4614.2, 1744.3, 18.2%), minutes spent stepping (104.0 ± 47.9, 16.5, 15.5%), sedentary minutes (737.2 ± 138.2, 53.7, 7.5%), MET-hours (25.0 ± 3.2, 1.3, 5.2%), minutes spent standing (163.2 ± 87.9, 34.4, 21.1%), minutes of light intensity activity (1.5-2.99 METs; 192.2 ± 99.1, 37.9, 19.4%), number of breaks from sitting/lying (48.1 ± 15.9, 5.2, 11.1%), the number of breaks per sitting/lying hour (4.1 ± 1.7, 0.6, 14.4%), the minutes of sitting/lying bouts that last at least 30 (475.5 ± 163.3, 52.5, 11.1%) and 60 minutes (271.4 ± 166.8, 59.7, 21.2%), percent of day spent sedentary (73.4 ±11.5, 0.04, 6.2%), percent of day spent in light intensity (19.1 ± 9.5, 0.04, 19.0%), and percent of day spent in moderate-to-vigorous activity (≥3 METs; 7.6 ± 3.6, 0.01, 17.4%). In contrast, total time spent in moderate-to-vigorous intensity activity (≥3 METs) was significantly different between weeks one (78.9 ± 39.6) and two (70.8 ± 33.9; p<0.05). In addition, the number of minutes meeting the ACSM physical activity guidelines were also significantly different between weeks one (27.7 ± 32.2) and two (20.2 ± 22.9; p<0.05). **CONCLUSION:** For college students, waking physical activity and sedentary behaviors assessed by activPAL are reproducible within an academic semester with the exception of moderate-to-vigorous physical activity. These results are likely explained by the lifestyle requirements demanded of a full-time college undergraduate.

2890   Board #173   June 1 2:00 PM - 3:30 PM

The Effect Of A Sit And Resistance Training Program On Sedentary Behavior

Danielle D. Wadsworth, David Pascoe, FACSM, James McDonald, Mynor Rodriguez Hernandez. *Auburn University, Auburn, AL.*
(No relevant relationships reported)

PURPOSE: Previous research has shown that Sprint Interval Training (SIT) is effective in eliciting physiological responses comparable to continuous forms of training. Despite these physiological benefits, there is some evidence that vigorous exercise is linked to negative affective states and may discourage continued exercise participation or result in compensatory behaviors. Therefore, the purpose of this study was to determine if physical activity compensation occurred following a 10-week exercise intervention and to examine how compensation affective intervention variables examined. **METHODS:** 39 women aged 19-35 (25.4±4.5 years) completed a 10-week exercise training study consisting of SIT and resistance training three times a week for a total of 30 sessions. Pre and post assessments included body composition by iDXA, VO$_{2max}$ and an accelerometer measured physical activity and sedentary behavior for seven days. Validated cut points determined the percentage of time spent in moderate to vigorous physical activity and sedentary behavior. **RESULTS:** Participants spent on average 600 ± 50.5 minutes of each day (82% of the day) in sedentary behavior prior to the intervention. After posttest, participants

spent on average 530.4 ± 101.4 minutes (78% of the day) in sedentary behavior, which is a 3.24% reduction (p<.001). There was no effect of MVPA on VO$_{2max}$ (p = .421), however, participants who lost fat mass over the course of the study spent significantly more time (p=.008) in MVPA outside of the study. **CONCLUSIONS:** Overall, participants did not compensate following an exercise intervention by increasing their sedentary behavior. However, differences in MVPA outside of the study affected changes in fat mass.

2891   Board #174   June 1 2:00 PM - 3:30 PM

Accelerometer-determined Physical Activity and Sedentary Behavior among Majority-minority Sample of Adults: The Houston Train Study

Ashleigh M. Johnson[1], Kelley Pettee Gabriel, FACSM[1], Deborah Salvo[1], Erin E. Dooley[1], Casey P. Durand[2], Gregory Knell[2], Samantha J. Kreis[1], Harold W. Kohl, III, FACSM[1]. [1]*The University of Texas Health Science Center at Houston (UTHealth) School of Public Health in Austin, Austin, TX.* [2]*The University of Texas Health Science Center at Houston (UTHealth) School of Public Health in Houston, Houston, TX.*
(No relevant relationships reported)

Based on self-reported data, minority populations are often found to be less active compared to whites, which may contribute to overall health disparities. The Houston Travel Related Activity in Neighborhoods (TRAIN) Study provides an opportunity to examine differences in accelerometer-determined (PA) levels among a majority-minority sample of adults.
PURPOSE: To describe and examine differences in accelerometer-determined PA and sedentary behavior among TRAIN participants at baseline, by race/ethnic groups and sex.
METHODS: Study participants were part of an ongoing natural experiment of transportation-related PA. At baseline, a group of participants self-selected to wear an ActiGraph wGT3X-BT monitor for 7 consecutive days during waking hours. Participants with ≥4 days with ≥ 10 hours/day were included in analysis. Freedson cut-points were used to quantify time spent sedentary (min/d) and in light- and moderate and vigorous-intensity physical activity (MVPA) (min/d). Vector magnitude (VM) estimates are also reported. Kruskal-Wallis tests were used to compare accelerometer based estimates by 1) race/ethnicity, and 2) sex and race/ethnicity groups.
RESULTS: 365 TRAIN participants had valid accelerometer data, 62.1% were female and 28.7% and 37.8% were black and Hispanic, respectively. There was a significant difference in VM (counts/min/day) across race/ethnicity groups with blacks and Hispanics having the highest and lowest median values, respectively (p<0.05). There were also differences for intensity-specific estimates. Median sedentary time (min/d) was highest in whites (591.0) and lowest in blacks (533.3), light intensity PA (min/d) was highest in blacks (256.2) and lowest in Hispanics (211.4), and MVPA (min/d) was highest in whites (17.9) and lowest in Hispanics (10.8) (p<0.05). Race/ethnicity differences were further stratified by sex. Among Hispanics, VM estimates were higher among men (461.5) than women (390.9) (p<0.05), which was also reflected in MVPA (min/d). In blacks, MVPA was higher among men (21.3) than women (11.3) (p<0.05). No other significant differences were noted.
CONCLUSIONS: For blacks, findings conflict with results typically found with self-reported data. Yet, findings for Hispanics align with existing literature, with the majority of disparity shown in women.

2892   Board #175   June 1 2:00 PM - 3:30 PM

The Effectiveness of Standing on a Balance Board for Increasing Energy Expenditure while Performing Sedentary Work

Megan C. Nelson, Madeline P. Casanova, Katie Eason, Elizabeth Biancosino, Chantal A. Vella, FACSM. *University of Idaho, Moscow, ID.*
(No relevant relationships reported)

It is estimated that occupational energy expenditure has decreased by 100 kcal·d^{-1}. Analogous to sitting, too much standing that is static with little movement poses health risks. Innovative technologies such as balance boards have been developed for use within an office setting to replace sitting and encourage movement while standing, yet little is known whether physiological benefits exist or if productivity is affected.
PURPOSE: To investigate differences in energy expenditure (EE), heart rate (HR), productivity, fatigue, and pain while performing desk work while sitting (SIT), standing (STAND), and standing on a balance board (BOARD).
METHODS: Thirty healthy adults (60% female; age 39.7 ± 11.8 y; BMI 26.7 ± 5.0 kg·m^{-2}) employed in sedentary-based jobs volunteered for this randomized crossover trial. Participants performed typing work in three different positions: SIT, STAND, and BOARD; each condition lasting 30 min. Oxygen consumption (VO$_2$) was measured via indirect calorimetry and EE was calculated using respiratory quotient and corresponding caloric equivalent values. Productivity was quantified by measuring words typed per min, accuracy, and typing mistakes. Overall feelings of fatigue and

pain were self-reported three times during each position using validated 10-cm visual analog scales. Repeated measures ANOVA were used to assess differences in outcome variables across conditions.
RESULTS: VO$_2$ was significantly different among all conditions regardless of current standing desk use (SIT 3.35 ± 0.53; STAND 3.77 ± 0.48; BOARD 3.92 ± 0.54 mL·kg^{-1}·min^{-1}, p<0.001). EE (kcal·min^{-1}) also differed (p<0.001) among SIT (1.27 ± 0.22), STAND (1.42 ± 0.26) and BOARD (1.48 ± 0.29). Compared to sitting (67 ± 9 bpm), HR was higher in STAND (76 ± 11 bpm) and BOARD (76 ± 11 bpm, p<0.001). Measures of productivity were similar across conditions (p>0.05). Mean self-reported fatigue and pain levels were similar across conditions (p>0.05). Fatigue progressively increased over each 30 min condition (p<0.001) whereas pain in SIT and BOARD increased from min 10 to 20, then leveled off between min 20 to 30. For STAND, pain continued to increase over time.
CONCLUSION: Compared with sitting, a balance board may be effective for increasing EE without interfering with productivity in an occupational setting.

2893　Board #176　　　June 1 2:00 PM - 3:30 PM

Intervention Targeting Reductions In Sedentary Time In Older Cancer Survivors: Characteristics Of Responders Versus Non-responders

Elizabeth Harding, Amy Tarnower, Charles Wiggins, Emily Williams, Matthew Schwartz, David Medrano, Anita Y. Kinney, Cindy K. Blair. *University of New Mexico, ALBUQUERQUE, NM.*

(No relevant relationships reported)

PURPOSE
We conducted a 16-week randomized controlled trial among older cancer survivors to disrupt sedentary time with short bouts of standing and stepping using prompts from a Jawbone UP2 tracker and smartphone app. Technical support was provided via 5 telephone calls. Primary analyses revealed limited change between intervention and control groups regarding reduction and breaks in sedentary time, and time spent stepping. The purpose of this secondary analysis is to provide insight as to the characteristics and behaviors of the participants that improved during the intervention (responders) versus those who did not improve (non-responders).
METHODS
Sedentary behavior and physical activity were measured in 26 older cancer survivors (mean age 69±3.1 years), using an ActivPAL activity monitor for 7 days pre- and post-intervention. The intervention group was divided into non-responders (n=12) and responders (n=14) based on improvement defined as: a decrease in daily sedentary time of 30 minutes or more, or an increase in daily light-intensity activity (LPA) of 30 minutes or more, or an increase in moderate-intensity physical activity (MPA) of 10 minutes or more. Independent sample t-tests were used to evaluate differences between groups regarding baseline demographic factors (age, sex, BMI), health characteristics (pain interference, fatigue, self-reported physical function, physical performance), sedentary behavior [sedentary minutes, breaks from sitting], and physical activity (LPA, MPA).
RESULTS
There were no significant differences in demographic factors (p-values 0.13 to 0.89) or baseline health characteristics (p-values 0.44 to 0.75) between responders and non-responders. Responders had more sedentary minutes/hour (42.4±4.3 vs. 36.1±8.1; p=0.03) and less LPA minutes/hour (standing + stepping: 14.3±3.4 vs.20.3±7.8; p=0.03) at baseline compared to non-responders.
CONCLUSION
These findings suggest that the greatest effect was observed in older cancer survivors who stood to benefit most from the intervention. Additional behavioral change techniques are needed to achieve more improvement.
FUNDING: American Cancer Society Institutional Research Grant and University of New Mexico Comprehensive Cancer Center Pilot Award.

Effects of a 16-Week Treadmill Exercise on Physical Activity and Sedentary Time in Older Women

Joshua R. Sparks, Charity B. Breneman, Ryan R. Porter, Steven N. Blair, FACSM, Xuewen F. Wang. *University of South Carolina- Columbia, Columbia, SC.* (Sponsor: Steven N. Blair, FACSM)

(No relevant relationships reported)

Aging is often accompanied by a decrease in physical activity (PA) and increase in sedentary time. Low PA and excessive sedentary time have been linked to adverse health outcomes. Less is known about whether exercise training influences sedentary time and PA in various intensities, and whether body weight and cardiorespiratory fitness (CRF) play a role in any of the associations. **PURPOSE:** To examine the influence of a 16-week treadmill walking protocol on time spent being sedentary and time spent performing light PA (LPA) and moderate-to-vigorous PA (MVPA), in older women, and to examine the influence of body weight and CRF. **METHODS:** Older

women (n=61; age=65.5±4.3 years) participated in a 16-week moderate-intensity treadmill walking program (35-65 minutes/session, 3 days/week). Women wore a SenseWear Mini Armband consecutively for 14 days, except during water activities, at baseline and at the end of intervention. The software provided by the manufacturer was used to estimate the metabolic equivalents (METs), and to classify PA into LPA (1.5 to ≤ 3.0 METS) and MVPA (> 3.0 METs). Sedentary time was calculated by subtracting time being asleep from time with METs < 1.5. Body weight and CRF (by a graded exercise test) were measured at baseline and end-intervention. Repeated measure analyses were used to compare between baseline and end-intervention in the time being sedentary and performing PA. Body weight and CRF were used as time-varying covariates. **RESULTS:** Time being sedentary significantly reduced from baseline to end-intervention by approximately 38 minutes (p<0.001). Contrary to sedentary time, LPA significantly increased by approximately 17 minutes (p<0.002), and MVPA significantly increased by 20 minutes (p<0.0001). Body weight was associated positively with sedentary time (p=0.007), and negatively with LPA (p=0.001) across the intervention, but not with MVPA (p=0.24). CRF was associated negatively with sedentary time (p=0.002), and positively with both LPA (p=0.04) and MVPA (p<0.0001) across the intervention. **CONCLUSION:** A 16-week moderate-intensity treadmill-based intervention decreased sedentary time, and increased time spent performing LPA and MVPA. Interestingly, MVPA time was associated with CRF, but not body weight.

2895　Board #178　　　June 1 2:00 PM - 3:30 PM

Accelerometer-Assessed Physical Activity And Sedentary Time Profiles Of Kidney Transplant Recipients

Jeff K. Vallance[1], Steven T. Johnson[1], Kevin Wen[2], Ngan N. Lam[2], Stephanie Thompson[2], Terry Boyle[3], Soroush Shojai[2]. [1]*Athabasca University, Athabasca, AB, Canada.* [2]*University of Alberta, Edmonton, AB, Canada.* [3]*University of South Australia, Adelaide, Australia.*

(No relevant relationships reported)

Physical activity may improve quality of life among kidney transplant recipients. Studies that have examined physical activity and sedentary time prevalence among kidney transplant recipients have used self-reported assessment tools, which may result in biased reporting. A better understanding of physical activity and sedentary patterns among transplant recipients is needed for the optimal design of targeted interventions. **PURPOSE:** To objectively assess physical activity and sedentary time profiles among kidney transplant recipients, and examine possible demographic and clinical correlates of physical activity and sedentary time. **METHODS:** Transplant recipients (diagnosed between 1993-2016) were recruited from the Northern Alberta Renal Program's Nephrology Information System database. Participants (N=133; 11% response rate) wore an Actigraph® GT3X+ accelerometer on their hip during waking hours for seven consecutive days. Commonly accepted activity count cutoffs (Freedson) were used to differentiate between sedentary, light, and moderate-to-vigorous intensity physical activity (MVPA). Accelerometer data were processed in 60-second epochs. **RESULTS:** Participants' average age was 58.4 years (SD=14.7), 57% were female, and the average duration since transplant was 27.2 months (SD=21.5). Participants wore their accelerometer for 6.5 days (SD=6.5). Participants recorded 9.4 (SD=4.1) hours per day of total sedentary time and averaged 3.7 bouts (SD=1.7) of sedentary time per day accumulated in at least 30-minute bouts, for a total of 2.9 hours (SD=1.5). For active behaviors, participants recorded 20.7 minutes of total MVPA per day and 5.7 minutes per day of MVPA accumulated in at least 10-minute bouts. Participants <60 years of age reported significantly more minutes of MVPA than participants ≥60 years of age (Mean Δ=15.8 min/day, CI: 9.7 to 22, p<.001). MVPA and sedentary time were not significantly associated with gender, BMI, or months since transplant. **CONCLUSION:** Accelerometer assessment of daily activity patterns indicated kidney transplant recipients showed high volumes of sedentary time, and low volumes of health-enhancing physical activity. Further research on effective interventions to favorably change this ratio and improve health outcomes of these patients is needed.

2896　Board #179　　　June 1 2:00 PM - 3:30 PM

Comparison Of Activpal And Actigraph On Detecting Sitting Vs. Standing In Three Classroom Postures

Saori Braun, Marquell Johnson, Jeffrey Janot, Sarah Reischel, Joshua Stewart, Chelsea Alger, Bo Casper. *University of Wisconsin-Eau Claire, Eau Claire, WI.* (Sponsor: Don Bredle, FACSM)

(No relevant relationships reported)

PURPOSE: In the premise of reducing sedentary behavior as a preventive means to minimizing the risk of developing chronic diseases, efforts have been put forth to modify workplace and classroom setting to be more activity-permissive. In order to monitor postural changes and their impact on health, appropriate selection of monitoring devices becomes critical. The purpose of the study, therefore, was to

examine the accuracy of activPAL and ActiGraph (AG) devices in differentiating sitting on a physio-ball, standing still, and sitting in a chair during a lecture-based classroom setting.
METHODS: A total of 28 males and females, aged 18-25 years, from two classes of the same 50-minute course participated in the study. Each participant wore activPAL3 on non-dominant thigh and AG GT3X-bt on right hip in three conditions, which were randomly ordered: 1) sitting on a physio-ball, 2) standing, or 3) sitting in a chair. For the purpose of standardization of the analyses, the first and the last five minutes were excluded from the analyses, thus, comparison of sitting and standing (min) between activPAL and AG devices was made during the mid-40 minutes of each class.
RESULTS: One participant missed a day of physio-ball, analyses involving values obtained during physio-ball consisted of 27 participants. During physio-ball sitting, activPAL detected the behavior as 38.33 ± 4.40 min of sitting and 1.35 ± 3.56 min of standing, while AG detected the behavior as 14.60 ± 12.97 min of sitting and 25.29 ± 13.02 minutes of standing. During standing, activPAL detected 38.34 ± 7.53 min of standing, while AG detecting 32.13 ± 10.28 min of standing. During sitting in a chair, activPAL measured 39.26 ± 1.44 min of sitting vs. AG measured 17.42 ± 15.50 min of sitting. Paired samples t tests indicated significant differences in sitting on physio-ball, standing, and sitting in a chair between the two devices ($p <. 001$, $p = .020$, and $p < .001$, respectively).
CONCLUSIONS: The activPAL devices were more accurate in identifying the three classroom postures. Further examination of the accuracy of AG worn on other body parts (e.g., wrist and thigh) in differentiating sitting vs. standing in a classroom or occupational setting is warranted.

Sedentary Time And Steps Across Methods For Determining End Of Daytime During 24-hour Activpal Monitoring

Bethany Barone Gibbs, Melissa A. Jones, Tyler D. Quinn, Subashan Perera, Christopher E. Kline. *University of Pittsburgh, Pittsburgh, PA.*
(No relevant relationships reported)

PURPOSE: Best practices to identify daytime end during 24-hour activPAL monitoring are not clear. **METHODS:** This study included 25 overweight/obese adults (64% male, mean (SD) age: 42 (12) yrs) from a randomized crossover study. Posture, activity (activPAL) and sleep (Actiwatch) were monitored for 24 hours on two simulated workdays (with/without use of a sit-stand desk) followed by free-living evening behavior. Average time spent sedentary and steps were calculated using four methods to determine daytime end: 1) criterion method using actigraphy and a standardized scoring algorithm to indicate bedtime, 2) standard 10PM bedtime, 3) participant diary-reported bedtime, or 4) hybrid approach combining activPAL data with participant diary. Validity between criterion and alternative methods was evaluated by calculating average magnitude of error, Pearson's correlations, and Bland-Altman plots. **RESULTS:** Criterion mean (SD, %) sedentary time was 11.5 (1.3, 72.1%) hr/day with 3,106 (1,219) step/day. Absolute estimates of sedentary time differed from criterion by 1.2 hr/day (10%) using a 10PM bedtime, 0.4 hr/day (3%) using the hybrid method, and 0.2 hr/day (2%) using the diary only. When normalized to wear time, sedentary time errors were small (10PM: 1.4%; hybrid: 0.6%; diary: 0.4%). Correlations between alternative and criterion estimates of absolute sedentary time were lowest for the 10PM bedtime (r=0.57, p=0.003), then hybrid (r=0.83, p<0.001), then diary (r=0.97, p<0.001), but all were highly correlated after normalizing for wear time (r≥0.95, p<0.001). Bland-Altman plots showed no pattern of error and limits of agreement (hr/day) that decreased from 10PM (-1.1, 3.3), to hybrid (-1.3, 1.8), to diary (-0.8, 0.5). Differences from criterion steps/day were highest using the 10PM method (329, 11%) and similar for the hybrid or diary methods (39, 1%). Steps were highly correlated comparing all alternative methods to criterion (r≥0.96, p<0.001). **CONCLUSIONS:** Using a standard 10PM bedtime resulted in the highest error in sedentary time and steps, though correlations to the criterion were ≥0.95 for all methods after normalizing to wear time. In this population, using participant diaries is preferred to accurately quantify absolute sedentary time, though all methods were acceptable with wear time normalization.

2898   Board #181   June 1 2:00 PM - 3:30 PM
The Relationship between Cell Phone Use, Physical Activity, and Sedentary Behavior in Adults Aged 18-80

Curtis Fennell[1], Jacob E. Barkley[2], Andrew Lepp[2]. *[1]University of Montevallo, Montevallo, AL. [2]Kent State University, Kent, OH.* (Sponsor: Ellen Glickman, FACSM)
(No relevant relationships reported)

Previous research, using multiple samples of undergraduate college students, suggests cell phone use is primarily a leisure behavior which most often occurs while sitting. This same research has identified a positive relationship between cell phone use and sedentary behavior, but not physical activity. **PURPOSE:** To examine these relationships among individuals older than traditional college students. **METHODS:**

An online survey was completed ($N = 421$; $n = 255$ females, 40 ± 16 years old) which assessed, using validated measures, total cell phone use, situational cell phone use (i.e. is the cell phone being used for leisure or work purposes and while sitting, standing, or during physical activity), sedentary behavior (i.e., sitting time), and physical activity behavior. A tertile split was then performed and participants were placed into the following groups based upon their cell total phone use: *high* ($n = 131$, 474 ± 268 min/d), *moderate* ($n = 138$, 190 ± 36 min/d), or *low* ($n = 152$, 81 ± 33 min/d) users. **RESULTS:** Mean cell phone use for the entire sample was 239 ± 224 min/d. Participants reported that, on average, 61% of their cell phone use was for leisure purposes and 80% of their cell phone use occurs while seated. Linear regression found that cell use was positively associated with sedentary behavior ($\beta = 0.157$, $p = 0.002$), negatively associated with age ($\beta = -0.128$, $p = 0.015$), and not related to physical activity ($\beta = 0.091$, $p = 0.086$) or sex ($\beta = 0.023$, $p = 0.638$). Analysis of variance revealed that the *high* cell phone use group (521 ± 266 min/d sitting) participated in significantly more ($p = 0.006$) sedentary behavior than *low* users (442 ± 214 min/d) with no differences ($p \geq 0.1$) between the *moderate* users (471 ± 253 min/d) and either the *low* or *high* use groups. **CONCLUSION:** Cell phone use in this sample of adults which on average were older than college age was similar to previous studies of college students. Participants reported that cell phones were primarily leisure devices and their use was positively associated with sedentary behavior but not physical activity. Specifically, *high* cell phone users reported 79 min/day or 15% greater sitting than *low* users. These associations were also independent of age and sex within this sample.

Impact Of Sit-stand Workstation Progressions On Stress, Focus, And Productivity In University Staff Members

Mark A. Schafer, K. Jason Crandall, T. Scott Lyons, FACSM, Kolbi Edens, Lydia Blankenship, Nuha Shaker, Robert Vondy. *Western Kentucky University, Bowling Green, KY.* (Sponsor: Scott Lyons, FACSM)
(No relevant relationships reported)

PURPOSE: The purpose of this study was to determine the impact of utilizing sit-stand workstations (Ergotron) throughout the workday on stress, focus, and productivity when following sit-stand progression protocols for 10 weeks. METHODS: Participants (N=60) were randomly assigned to one of three groups. Group 1 and 2 followed a prescribed protocol to progress up to 30 and 20 minutes of standing per hour, respectively. The protocol consisted of reminder emails delivered to participants each hour to reinforce prescribed standing times. Group 3 was instructed to sit and stand according to their preference throughout the day. Stress, focus, and productivity during standing and sitting time were measured using the visual analogue scale (VAS) at the end of each day. Data were analyzed using mixed-designrepeated measures ANOVA with significance set at p < 0.05. RESULTS: For each group, stress was significantly lower and focus and productivity were significantly higher standing compared to sitting (p = 0.01) over the 10 weeks. CONCLUSIONS: The results indicate that there is an increase in focus and productivity, along with reductions in stress, when standing compared to sitting throughout the workday. Furthermore, there was no influence of standing time progression throughout the 10 weeks or total standing time per hour. Future investigations should examine the long-term utilization and compliance of the sit-stand workstations and the potential impact on overall health.

The Physical And Psychological Effects Of Standing Desks In Office Workers

Hannah E. Dohm, Dale D. Brown, FACSM, Kristen M. Lagally, FACSM, Kelly R. Laurson. *Illinois State University, Normal, IL.* (Sponsor: Drs. Dale D. Brown and Kristen M. Lagally, FACSM)
(No relevant relationships reported)

The present study demonstrates differences between energy expenditure in typical office workers and whether or not sit-stand desk options are beneficial. PURPOSE: The purpose of the study was to determine differences in energy expenditure between sitting and standing in typically sedentary office workers. A secondary purpose of this study was to determine mindset differences with regards to job boredom, job stress, and job satisfaction. METHODS: Participants (N = 26, 4 males and 22 females) were from two moderately sized communities in the Midwest that had standing desk options available to them. Data was collected using BodyMedia SenseWear armbands for energy expenditure and self-reported Likert-scale surveys for psychological data. Data was collected during four sessions; two sitting sessions where participants were asked to not use their standing desk option, and two standing sessions where participants were allowed to stand as they desired. Data was analyzed using paired-samples t-tests to determine mean differences between energy expenditure and survey data. RESULTS: Results of the *t*-test for energy expenditure indicated the standing condition expended an average of 7.25 kcal more per hour than the sitting condition (t (24) -3.352, p = 0.003). No differences were found between average total survey data

or specific question survey results (all $p > 0.05$). CONCLUSIONS: The results of this study suggest there is a statistically significant increase in energy expenditure when utilizing a standing desk option at the typical office workstation. Participants expressed improvements in mindset, but this difference was not statistically significant. Overall, individuals that participate in standing throughout the day rather than strictly sitting can increase energy expenditure while at their normal workstation, potentially resulting in increased weight loss and decreased negative health risk factors for typically sedentary office workers.

Effects Of Isotemporal Substitution Of Sedentary Time (total And Prolonged Bouts) On Mental Wellbeing

Jacob Meyer[1], Laura Ellingson, FACSM[1], Matthew Buman, FACSM[2], Robin Shook[3], Gregory Hand, FACSM[4], Steven Blair, FACSM[5]. [1]*Iowa State University, Ames, IA.* [2]*Arizona State University, Tempe, AZ.* [3]*Children's Mercy Hospital, Kansas City, MO.* [4]*West Virginia University, Morgantown, WV.* [5]*University of South Carolina, Columbia, SC.* (Sponsor: Steven Blair, FACSM)
(No relevant relationships reported)

Sedentary time is ubiquitous and inversely associated with health and wellbeing. Full 24-hour objective monitoring is rare, yet necessary, to understand interrelationships between time spent asleep, sedentary and active and their influences on wellbeing. **PURPOSE**: Our purpose was to use isotemporal substitution to examine the effects of replacing sedentary time (total and prolonged (> 30 min) bouts) with shorter sedentary bouts (< 30 mins), activity, or sleep on mood and stress at baseline and changes in mood/stress over one year. **METHODS**: Healthy young adults (age: 20-35; n=423 baseline; n=270 at one year; 48% women) wore a Sensewear Armband (SWA) 24 hours/day for 10 days and completed the Profile of Mood States (POMS) and the Perceived Stress Scale (PSS) at baseline and one year. Minutes spent sedentary, in light activity or MVPA, and sleeping were assessed with the SWA. Isotemporal substitution was performed separately for replacing one hour of a) total sedentary time and b) time in prolonged bouts with one hour of shorter sedentary bouts, light activity (1.5-3.0 METs), MVPA (> 3.0 METs) or sleep, on mood and stress at baseline and changes across one year. **RESULTS**: At baseline: substituting 60 mins into MVPA from total sedentary time (standardized beta [95% CI]; -.107 [-0.199, -0.014]) or time in prolonged bouts (-0.119 [-0.212, -0.025]) improved mood, as did swapping prolonged for shorter bouts (-0.106 [-0.211, 0.000]). Substituting time in prolonged bouts with sleep decreased current stress (-0.132 [-0.255, -0.009]) and improved mood (-0.136 [-0.257, -0.015]). When predicting changes in wellbeing at one year: substituting total sedentary time with light activity improved the change in mood at one year (-.141 [-0.280, -.002]), while substituting prolonged bouts with light activity non-significantly improved changes in mood (-.138 [-0.282, 0.006]). **CONCLUSIONS**: These results suggest that replacing one hour of sedentary time (especially that accumulated in prolonged bouts) with either more sleep or light activity could be effective for improving current and future mental wellbeing in healthy young adults. Longitudinal studies including objective 24-hour monitoring such as this are instrumental for informing future interventions targeting this set of behaviors.

Racial and Ethnic Differences in Time Spent Sitting - The Booster Break Study

Matthew D. Leatherwood[1], Raheem J. Paxton[1], John C. Higginbotham[1], Wendell C. Taylor[2]. [1]*The University of Alabama, Tuscaloosa, AL.* [2]*The University of Texas Health Science Center, Houston, TX.*
(No relevant relationships reported)

PURPOSE: To examine the racial and ethnic differences among various types of sedentary behavior (SB) in a sample of sedentary office workers. **METHODS**: Study participants were recruited from five worksites in a large metropolitan city in the United States (N = 149, 67% minority, 83% female) All participants sat for at least 5-hours during a typical workday. SB was measured using a 7-item modified version of the Sedentary Behavior Questionnaire (SBQ) and the two-item sedentary behavior questions assessed in the International Physical Activity Questionnaire. Racial differences were examined with descriptive statistics as regression models. Statistical significance was determined at p < 0.05 with a two-sided test. **RESULTS**: Sedentary behavior ranged from a median of 0 minutes/day for viewing movies or videos to 60 min/day for watching television and riding in or driving a vehicle. Total median time spent sitting during the weekday was 480 min/day, whereas total time spent sitting during the weekend was 270 min/day. Our adjusted models indicated statistically significant racial and ethnic differences for sitting while talking on the phone (p < 0.001), watching television (p = 0.042), riding in or driving a vehicle (p = 0.027), total sitting time during the weekdays (p = 0.008), and weekend (p = 0.012). Median scores were higher among Blacks than Whites for both sitting and

talking on the phone and while watching television (Blacks = 73 and 131, Whites = 26 and 86 min/day). Total time spent sitting on the weekend was higher among Blacks than both Hispanics and Whites (Blacks = 541, Whites = 346, Hispanics = 306 min/day). However, both Blacks and Whites had higher median minutes spent in total sedentary time during the weekday than Hispanics. **CONCLUSION:** According to these data, racial and ethnic differences exist between various types of SB. Healthcare professionals should consider these differences when designing culturally tailored interventions designed to curve sedentary behavior. Supported by NIH Grants K01CA158000, R03NR010291, and CA016672

Changes In Leisure Sedentary Behavior Across Retirement Transition: Finnish Retirement And Aging Study (FIREA)

Tuija Leskinen[1], Anna Pulakka[1], Olli Heinonen[1], Jaana Pentti[1], Mika Kivimäki[2], Jussi Vahtera[1], Sari Stenholm[1]. [1]*University of Turku, Turku, Finland.* [2]*University of Helsinki, Helsinki, Finland.*
(No relevant relationships reported)

Retirement is a major life transition and it may influence health behaviors and time use. **PURPOSE**: To examine changes in leisure sedentary behavior across retirement transition. In addition, we examined which and how pre-retirement characteristics predicted these changes. **METHODS**: The study population consisted of 1,354 participants from the Finnish Retirement and Aging Study (FIREA). Repeated postal survey including questions on sedentary behavior domains (television viewing, computer use at home, sitting in a vehicle and other sitting) were conducted once a year across retirement transition, covering on average three study waves. **RESULTS**: Total sedentary time increased by 67 (95% CI 58-75) minutes/day during retirement transition and continued to increase by 27 minutes/day two years after retirement transition (period*time interaction p<.0001). Of the domain-specific sedentary behaviors, television viewing time increased by 25 (95% CI 21-29) , computer use at home by 19 (95% CI 16-22), and other sitting time by 36 (95% CI 31-41) minutes/day, while time sitting in a vehicle decreased by 6 (95% CI 3-10) minutes/day during retirement transition. Women (69 vs. 50 minutes/day, sex*time interaction p=0.04) and persons who had high occupational sitting time, sleep difficulties, mental disorders or poor self-reported health before retirement were most likely to increase in sedentary behavior during retirement transition. **CONCLUSIONS**: Total leisure-related sedentary time and especially television viewing time increased across retirement transition. As both total sedentary behavior and television viewing are associated with adverse health outcomes and mortality among older adults, more attention should be paid to reducing time spend on sedentary behaviors among recently retired adults. Supported by Academy of Finland Grants 286294 and 294154, Finnish Ministry of Education and Culture and Juho Vainio Foundation.

Objectively-measured And Self-reported Sedentary Behavior And Its Association With Mental Wellbeing In College Students

Keith M. Thraen-Borowski[1], Alex J. Hofstetter[1], Elizabeth G. Mills[1], Mackenzie R. Anderson[1], Rachel A. Valente[1], Laura D. Ellingson[2], Jacob D. Meyer[2]. [1]*Loras College, Dubuque, IA.* [2]*Iowa State University, Ames, IA.*
(No relevant relationships reported)

Sedentary behavior (SB) is an emerging health risk. While behavior patterns are often established during young adulthood, little is known regarding the accumulation of SB in this population and its association with mental wellbeing.
Purpose: To describe SB patterns in college-aged men and women and to compare objectively-measured SB with self-reported SB and their associations with mental wellbeing.
Methods: Participants were recruited as part of a larger study evaluating feedback mechanisms for lessening SB. Baseline assessments of objectively-measured SB were collected with an inclinometer (activPAL), worn for seven days. Participants subsequently self-reported sedentary time (IPAQ), health-related quality of life (SF-36), and mood (POMS). Descriptive statistics and Pearson's correlation coefficients were used to characterize SB and the cross-sectional relationship between SB and mental wellbeing constructs, including fatigue, pain, anxiety, depression, anger, vigor, and confusion.
Results: Thirty-five participants (age = 19.4 ±1.1 (mean±SD); 64% male) wore the activPAL for 6.9 ± 0.5 days. Per the activPAL, subjects accumulated 602.65 ± 82.4 min/day of sedentary time, with 343.5 ± 77.3 min/day accumulated in bouts of > 30 minutes. They had 48.8 ± 12.8 breaks in SB per day, averaging 5.1 ± 1.4 min/break. Per the IPAQ, SB was significantly lower at 406.59 ± 117.94 min/day (p<0.01). Further, objectively-measured total SB was not significantly correlated with self-reported SB (r= -0.04, p= 0.81), though bouts of SB in > 30 min was (r=0.36, p=0.04). There were no significant differences in objectively-measured SB, number of breaks in

SB, or average break rate by gender or BMI category (p>0.05 for all). SB (objectively-measured or self-reported) was not significantly associated with any of the mental wellbeing outcomes (p>0.05 for all).
Conclusions: College-aged men and women engage in large amounts of SB. The discrepancy between self-report and objective measures suggests they may be unaware of this important health behavior, and may be especially unaware of incidental SB accumulated in shorter bouts. Though SB was unrelated to mental wellbeing in this young healthy population, the development of sedentary habits during young adulthood may be problematic for future health outcomes.

Determinants Of Sedentary Behavior In Adults: Who Is At Risk Of High Sedentary Time?

Esmée A. Bakker[1], Duck-chul Lee, FACSM[2], Maria TE Hopman, FACSM[1], André LM Verbeek[1], Dick HJ Thijssen[3], Thijs MH Eijsvogels[1]. [1]Radboud university medical centre, Nijmegen, Netherlands. [2]Iowa State University, Nijmegen, IA. [3]Liverpool John Moores University, Liverpool, United Kingdom. (Sponsor: Prof. Dr. Maria Hopman, FACSM)

(No relevant relationships reported)

Sedentariness is associated with increased risks for cardiovascular diseases, cancer, type 2 diabetes, and mortality. In order to target sedentary behavior efficiently, we need to identify determinants of sedentary behavior.
PURPOSE: To identify subject- and lifestyle-related determinants for the domains of sedentary behavior (transportation, occupation, leisure-time). **METHODS:** Subject characteristics (age, sex, weight, height, marital status, education level, employment, medical history) and lifestyle factors (sleep, smoking, alcohol consumption, physical activity) were collected via an online questionnaire. Sedentary time was assessed using the Sedentary Behavior Questionnaire and estimated for 9 different activities during weekdays and weekend days. Logistic regression calculated odds ratios and 95% confidence intervals (OR [95% CI]) of being sedentary during transportation, occupation and leisure time dichotomized at the 75th percentile (60 minutes/day, 275 minutes/day and 410 minutes/day, respectively). **RESULTS:** This study included 7,648 participants (median age 55, 55% men). Being sedentary during transportation and work was associated with younger age (0.99 per year [0.98-0.99]; 0.97 per year [0.96-0.97], respectively), men (1.97 [1.76-2.20]; 1.58 [1.41-1.78], respectively) and employment (1.68 [1.45-1.93]; 7.07 [5.54-9.03], respectively). Also BMI was associated with sedentary time (1.05 per kg/m^2 [1.04-1.07]) during transportation. Being sedentary during work was linked with a higher education level (5.29 [3.64-7.67]), and inversely related to former smoking (0.71 [0.54-0.93]) and being a cancer survivor (0.73 [0.56-0.96]). In contrast, higher amounts of sedentary time during leisure-time were associated with older age (1.03 per year [1.02-1.03]), unemployment (1.58 [1.38-1.81]), BMI (1.04 per kg/m^2 [1.02-1.06]), being unmarried (1.36 [1.18-1.56]) and worse health status (1.12 per grade [1.03-1.23]). **CONCLUSION:** Several subject and lifestyle-factors relate to a sedentary lifestyle, but characteristics markedly differ between different domains of sedentary time. Domain specific determinants should be included when designing new interventions to reduce sedentary behavior.

Sedentary Time and Cumulative Risk of Preserved and Reduced Ejection Fraction Heart Failure: MESA

Brandi S. Rariden[1], Michael R. Richardson[1], Tammie M. Johnson[1], Clinton A. Brawner, FACSM[2], Sherry O. Pinkstaff[1], James R. Churilla, FACSM[1]. [1]University of North Florida, Jacksonville, FL. [2]Henry Ford Hospital, Detroit, MI. (Sponsor: James R. Churilla, FACSM)

(No relevant relationships reported)

Purpose: Examine the relationship between self-reported sedentary time and cumulative risk of preserved ejection fraction heart failure (HFpEF) and reduced ejection fraction heart failure (HFrEF) using a diverse cohort of U.S. adults 45-84 years of age. **Methods**: Using data from the Multi-Ethnic Study of Atherosclerosis (MESA), we identified 6,814 subjects (52.9% female). All were free of baseline cardiovascular disease. Cox regression was used to calculate the hazard ratio (HR) associated with baseline sedentary time and risk of HFpEF and HFrEF. Weekly self-reported sedentary time was dichotomized based on the 75th percentile (1,890 min/wk). **Results**: During ~11.2 years of follow-up there were 178 first incident HF diagnoses; 74 HFpEF, 69 HFrEF and 35 with unknown EF. In the age adjusted model, sedentary time >1,890 min/wk was a significant predictor of HFpEF (HR 1.75, p=0.03), but not HFrEF (HR 1.36, p=0.24). The relationship with HFpEF remained significant in separate fully adjusted models including body mass index (HR 1.87, p=0.02) or waist circumference (HR 1.86, p=0.02) while the relationship with HFrEF did not reach statistical significance. These models were also adjusted for physical activity (MET·min·wk^{-1}). **Conclusion**: Sedentary time >1,890 min/wk (~4.5 h/d) is an independent predictor of HFpEF, but not HFrEF.

Sitting Is The New Smoking And Teens Report Doing A Lot Of It

Sarah G. Sanders, Betty J. Skipper, Karen Scherzinger, Elizabeth Yakes Jimenez, Alberta S. Kong. *University of New Mexico, Albuquerque, NM.*

(No relevant relationships reported)

Purpose: Sedentary time has been independently associated with poor chronic disease outcomes in adults, regardless of physical activity level. Thus intervening to decrease sedentary time in adolescents could have important long-term health implications. The aim of this analysis is to assess differences in sedentary time and activities of teens by weight status and sociodemographic factors at baseline of a cluster-randomized, longitudinal study of an intervention for adolescent obesity prevention and management (ACTION PAC). **Methods:** 9th and 10th grade students (n=834) from 8 public high schools in the Southwest completed a physical activity recall during 3 consecutive days (1 weekend day; 2 weekdays) for 30-minute blocks from 5 AM to midnight at baseline. Metabolic equivalents (METs) were assigned based on reported activity and intensity; time blocks with METs ≤ 1.5 were considered sedentary. Electronics-related activities were aggregated as screen-time. Height and weight were collected using standardized methods and sociodemographic information was collected via questionnaire. A multilevel linear regression model was constructed to examine the association of sedentary activities and BMI category (SAS 9.4, PROC MIXED); sex, race/ethnicity, parental education, and household income were assessed as covariates. **Results:** On average, participants were sedentary for 71% of their waking time; 52 participants (6%) reported entire days spent in sedentary activities. Participants in all categories spent most of their sedentary time sitting in class (7.2 blocks/d), followed by screen time (3.7 blocks/d) and car time (2.0 blocks/d). Participants with BMI ≥95th percentile reported more screen time relative to the group with a BMI <85th percentile (4.3 vs. 3.7 blocks/d, p=.048); however, this was attenuated when participant sex was added to the model (p=0.08). Males reported higher mean screen time than females (4.3 vs. 3.2 blocks/d, p<0.0001), with the largest difference in video gaming (1.2 vs 0.2 blocks/d, p<0.0001). **Conclusions:** Teens report large amounts of sedentary time, with no significant differences by weight status. Decreasing sedentary time within the school day and replacing screen time with active endeavors may be an important focus of interventions. Supported by NIH Grant R01HL118734

"Health-enhancing" Breaks From Sitting- Variations By Gender, Age, Adiposity And Diabetes Status

Jennifer Blankenship[1], Elisabeth Winkler[2], Genevieve Healy[2], Neville Owen[3], David Dunstan[3]. [1]University of Colorado Anschutz Medical Campus, Aurora, CO. [2]The University of Queensland, Brisbane, Australia. [3]Baker Heart and Diabetes Institute, Melbourne, Australia.

(No relevant relationships reported)

INTRODUCTION: The most recent American Diabetes Association (ADA) Physical Activity/Exercise position statement included specific guidelines to reduce sitting time and interrupt bouts of sitting at least every 30 minutes with light physical activity. In the experimental evidence underpinning these recommendations, the shortest breaks associated with health enhancement were 5 minutes of standing and 2 minutes of light/moderate ambulation. **PURPOSE:** We quantified the frequency of such health-enhancing breaks (HEBs) from sitting in the free-living environment, and characterized variations by gender, age, adiposity, and diabetes status. **METHODS**: Data were from a subsample of 727 AusDiab study (2011-12) wave 3 participants who wore the activPAL3 device for ≥4 days. A break (any upright event following sitting) was categorized as a HEB if it contained ≥5 minutes upright time (upright HEB) or ≥2 minutes stepping time (ambulatory HEB). Linearized variance estimation corrected for the multistage design and significance was set at p<0.05. **SUMMARY OF RESULTS:** On average (mean ± SD), per day, there were 53.1 ± 14.8 breaks in total, but only 19.7 ± 4.8 HEBs: 18.4 ± 4.5 upright HEBs and 13.6 ± 4.5 ambulatory HEBs, with many HEBs meeting both criteria. Older age, higher BMI and having diabetes were all significantly associated with fewer breaks of all types. After mutual adjustment, these associations remained significant except for the association between total breaks and diabetes, which was heavily attenuated (p=0.573). Women differed significantly from men only in having more upright HEBs; following adjustment, this association was borderline significant (p=0.050). Differences were mostly small-to-moderate (approximately 0.2 to 0.5 SD) with the greatest differences (≥0.5 SD) being for obesity and diabetes status. **DISCUSSION:** These findings in the free-living environment, using accurate accumulation measures, indicate that very few breaks from sitting are HEB; and, that the sociodemographic patterning of HEBs and total breaks were not identical, especially with respect to gender. Notably, while the ADA recommends adults with diabetes break up their sitting time, this population, along with those who were obese, performed the fewest HEBs.

The Effects of 6 weeks of Cissus Quadrangularis Supplementation and High Intensity Exercise Training

Eric E. Noreen, Jaclyn Turet, Daniel Mallozzi. *Gettysburg College, Gettysburg, PA.*
(No relevant relationships reported)

Previous studies have shown that supplementation with Cissus Quadrangularis (CQ) can positively alter body composition in sedentary adults. However, it is unknown if this same effect is observed in active adults. **PURPOSE:** The purpose of this study was to determine the effects of 6 wks of supplementation with CQ on body composition and exercise performance in healthy adults enrolled in a crossfit class. **METHODS:** A total of 18 adults (9 males, 9 females, 40.2±8.3 y; mean±SD) completed this study. All subjects had been enrolled in crossfit classes prior to the study. Baseline body composition was assessed by whole body densitometry using air displacement plethysmography, and exercise performance was assessed using a time to completion 1000 m rowing test and a 3 repetition max for the standing press and back squat. Following baseline testing, subjects were randomly assigned in a double-blind manner into one of two groups: 3.2 g/d of CQ; or 3.2 g/d of a maltodextrin placebo (PL). Subjects consumed half of the daily dose in the morning and half in the evening on an empty stomach. All testing was repeated following 6 wks of treatment. Pre to post differences were analyzed using a treatment by time repeated measures ANOVA. **RESULTS:** After 6 wks of treatment, there were no significant differences observed between the CQ or PL group for change in body weight (CQ= -0.2±0.8 kg, PL= -0.07±1.5 kg, p=0.77), fat mass (CQ= -1.1±0.7 kg, PL= -1.0±1.9 kg, p=0.96), fat free mass (CQ= +0.8±0.7 kg, PL= +0.7±1.5 kg, p=0.89), body fat % (CQ= -1.2±0.7 % body fat, PL= -1.1±1.9 % body fat, p=0.94), 3 rep max back squats (CQ= +16.7±11.5 lbs, PL= +16.7±13.2 lbs, p=1.0), 3 rep standing press (CQ= +8.3±6.1 lbs, PL= +3.30±5.6 lbs, p=0.08), or 1000 m rowing test (CQ= -3.0±6.0s, PL= -3.9±9.3s, p=0.81). **CONCLUSION:** Compared to the placebo, 6wk of supplementation with CQ did not alter the body composition or exercise performance adaptations to crossfit training in experienced crossfitters.

The Effects Of Resveratrol-based Polyphenol Supplementation On Indices Of Exercise-induced Muscle Damage

Samantha Silva, Rachel Wes, Adam Osmond, Edward Jo. *Cal Poly Pomona, Pomona, CA.*
(No relevant relationships reported)

Exercise-induced muscle damage (EIMD) symptoms may be attenuated through dietary polyphenol consumption by reducing acute inflammation and oxidative stress, protein degradation, and soreness. However, it is unclear if long-term supplementation of a multi-ingredient resveratrol-based polyphenolic compound mitigates EIMD symptoms and facilitates performance recovery. **PURPOSE:** To investigate the effects of a resveratrol-based polyphenol supplement on indices of EIMD. **METHODS:** Male and female subjects completed a muscle damaging exercise protocol consisting of eccentric-loaded resistance exercise (ECRE) followed by four weeks of resveratrol-polyphenol (RES) (n=10) or placebo (CTL) (n=12) supplementation. Perceived soreness, pain threshold and tolerance, range of motion, and muscular performance were measured before and 24 and 48 hours after ECRE. **RESULTS:** CTL demonstrated increased resting soreness at 24 (p=0.02) and 48 hours (p=0.03) post-EIMD compared to baseline while RES reported increased soreness at 24 hours post EIMD and by 48 hours soreness level returned to baseline (p=0.0003). CTL and RES demonstrated increased soreness under muscular tension at 24 (p<0.0005) and 48 hours (p=0.01 and p=0.007, respectively) post-EIMD compared to baseline with no significant interaction. CTL exhibited decreased pain threshold from baseline to 24 hours post-EIMD (p=0.03). CTL also displayed decreased pain tolerance in the vastus intermedius from baseline to 24 hours post-EIMD (p=0.03) and the vastus lateralis from baseline to 24 (p=0.003) and 48 hours (p=0.003). There were no significant interactions for pain threshold or pain tolerance for any test site. In terms of lower-body power, CTL showed a significant decrease in mean (p=0.04) and peak power (p=0.04) from baseline to 24 hours post-EIMD. There were no significant changes from baseline to 48 hours post-EIMD for CTL. RES demonstrated no changes from baseline for power at any post-EIMD time point. **CONCLUSION:** Multi-day

supplementation of a resveratrol-based polyphenolic substance may support the attenuation of soreness and recovery of performance following EIMD, however its effects on skeletal muscle tissue healing and regeneration remains unknown.

Dietary Antioxidants-contained Foods Promote Skeletal Muscle Adaptation And Reduce Fatigue Induced By Resistance Training

Aki Kawamura. *Kyoto prefectural university, Kyoto, Japan.*
(No relevant relationships reported)

PURPOSE: To investigate the effects of antioxidants-contained foods on muscle adaptation and fatigue induced by resistance training. Here, we focused on three antioxidants which can promote protein synthesis. **METHODS**: Twenty-six healthy men were divided into control (C) and antioxidant (A) groups. All subjects were performed a resistance training program twice a week for 10 weeks. Salmon flake, vegetable juice, and lingonberry jam which contain astaxanthin, β-carotene, and resveratrol, were provided for the A group. Body composition, nutritional intake, maximal voluntary contraction (MVC), oxygen consumption, subjective fatigue, and serum carbonylated protein were measured in pre- and post-intervention. **RESULTS**: Lean body mass was significantly increased in both groups (p < 0.05). Intakes of astaxanthin, β-carotene, and resveratrol were significantly increased in the A group (p < 0.01). Although MVC (kg) of leg extension was significantly higher in post-intervention (C: 26.2 ± 1.7, A: 31.1 ± 2.1) than in pre-intervention (C: 24.2 ± 2.0, A: 25.3 ± 2.4) (C: p = 0.04, A: p= 0.005) in both groups, the degree of change was higher in the A group (C: 2.0 ± 0.8, A: 5.7 ± 1.5) (p = 0.065). Oxygen consumption (ml/kg/min) was significantly higher in post-intervention (3.6 ± 0.1) than in pre-intervention (3.4 ± 0.1) (p = 0.049) in the A group, but not changed in the C group. The degree of subjective fatigue was significantly lower in post-intervention (2.0 ± 0.4) than in pre-intervention (3.1 ± 0.6) (p = 0.028) in the A group, but not changed in the C group. In addition, serum carbonylated protein (nmol/mg) was significantly lower in post-exercise (0.12 ± 0.01) than in pre-exercise (0.15 ± 0.01) (p = 0.026) in post-intervention of the A group only. **CONCLUSIONS**: Intakes of astaxanthin, β-carotene, and resveratrol may promote resistance training-induced muscle adaptation by reducing fatigue and oxidative stress, leading to higher muscle strength.

Effect of New Zealand Blackcurrant Extract on Substrate Oxidation and Cycling Performance in Normobaric Hypoxia

Mark E. Willems[1], Tim Berendsen[2], Mehmet A. Sahin[3], Stephen D. Myers[1], Sam D. Blacker[1], Matthew D. Cook[1]. *[1]University of Chichester, Chichester, United Kingdom. [2]Maastricht University, Maastricht, Netherlands. [3]Haccettepe University, Ankara, Turkey.*
(No relevant relationships reported)

Blackcurrant is high in anthocyanin content. We have shown enhanced whole-body fat oxidation and increased time trial performance during cycling, in addition to increased femoral artery diameter during an sustained submaximal isometric contraction of the *m.quadriceps* with intake of New Zealand blackcurrant (NZBC) extract in normobaric normoxia (Cook et al., 2015, 2017). The effect of blackcurrant on metabolic and physiological responses and performance during cycling in normobaric hypoxia are not known. **PURPOSE:** To examine the effect of NZBC extract on intensity-dependent physiological and metabolic responses and 16.1-km cycling time trial in trained cyclists in normobaric hypoxia. **METHODS:** The study used a double-blind randomized cross-over design. Eleven healthy men from cycling and triathlon clubs with at least 3 yrs experience and cycling 8-10 hr·wk⁻¹ (age: 38±11 yrs, height: 179±4 cm, body mass: 76±8 kg, $\dot{V}O2max$: 47±5 mL·kg⁻¹·min⁻¹, maximum power: 398±38 W, mean±SD) ingested NZBC extract (600 mg·day⁻¹ containing 220 mg anthocyanins) or placebo (PL) for 7 days (washout 14 days). Participants performed bouts of 10 min at 45, 55 and 65% $\dot{V}O_{2max}$, using indirect calorimetry and blood sampling, followed by a 16.1 km time-trial on a SRM ergometer (SRM International, Germany). Participants were familiarized for the time-trial. All testing took place in a temperature controlled (15°C) normobaric hypoxic chamber set at an altitude of ~2500 m (15% FiO₂) (TIS Services, Medstead, UK) in morning sessions. Data was analysed using paired t-tests. **RESULTS:** At each intensity, NZBC extract had no effect on metabolic and physiological responses (e.g. at 65% $\dot{V}O_{2max}$, heart rate - PL: 133±12, NZBC; 132±12 beats·min⁻¹; fat oxidation - PL: 0.24±0.12, NZBC: 0.20±0.16 g·min⁻¹; carbohydrate oxidation - PL: 2.34±0.42, NZBC: 2.48±0.35 g·min⁻¹; lactate - PL: 1.37±0.45, NZBC: 1.56±0.57 mmol·L⁻¹). No improvements in 16.1 km time-trial performance were observed (PL: 1685±92, NZBC: 1685±99 sec). **CONCLUSION:** Seven day intake of New Zealand blackcurrant extract does not change whole-body fat oxidation and 16.1

km time-trial performance during cycling in normobaric hypoxia. Supplements were provided by Health Currancy Ltd (UK). Blackcurrants New Zealand Inc (NZ) provided funding for conference attendance.

Effects Of Montmorency Tart Cherry (L. Prunus Cerasus) Consumption On Nitric Oxide Biomarkers And Exercise Performance.

Karen M. Keane[1], Stephen J. Bailey[2], Anni Vanhatalo, FACSM[3], Andrew M. Jones, FACSM[3], Glyn Howatson, FACSM[1]. [1]Northumbria University, Newcastle Upon Tyne, United Kingdom. [2]Loughborough University, Loughborough, United Kingdom. [3]University of Exeter, Exeter, United Kingdom. (Sponsor: Professor Glyn Howatson, FACSM)
(No relevant relationships reported)

Montmorency tart cherries contain numerous polyphenols that have been shown to improve blood flow and blood pressure. These effects might be linked to increased nitric oxide (NO) synthesis and contribute to improved exercise performance, but this has yet to be investigated. **PURPOSE**: To investigate the effects of supplementation with Montmorency tart cherry juice (MC) on plasma nitrite concentration ($[NO_2]$), a sensitive NO biomarker, vascular function and exercise performance in trained cyclists. **METHODS**: In a randomized, double blind, placebo-controlled, crossover study, 10 physically active males (mean ± SD age; 28 ± 7 years, stature 1.83 ± 0.06 m, body mass 78.0 ± 8.5 kg and VO_{2peak} 59.0 ± 7.0 ml/kg/min) acutely ingested 30 mL of either MC or Placebo (Pla) and completed a 6 min moderate- and severe-intensity cycling bout 1.5 h post ingestion on two occasions for each experimental condition. The severe-intensity cycling test was continued to exhaustion on one occasion and immediately followed by a 60 s all-out sprint on the other occasion. Blood pressure, pulse wave measures, tissue oxygenation index and plasma $[NO_2]$ were assessed pre and 1.5 h post MC and Pla ingestion. **RESULTS**: Time to exhaustion was not different between conditions (P > 0.05), but peak power over the first 20 s (363 ± 42 vs. 330 ± 26 W) and total work completed during the 60 s all-out sprint (21 ± 3 vs. 19 ± 3 kJ) were 10% higher in the MC trial compared to the Pla trial (P < 0.05). Systolic blood pressure was 5 ± 2 mmHg lower 1.5 h post MC supplementation compared to Pla supplementation (P < 0.05). There were no differences in pulse wave measures, plasma nitrite concentration or tissue oxygenation index between the MC and Pla trials (P > 0.05). **CONCLUSIONS**: These results suggest that acute supplementation with MC can lower blood pressure and improve some aspects of exercise performance, specifically end-sprint performance, in trained endurance cyclists. These data reveal a practical, non-pharmacological, dietary intervention that may have implications for enhancing vascular health and exercise performance in trained cyclists.

2914   Board #197   June 1 3:30 PM - 5:00 PM

Effects Of Blackcurrant Extract On Peripheral Blood Flow And Muscular Endurance

Matthew J. Barnes[1], Blake G. Perry[2], Roger D. Hurst[3], Dominic Lomiwes[3]. [1]Massey University, Palmerston North, New Zealand. [2]Massey University, Wellington, New Zealand. [3]Plant and Food Research, Palmerston North, New Zealand.
(No relevant relationships reported)

The consumption of blackcurrants has previously been shown to increase blood flow to the hands and eyes in humans at rest via vasodilatory mechanisms attributed to polyphenolics. While an increase in blood flow to the hands at rest may have health related benefits, such as improving resting circulation, it is unclear whether there is a benefit during fatiguing exercise. An increase in blood flow to contracting skeletal muscle during exercise may, in theory, delay the onset of fatigue by improving oxygen and nutrient delivery to the muscle while additionally increasing the rate at which metabolic waste products and biochemical agents of fatigue are removed.**PURPOSE**: To investigate the effects of New Zealand blackcurrant extract on peripheral (forearm) blood flow and muscular performance.
METHODS: Ten healthy males participated in two trials during which they ingested either blackcurrant extract (BC), delivering 1.87 mg anthocyanins/kg bodyweight, or a placebo powder (PP) containing equivalent amounts glucose, fructose and sucrose to BC; treatment allocation was randomly allocated in a balanced fashion and participants were blinded to the treatments. Participants sat at rest and measures of forearm blood flow (FBF), using venous occlusion plethysmography, heart rate (HR), systolic (SBP) and diastolic blood pressure (DBP) were made prior to and every 30 min after treatment ingestion, for 2 h. After 2 h participants completed intermittent isometric handgrip exercise to volitional fatigue. Differences within and between trials for all criterion measures were analysed using two-way repeated measures ANOVA. **RESULTS**: A treatment effect (p = 0.014), time effect (p = 0.05) and a treatment x time interaction (p = 0.005) were observed for FBF. FBF decreased over the 2 h period with PP only (90 min = - 35.8 ± 28.8 %, p =0.047; 120 min = - 39.4 ± 29.1 %, p =0.028), no change was observed with BC. HR, SBP and DBP changed over time

(all p < 0.001) however no difference between treatments was found. The number of repetitions completed during hand grip exercise did not differ between treatments (BC = 73.6 ± 28.8 repetitions vs PP = 77.2 ± 44.5 repetitions, p = 0.68).**CONCLUSIONS**: New Zealand blackcurrant extract maintains peripheral blood flow during a period of prolonged sitting, however this effect does not alter fatiguing hand grip performance.

2915   Board #198   June 1 3:30 PM - 5:00 PM

Effects Of Acute Golden Root Extract (rhodiola Rosea) Supplementation On Anaerobic Exercise Capacity

Christopher G. Ballmann, Shelby Maze, Abby Wells, Mallory Marshall, John Petrella, FACSM, Rebecca Rogers. *Samford University, Birmingham, AL.* (Sponsor: John Petrella, FACSM)
(No relevant relationships reported)

PURPOSE: : The purpose of this study was to examine the effects of acute golden root extract (GRE) supplementation on repeated Wingate exercise performance. **METHODS**: College aged female participants (age =19.0 yrs ± 0.63, height= 66.3 in ± 1.8, weight= 152.8 lbs ± 19.9) were recruited for this study. In a within groups counterbalanced study design, participants were supplemented with either 1,500 mg/ day of GRE or placebo (gluten-free cornstarch) for 3 days. Participants also took an additional 500 mg dose of corresponding treatment 30 minutes prior to testing of each trial. During each exercise trial, participants completed 3x 15 second Wingate cycle tests separated by 2 minute recovery periods. Each exercise trial was separated by a 1 week washout period. **RESULTS**: Over the 3x 15 second Wingate cycle tests, mean watts (p= 0.01), mean anaerobic capacity (p=0.025), and total work (p=0.018) were higher in the GRE treatment trial versus placebo. However, mean anaerobic power (p= 0.185), mean peak watts (p= 0.078), and fatigue index (p= 0.186) were unaffected regardless of treatment. **CONCLUSIONS**: This study suggests that acute GRE supplementation improves repeated Wingate performance suggesting a role for GRE as an ergogenic aid.

Nutritional Analysis of Ginger (ZingibreOfficinale) Drink: Potentials for Sport Performance

Muhammed A. Muhammed[1], Olufunmilola L. Dominic[1], Iliasu Y. Seidina[1], Emmanuel O. Sarpong[2], Adetayo E. Talabi[1]. [1]University of Ilorin, Ilorin, Nigeria. [2]University of Education, Winneba, Winneba, Ghana.
(No relevant relationships reported)

PURPOSE:Sport and energy drinks for performance enhancement is a common practice among athletes. These supplements reportedly increases health risks including; dehydration, anxiety, headache, sleep disturbances, caffeine intoxication, withdrawal syndrome, dependence and over working of body systems leading to exploration of alternative traditional herbal supplements like ginger which has both dietary and medicinal values. The purpose of this study is to determine nutritional values of ginger drink and ascertain their potentials for enhancing sport performance. **METHODS**: Experimental research design was adopted to analyse two versions of ginger drinks prepared using ginger rhizomes (Botanical Identification: UIL/001/1083) was obtained from an open market in Ilorin, Nigeria. Ethical clearance was obtained from the University of Ilorin Ethical Review Committee. The ginger rhizomes was used to prepare 2ml/98ml (H2O) and 3ml/97ml (H2O) of ginger concentration. Six samples; (i) 2ml & (ii) 3ml with 1 cube of sugar (1CS) each (iii) 2ml & (iv) 3ml with 2 cubes of sugar (2CS) each (v) 2ml & (vi) 3ml each with no sugar (NS) were prepared and subjected to proximate analysis at the Department of Industrial Chemistry, University of Ilorin, Nigeria. Statistical analysis was descriptive and nutritional components were reported as percentage per 100ml. **RESULTS**: Nutritional values of the ginger drinks were similar; all six samples contained protein, fat, carbohydrate, vitamins and essential minerals; the energyvalue was 168 kj/100ml, which was richer than most energy/sport drinks commonly consumed in Nigeria. These indicated ginger drink might effectively enhance glucose supply for ATP synthesis, delay fatigue, reduce exercise-induced oxidative stress, boost recovery and sport performance. Ginger drink containing 1CS had increased pH/100ml; 3.50% for both 2ml/98ml (H_2O) and 3ml/97ml (H_2O) but ginger drink containing 2CS had the same pH with NS ginger drink; 3.18% for 2ml/98ml (H_2O) and 3.09% for 3ml/97ml (H_2O). **CONCLUSIONS**: Ginger drink is nutritious and might reliably enhance sport performance. Ginger drink with 2CS had less pH implying more potential for sport performance. A follow-up study is ongoing to ascertain the effects of ginger drink on anaerobic and aerobic capacity of athletes.

Abstracts were prepared by the authors and printed as submitted.

The Effect of Curcumin on Inflammation and Exercise Induced Muscle Damage in Healthy Adults

Alexa Gerchman[1], Angela Hillman[2], Erin O'Hora[1]. *[1]Marywood University, Scranton, PA. [2]Ohio University, Athens, OH.*
(No relevant relationships reported)

Curcumin has become a popular nutraceutical product used to decrease inflammation and recently in recovery from exercise. **PURPOSE:** To determine the effect of curcumin on inflammation and exercise induced muscle damage after plyometric exercise. **METHODS:** Participants (n=22; Age: 21.48 ± 1.63 years, Height: 176.37 ± 8.12 cm, Weight: 79.16 ± 11.30 kg) were given either curcumin (500 mg with 95% total curcuminoids) or placebo (maltodextrin) supplements twice daily for 9 days (5 days pre exercise, day of exercise and 3 days post exercise. Participants completed 5 sets of 20 drop jumps on day 6. Blood sampling and recovery tests were assessed at pre-supplementation, 24-hours pre-exercise and 0, 24, 48 and 72-hours post-exercise. Blood markers included creatine kinase (CK) and erythrocyte sedimentation rate (ESR). Muscle damage symptoms were measured via thigh circumference, vertical jump and subjective measurement of pain (VAS) during a squat and a squat jump. **RESULTS:** Both groups experienced symptoms of muscle damage in the 24 hours post exercise with elevated CK (403 ± 390 ul), increased VAS pain scores with squatting (37 ± 30 mm), and pain with squat jump (36 ± 31 mm). Vertical jump also decreased over time in the placebo group (19.8 ± 4.8 inches vs. 21.4 ± 3.2 inches, placebo vs. curcumin; p = 0.01). There was no significant change over time or between groups in thigh circumference. CK was not significantly different between groups despite being ≥200 ul greater 24 hr post exercise in placebo vs. curcumin (528 ± 573 ul vs. 325 ± 178 ul, respectively). ESR was significantly greater immediately post exercise in the placebo vs. curcumin group (6.3 ± 5.6 vs. 3.4 ± 2.6 mm/hr), however these were within the normal range limit for this test. **CONCLUSION:** These data suggest curcumin may aid in pain reduction and potentially inflammation following plyometric exercise. However, future studies need to confirm the efficacy of curcumin for relieving signs and symptoms of exercise-induced muscle damage. Potential targets for future research include dosing protocols and strategies (i.e., daily dosage and required length to provide benefit).

The Effects of Blueberry Supplementation on Exercise-Induced Muscle Damage

Lyndsay J. Lee, Paul C. Miller, FACSM, Takudzwa A. Madzima. *Elon University, Elon, NC.*
(No relevant relationships reported)

Blueberries have been reported to possess several anti-inflammatory properties. Previous studies examining the anti-inflammatory effect of blueberries on acute inflammation caused by exercise-induced muscle damage are largely inconclusive. This may be due to the dose used in these studies not accounting for an individual's lean mass (LM), the compartment directly involved during exercise, when determining appropriate blueberry dosage. **PURPOSE:** To examine the effect of blueberry supplementation (BB) at a dose relative to LM on delayed onset muscle soreness (DOMS) and recovery. **METHODS:** Fourteen recreationally active women (age: 21±1yr; body fat: 24.8±4.5%) participated in this double blind, matched-pairs study. Participants were matched by LM and randomly assigned to either a BB or a placebo (PLA) group. Leg strength was assessed via one-repetition maximum (1RM) on a leg press. Participants consumed a daily dose of freeze-dried BB powder (1.6g BB/kg$_{LM}$) or a PLA (1.6g PLA/kg$_{LM}$) for 7 days prior to induction of DOMS. Participants completed 6 sets of 10 repetitions at 70% 1RM on the leg press to induce DOMS. Perceived soreness (questionnaire), pressure-pain threshold (dolorimeter), and average power (AP; Biodex™) of the right thigh muscles were assessed immediately before (PRE) and after (POST), 24, 48, and 72h post induction of DOMS. Repeated measures ANOVAs were used for analyses. Significance was set at $p<0.05$. **RESULTS:** There were no group x time interactions for perceived soreness, pressure-pain threshold, and AP, however, significant time effects were observed for these variables. When comparing pre to post 24hr ($p<0.001$), 48hr ($p=0.001$), and 72hr ($p=0.011$) perceived soreness of the thigh muscles significantly increased. Pressure-pain threshold of the thigh muscles decreased significantly from pre to post 24hr ($p=0.023$), 48hr ($p=0.001$), and 72hr ($p=0.024$). Isokinetic leg extension AP decreased from pre to post 24hr (BB: 83±17 to 76±22Nm; PLA: 85±21 to 79±26Nm; $p=0.02$). **CONCLUSION:** Consumption of BB for 7 days prior to DOMS induction on a leg press does not affect rating of perceived soreness, pain threshold, nor attenuate decreases in performance compared to a PLA in recreationally active women.

2919   Board #202   June 1 3:30 PM - 5:00 PM

The Effects Of Rhodiola Rosea Supplementation On Time To Fatigue And Recovery After Exercise In Rats

Gerseli Angeli[1], Turibio Barros Neto[1], Donald Kirkendall, FACSM[2]. *[1]São Paulo Federal University, São Paulo, Brazil. [2]Duke University, Durham, NC.* (Sponsor: Donald Kirkendall, FACSM)
(No relevant relationships reported)

Rhodiola rosea is one of the most popular adaptogens claimed to promote physical/cognitive vitality, with ability to reduce the effects of prolonged and minor physical exhaustion that results in fatigue. PURPOSE: To determine the effects of Rhodiola rosea standardized extract supplementation on exercise tolerance and muscular recovery in rats submitted to a 8 weeks swimming training protocol. The study was designed to evaluate the interaction between the Rhodiola rosea supplementation and a physical training program in the variables of the enzymatic adaptations and their gene expressions related to the glycogen resynthesis after exercise. METHODS The study was conducted with 30 rats: Control group (n=10) Exercise group (n=10) and Rhodiola+exercise group (n=10). The training and supplementation protocol consisted in a 8 weeks period. In the Rhodiola+exercise group the animals received 50 mg/kg/day of the product by gavage (intragastric administration). The training protocol consisted in a swimming time of approximately 2h/day 5 days/week. The animals were also submitted to a time to fatigue evaluation test pre and post the 8 weeks program. The analyzed variables were: muscle and hepatic glycogen, gene expression of glycogen synthase and time to fatigue. RESULTS: Post exercise muscular glycogen content was lower in the Rhodiola+Exercise group (0,13±0,01 mg/100mg of tissue) compared with the exercise group (0,64±0,02 mg/100mg of tissue). Post exercise liver glycogen content was also lower in the Rhodiola+Exercise group (0,89±0,01 mg/100mg of tissue) compared with the exercise group (1,77±0,16 mg/100mg of tissue). Gene expression (mRNA) of glycogen synthase was higher in the Rhodiola+Exercise group (1,29±0,43) compared with the exercise group (1,05±0,32). The time to exhaustion was higher in the Rhodiola+Exercise group (93,0±0,34 minutes) compared with the exercise group (71,8±0,43 minutes). CONCLUSION: 8 weeks of Rhodiola rosea supplementation improved the muscle and glycogen mobilization, increasing the time to fatigue. The Rhodiola rosea also increased the gene expression of the glycogen synthase which suggests its benefits on the recovery time after an intense exercise.

Curcuma Longa Extract Reduces Muscle Soreness And Myoglobin Following A Half-marathon: A Double-blind, Placebo-controlled, Randomized

João Felipe Mota[1], Flávia Rasmussen Faria[1], Aline Corado Gomes[1], Kennia Rocha Rezende[1], Gustavo Duarte Pimentel[1], Camila Lemos Pinto[2], Marcelo Saldanha Aoki[3]. *[1]Federal University of Goias, Goiânia, Brazil. [2]University of Alberta, Edmonton, AB, Canada. [3]University of São Paulo, Sao Paulo, Brazil.*
(No relevant relationships reported)

Strenuous exercise result in muscle damage. Oral curcumin appears to reduce pain associated with delayed onset muscle soreness and enhance recovery of muscle performance. **PURPOSE:** The purpose of this study was to examine the chronic effect of curcuma intake after a half-marathon run on indirect markers of muscle damage**. METHODS:** Twenty-eight men completed a double-blind randomized-controlled trial. *Curcuma Longa L.* extract (SG - 1,5g/ day) or placebo (PG - microcrystalline cellulose) was taken twice daily (two capsules during the lunch and one capsule during the dinner) for 4 weeks, then three capsules immediately before the half marathon. Measurements were made at baseline (M0), 20 days after supplementation (M1), immediately before (Pre), after the half marathon (Post), two hours after the half marathon (2 h post), 24 hours after the half marathon (24 h post), and 48 hours after the half marathon (48 h post), comprising: CK, LDH, ALT, AST, myoglobin and muscle soreness. **RESULTS:** SG decreased muscle soreness in palpation of biceps femoris 48-h after half-marathon run (P < 0.05). No difference between groups was observed in ALT, AST, CK, LDH. Myoglobin concentrations were lower after 2 h post competition in SG when compared to PG (62.1 ± 8.26 vs. 107.9 ± 18.5 ng/mL; P < 0.05). **CONCLUSIONS:** Curcuma Longa extract reduces muscle soreness and myoglobin concentration after a half-marathon run. Supported by CNPq Grant 484023/2013-6.

Grain Fermented Beverage Treatment Induces Mitochondrial Biogenesis in C2C12 Myotubes

Tsubasa Shibaguchi[1], Atsushi Tsuji[2], Yuya Yamazaki[2], Keizo Matsui[3], Kazumi Masuda[1]. [1]Kanazawa University, Kanazawa City, Japan. [2]Industrial Research Institute of Ishikawa, Kanazawa City, Japan. [3]Fukumitsuya Sake Brewery, Kanazawa City, Japan.

(No relevant relationships reported)

PURPOSE: Growing evidences indicate that a part of nutrients, such as amino acids and polyphenols, has an ability to induce mitochondrial biogenesis in skeletal muscle. We have recently developed a new grain fermented beverage (GFB) multiply containing carbohydrates, amino acids, citric acid, grain-derived phenolic acids, and so on. However, although we previously reported that post-exercise GFB intake promotes glycogen supercompensation both in skeletal muscle and liver (Shibaguchi et al. 2017), the influence of this drink on mitochondrial biogenesis in skeletal muscle remain unknown. The aim of this study was to investigate the effects of GFB treatment on mitochondrial biogenesis in skeletal muscle cells.
METHODS: Mouse C2C12 myoblasts were grown in Dulbecco's modified Eagle's medium (DMEM) with 10% fetal bovine serum and differentiated in DMEM with 2% calf serum. After 5 days of differentiation, the myotubes were treated with 3% sterilized water (control), 3% glucose solution (149 g/L), or 3% GFB (149 g/L glucose + fructose) containing DMEM with 2% calf serum for 72 h. Protein expression of mitochondrial-related proteins was analyzed by western blotting.
RESULTS: There were no significant differences in the total protein content in differentiated C2C12 cells among three groups. However, only GFB treatment tended to increase the protein level of COX-IV compared with the control (P = 0.07). A similar trend was also observed in VDAC contents, but not significant (P > 0.10).
CONCLUSIONS: Our results suggested that GFB treatment can induce mitochondrial biogenesis in skeletal muscle cells. Further studies are needed to clarify the mechanisms of these phenomena.

A Comparison of Commercially-Available Echinacea Supplements based off Product Label Information

David S. Senchina. *Drake University, Des Moines, IA.*

(No relevant relationships reported)

Echinacea is one of the most popular herbal supplements among athletes, purportedly for preventing or treating upper respiratory infections. **PURPOSE:** To compare the compositions of commercially available Echinacea supplements based off product label information. **METHODS:** Approximately 250 distinct capsules/tablets and tinctures were identified from online vendors or stores in central Iowa; of these, only 76 capsule/tablet supplements and 17 tinctures provided sufficient product information for comparison (species, type of plant material, extraction method, standardization, and amount). Hierarchical clustering analysis ("phenetics") with Ward's linkage was used to generate dendrograms representing major groups ("clades") of supplements. **RESULTS:** Across the 93 included supplements, the most common species was *E. purpurea* (83%), the most common tissue was aboveground parts (62%), and 20% claimed some form of standardization (most used echinacoside). Twenty percent of supplements combined species, and 22% combined plant material types. Within the capsule/tablet category, 68% used raw plant material (versus extraction). Hierarchical clustering analysis revealed that plant material type explained the largest amount of variation: separate dendrograms for both the capsules/tablet and tincture categories depicted two major clades based on whether the supplement was made from aboveground or belowground parts. **DISCUSSION:** Based on label comparisons, Echinacea supplements differed tremendously in composition. Many studies have indicated that products made from belowground parts and *E. angustifolia* may elicit stronger immunomodulatory outcomes than those from aboveground parts and *E. purpurea*, respectively, suggesting that many current commercially-available supplements may not contain the optimal components. Variation in supplement composition likely explains heterogeneous clinical outcomes in athletes.

Effects of Microencapsulated Diindolylmethane on Resting and Exercise Metabolism in Overweight and Obese College Aged Men

David Bellar[1], Amber Sharp[1], Lawrence Judge[2]. [1]University of Louisiana at Lafayette, Lafayette, LA. [2]Ball State University, Muncie, IN.

(No relevant relationships reported)

DIM is present in cruciferous vegetables and further produced after ingestion of crucifers. DIM has been studied for numerous potential health benefits. **PURPOSE:** The present investigation sought to evaluate the effects of DIM on resting and exercise metabolism, fasted glucose, blood lipids and estrogen metabolites after 7 days of supplementation. **METHODS:** The present investigation was a double-blind, cross-over design. Eight overweight college aged males volunteered to participate (Age: 22±2.9yrs; height: 180.9±7.4; BF%: 34.6±5.8). Participants were given DIM (150mg) or placebo twice daily for seven days before returning to the lab, providing blood and urine samples for analysis, undergoing a resting metabolic rate (RMR) assessment and exercising for 20 minutes at a moderate intensity (50% VO2 peak). Prior to crossing over to the other treatment, subjects had a 7 day washout period. **RESULTS:** Paired samples T-test did not reveal differences for total cholesterol (t=0.49, p=032 DIM 149mg/dL±19.2, placebo 161mg/dL±16.7), triglycerides (t=0.29, p=0.38 DIM 137.6mg/dL±31.2, placebo 149mg/dL±19.5), Fasted Glucose (t=0.03, p=0.55 DIM 101.8mg/dL±6.9, placebo 101.6mg/dL±2.9), RMR (t=0.37, p=0.35 DIM 2756.4 kcal/24hr±226.6, placebo 2796.6 kcal/24hr±161.4). Additionally, there were no significant differences found for exercise respiratory exchange ratio (RER), glucose or lactate between treatments (t<0.86, p>0.36). Urine sample were analyzed for 2-hyrdoxyestrone (2OHE1) and 16 α -hydroxyestrone (16α-OH-E1) levels using a commercially available immunoassay. Analysis of results did not reveal differences for 2OHE1 (F=0.23, p=0.63 DIM 4.58 ng/ml±4.28 vs placebo 3.80 ng/ml±3.18) or 16α-OH-E1 (F=0.001, p=0.93 DIM 13.34 ng/ml±14.24 placebo 13.87 ng/ml±12.83). When examined as a ratio 2OHE1/16α-OH-E1 Anova did reveal a significant increase associated with DIM ingestion (F=2.28, p=0.04, ES=0.67). **CONCLUSION:** Based upon the data from the present study supplemental DIM does not appear to alter metabolism at rest or exercise in overweight young men. The higher 2OHE1 to 16-OH-E1 warrants further investigation as this ratio has been associated with positive health outcomes.

Curcumin Supplementation Decreases Homocysteine and Increases HDL in Young, Obese Men

Marilyn S. Campbell[1], An Ouyang[1], Richard J. Charnigo[1], Philip M. Westgate[1], I. M. Krishnakumar[2], Bradley S. Fleenor[3]. [1]University of Kentucky, Lexington, KY. [2]Akay Flavours & Aromatics Pvt., Ltd., Cochin, India. [3]Ball State University, Muncie, IN.

Reported Relationships: M.S. Campbell: *Contracted Research - Including Principle Investigator; Akay Flavours and Aromatics, Ltd..*

Obesity increases cardiovascular disease risk and is associated with generalized metabolic dysfunction that may contribute to vascular endothelial dysfunction. Curcumin, an active component of the Asian-Indian spice turmeric, is known to improve vascular function in various populations, but the effects of this constituent are largely unknown in young, obese individuals. **PURPOSE:** To determine if 12 weeks of curcumin supplementation in young, apparently-healthy obese men would improve resting serum homocysteine, cholesterol, glucose, and insulin values that would be associated with improvements in endothelial function. **METHODS:** Twenty-two young (26.27 ± 4.18 years), obese (BMI = 33.20 ± 3.42 kg/m²) men were matched based on BMI and randomized into the intervention (curcumin formulated with fenugreek soluble dietary fiber) or placebo (fenugreek soluble fiber only) group for 12 weeks. Pre- and post-intervention blood was collected by venipuncture, and endothelial function was assessed with the Endo-PAT 2000 via the reactive hyperemia index (RHI). Enzyme-linked immunosorbent assays were used to assess homocysteine, high-density lipoprotein (HDL), low-density lipoprotein (LDL)/very low-density lipoprotein (VLDL), glucose, and insulin. A multilevel linear regression model with random effects and an unstructured covariance matrix was employed to analyze treatment effect over the 12-week study with the Kenward and Rogers degrees of freedom method. **RESULTS:** Compared with placebo, the 12-week curcumin intervention reduced homocysteine levels (-26.7 v. +17.6, P = 0.038, group by time interaction) and increased HDL levels (+15.2 v. -17.4, P = 0.047, group by time interaction). The changes from baseline to 12 weeks in low-density lipoprotein (LDL)/very low-density lipoprotein (VLDL), glucose, and insulin were not significantly different between groups (P > 0.05). There was also no significant difference between groups on the change in RHI from baseline to 12 weeks (-0.06 v. -1.18, P = 0.667). **CONCLUSION:** Enhanced bioavailable curcumin may be an effective strategy to improve homocysteine and HDL levels in young apparently-healthy obese men that, in turn, may reduce future CVD risk.

Abstracts were prepared by the authors and printed as submitted.

Bitter Melon Intake Versus Exercise For Postprandial Glucose Among Patients With Type 2 Diabetes

Tongyu Ma, Chong-Do Lee, FACSM. *Arizona State University, Phoenix, AZ.*

(No relevant relationships reported)

Although exercise has been shown as effective in lowering postprandial hyperglycemia in patients with type 2 diabetes, alternative approaches for those patients who face substantial barriers to physical activity remain less explored.
PURPOSE: The aim of this study is to compare the effects of bitter melon intake versus exercise on postprandial glucose responses in type 2 diabetic patients who receive hypoglycemic agents. .
METHODS: Using a 2 x 2 randomized cross-over design, a total of 8 patients with type 2 diabetes were randomly assigned to two sequences of treatments, including 1) 100 ml of bitter melon juice administered 15 minutes prior to the 75-g oral glucose load; 2) 30 minutes of moderate-intensity walking performed 15 minutes after the oral glucose load. All participants completed 2-hour oral glucose tolerance test after bitter melon or exercise interventions. Linear mixed models were used to test the effects of treatment, time, and treatment x time interaction on postprandial glucose values after adjustment for covariates. General linear model was used to test incremental area under curve (iAUC) difference between bitter melon and exercise groups after adjustment for covariates.
RESULTS: The baseline glucose levels between bitter melon and waking conditions were similar (6.6 ± 0.9 vs. 6.8 ± 0.7 mmol/L, P=0.57). There were no statistical differences for the mean glucose during the 2-h postprandial period (13.7 ± 2.8 vs. 13.0 ± 2.4 mmol/L, P=.56) and 2-h postprandial glucose iAUC (12.6 ± 4.8 vs. 10.7 ± 3.6 mmol/L·h, P=0.38) between the bitter melon and walking conditions. There was no treatment x time interaction on glucose values (P=0.56). When comparing the glucose levels between the two conditions at each time point, there was also no statistical difference in glucose values at 30 minutes (12.4 ± 2.1 vs 10.5 ± 2.1 mmol/L, P=0.086), at 60 minutes (14.5 ± 2.8 vs 13.6 ± 2.7 mmol/L, P=0.56), 90 minutes (14.7 ± 3.7 vs 14.4 ± 3.3 mmol/L, P=0.88), or 120 minutes (13.5 ± 4.6 vs 13.4 ± 3.9 mmol/L, P=0.95), respectively, between bitter melon and waking conditions.
CONCLUSIONS: Our findings suggest that, among patients with type 2 diabetes, the intake of 100 ml of bitter melon juice can elicit similar postprandial glucose responses, as compared with performing 30 minutes of walking at moderate-intensity.

Curcumin Supplementation Mitigates NASH Development and Progression in Female Wistar Rats

Mary Moore[1], Rory Cunningham[1], Angelique N. Moore[2], James C. Healy[2], Michael D. Roberts[2], Scott Rector, FACSM[1], Jeffrey S. Martin[2]. *[1]The University of Missouri & Truman VA, Columbia, MO. [2]Auburn University, Auburn, AL.* (Sponsor: Scott Rector, FACSM)

(No relevant relationships reported)

PURPOSE: Nonalcoholic steatohepatitis (NASH) is independently associated with mortality risk and currently there are no proven pharmacological therapies for treatment. Limited existing evidence suggests that curcumin, a naturally occurring plant polyphenolic compound known to exert anti-inflammatory and antioxidant effects, may have beneficial effects on attenuating NASH development. Here we sought to determine whether curcumin supplementation could be used in both the prevention and treatment of NASH with fibrosis.
METHODS: Female Wistar rats (N=48) were fed a 'western diet' (WD) high in fat (43% kcal) and cholesterol, and administered CC14 injections (0.5 mL/kg) at weeks 1, 2, 4 and 6 to induce a NASH with fibrosis phenotype. Rats were randomized to 4 groups (n=12/group): Fed WD for 8 weeks (WD8), fed WD enriched with curcumin (WD8+C; 0.2% curcumin, BCM-95, Dolcas Biotech), fed WD for 12 weeks (WD12) or fed WD for 8 weeks followed by 4 weeks WD+C (WD12+C).
RESULTS: Dietary curcumin supplementation (WD+8C) significantly attenuated (p<0.05) histological liver inflammation, molecular markers of fibrosis (Col1a1 mRNA) and serum markers of liver injury (AST) compared with WD8. In addition, curcumin supplementation (WD12+C) also partially reversed WD+CCl4 induced NASH, including reduced (p<0.05) hepatocellular inflammation, steatosis and NAFLD Activity Scores (NAS) compared with WD12. Furthermore, 4 weeks of curcumin supplementation also reduced molecular markers of hepatic fibrosis (Col1a1 mRNA) and inflammation (TNF-α, FABP4, SPP1 mRNA), as well as serum measures of macrophage infiltration (CCL5, IL-17a) and liver injury (AST, ALP). These witnessed changes were independent of differences in body mass or adiposity and were not related to changes in markers of hepatic total macrophages/Kupffer cells (F480, CD68).
CONCLUSIONS: Here we report that curcumin supplementation was partially effective at both preventing and also treating NASH in WD+CC14 challenged Wistar rats. These beneficial effects were more prominent in the reversal of NASH with

fibrosis and was particularly effective in attenuating hepatocellular inflammation. Further study is warranted to examine the anti-inflammatory properties of curcumin in the treatment of NASH.

Effects of Aerobic Training and Pomegranate Juice on Oxidative Stress Markers in Women with Type-II Diabetes

Majid S. Koozehchian[1], Ahmad Abdi[2], Javad Mehrabani[3], Maryam Kaveh B[4], Amin Daneshfar[5], Gholamali Owlia[6], Jeff Chandler[1]. *[1]Jacksonville State University, Jacksonville, AL. [2]Azad University, Amol, Iran, Islamic Republic of. [3]University of Guilan, Rasht, Iran, Islamic Republic of. [4]Karnataka College of Pharmacy, Bangalore, India. [5]University of Canterbury, Christchurch, New Zealand. [6]Texas Southern University, Houston, TX.*

(No relevant relationships reported)

PURPOSE: The aim of this study was to examine the effects of long-term aerobic exercise training and ingesting pomegranate juice on selected plasma oxidative stress markers in middle-aged women with type II diabetes.
METHODS: In a randomized, placebo-controlled design, 33 female participants (age= 52 ± 2 y; stature= 157 ± 6 cm; body mass= 69.9 ± 11.3 kg; body mass index= 27.8 ± 3.29 kg/m²; Control [CON] n=7, supplement [SUP] n=9, aerobic training [AT] n=9, supplement-aerobic training n=8 [SAT]) participated in the study. Primary outcomes were total antioxidant capacity (TAC), superoxide dismutase (SOD), glutathione (GSH), and glutathione peroxidase (GPx) which were measured at baseline and at week 6. All participants were asked to maintain their normal dietary intake during the study period. Participants in both AT and SAT groups were required to follow six weeks of aerobic exercise training program, three sessions a week for at least 45 min per session. Those involved in the SUP and SAT groups had a daily oral ingestion of pomegranate juice (150 ml) for a 6-weeks period [SUP, evening; SAT, an hour after exercise]. The CON group did not receive any intervention. Data were analyzed by GLM and presented as mean (SD).
RESULTS: We observed a significant increase in plasma TAC and GPx only in SAT (p=0.001). There was a significant increase in plasma SOD in the SUP, AT, and SAT, but not in the CON (p=0.001). There was a significant improvement in plasma GSH in the SAT compared to the CON and SUP (0.034).
CONCLUSIONS: Our results indicate that combining aerobic exercise training and pomegranate juice supplementation can have beneficial impact on the antioxidant defense system of the body and reduce oxidative stress in middle-aged women with type-II diabetes.

Allyl Isothiocyanate Enhances Brain Neuronal Plasticity Proteins Via Inhibition Of Inflammation Proteins

Vijaya Juturu[1], Berrak Caglayan[2], Ertugrul Kilic[2], Arman Dalay[2], Mehmet Tuzcu[3], Fusun Erten[3], Mehmet Yalcin Gunal[2], Serdar Altunay[2], Cemal Orhan[3], Kazım Sahin[3]. *[1]OmniActive Health Technologies Inc, Morristown, NJ. [2]Istanbul Medipol University, Istanbul, Turkey. [3]Firat University, Elazig, Turkey.*

Reported Relationships: V. Juturu: *Salary; Employee.*

Background: Oxidative stress caused by the overproduction of reactive oxygen species (ROS) is considered to be responsible for the detrimental effects of traumatic brain injury (TBI), such as disruption of the membrane phospholipid architecture, DNA damage or dysfunction of brain-derived neurotrophic factor (BDNF). The objective of this study was to investigate whether allyl isothiocyanate (AITC) reduce inflammatory mediator levels, serum immunoglobulin G marker for blood-brain barrier and reduces edema and infarction progression in brain.**Purpose:** We hypothesized that treatment of TBI with the antioxidant molecule, allyl isothiocyanate (AITC) in mustard oil, could provide beneficial health outcomes by alleviating the damage caused by ROS in the brain. **Methods:** We induced TBI in male Balb/c mice using a liquid nitrogen-cooled copper probe for 60 seconds and immediately after the cold injury-induced trauma, animals were treated with either vehicle control or AITC (10 mg/kg, ActivAIT). Twenty-four hours after the injury, animals were sacrificed and tissues were collected. The volume of injury which was calculated from the cresyl violet stained coronal brain sections was significantly lower in the AITC group. BBB integrity was evaluated by serum IgG. **Results:** AITC significantly increased protein expressions of brain neuronal plasticity marker proteins; GAP-43, NCAM, Nrf2 and BDNF. Moreover, expressions of inflammation-related proteins; NF-kB, IL1B and IL6 and glial scar marker, GFAP, were significantly reduced in the AITC-treated group, suggesting a protective role of AITC in the neuro-inflammation processes. **Conclusion**: In conclusion, our results demonstrate that the antioxidant molecule AITC when

applied immediately after the TBI in mice, provides beneficial effects on inflammatory processes, while promoting the expressions of plasticity proteins and therefore, could be a candidate molecule for future clinical studies in human patients.

Carbohydrate Mouth Rinse Improves Peak Treadmill Speed and Time to Exhaustion in Overweight Adults

Moath F. Bataineh[1], Ayesha S. Al Dhaheri[2]. [1]*Hashemite University, Zarqa, Jordan.* [2]*United Arab Emirates University, Al Ain, United Arab Emirates.*

(No relevant relationships reported)

Mouth rinsing a carbohydrate solution improves exercise performance in athletes, but whether it benefits exercise performance in overweight adults is unknown. **PURPOSE:** This study determined the effect of carbohydrate mouth rinse on running performance and energy intake in overweight participants. **METHODS:** In a counterbalanced and placebo controlled design, 21 males (Age: 21.0 ± 1.8; BMI: 27.6 ± 1.1) with depleted glycogen stores, completed a graded treadmill exercise test to exhaustion following a 10-s mouth rinse with a solution of either 7.5% carbohydrate (CHO), placebo (PLA), or a no rinse (CON), followed by standardized meal. Anthropometrics, 24-hour energy intake, heart rate (HR), oxygen consumption (VO2), and rating of perceived exertion (RPE) were measured. **RESULTS:** All participants completed the trials. Mean time to exhaustion in seconds per treatment was greater for CHO (1048.7 ± 91.8) versus PLA (1034.4 ± 83.6, p = 0.02), and CON (1012.2 ± 75.7, p = 0.001) ($p\eta^2 = 0.430$). Peak treadmill speed (km/h) was greater for CHO (11.5 ± 0.8) versus PLA (11.3 ± 0.7, p = 0.011), and CON (11.2 ± 0.6, p = 0.003) ($p\eta^2 = 0.354$). Subsequent trial energy intake (Kcal) was lower for CHO (577.5 ± 50.5) versus PLA (622.8 ± 78.3, p < 0.0001), and CON (615.2 ± 69.4, p < 0.0001) ($p\eta^2 = 0.530$). The 24-hour energy intake, HR, VO2 and RPE did not change (P > 0.05). **CONCLUSION:** Carbohydrate mouth rinse improves both running duration and speed in overweight adults with depleted glycogen stores.

Short-term DHEA Intake And Hormonal Responses In Young Recreationally Trained Athletes

Katia Collomp[1], Corinne Buisson[2], Nicolas Gravisse[1], Soraya Belgherbi[1], Zakaria Labsy[3], Manh-Cuong Do[3], Olivier Gagey[3], Sophie Dufay[4], Nancy Vibarel-Rebot[1], Michel Audran[2]. [1]*University of Orleans, Orléans, France.* [2]*AFLD, Chatenay-Malabry, France.* [3]*University of Paris Sud, Orsay, France.* [4]*AGEPS, Paris, France.*

(No relevant relationships reported)

PURPOSE: Dehydroepiandrosterone (DHEA) figures on the World Anti-Doping Agency (WADA) list of prohibited substances in sport because it is assumed that athletes expect a significant increase in testosterone through DHEA administration. The literature on the hormonal effects of DHEA intake nevertheless appears to be very scant in healthy young subjects, especially women. We therefore propose to examine the effects of DHEA on adrenal and gonadal hormones in healthy young male and female recreationally trained volunteers.
METHODS: The study followed a double-blind, randomized-order crossover design. Lean healthy young men (n=10) and women (n=11), with all women using oral contraceptives, were treated daily with 100 mg of DHEA and placebo for 4 weeks. DHEA, DHEA-sulfate (DHEA-S), androstenedione, total testosterone (Tes), free testosterone (fTes), dihydrotestosterone (DHT), SHBG, estrone, and cortisol were measured before, in the middle and at the end of each treatment, as were blood glucose, liver transaminases and lipid status.
RESULTS: As classically reported, the young male volunteers had significantly higher basal Tes, fTes, DHT (p<0.01) concentrations and a significantly lower SHBG concentration (p<0.05) than the young female volunteers before treatment. Women had higher cortisol and cholesterol values (p<0.05) than men. No significant change was observed for the other parameters. In the middle and at the end of DHEA treatment, we observed a significant increase in DHEA, DHEA-S, androstenedione, Tes, fTes, DHT and estrone in both men and women, but the increases in Tes and fTest were more marked in women (p<0.001) than men (p<0.05). No changes were found in the other parameters, irrespective of gender.

CONCLUSION: In young athletes, DHEA administration induces significant blood hormonal changes, some modulated by gender, which can be used as biomarkers of doping.

2931   Board #214   June 1 3:30 PM - 5:00 PM

Neuroprotective Effect of Omega-3 Fatty Acids on Head Trauma in American Football Athletes

K. Michele Kirk[1], David A. Gable[1], Jason D. Stone[1], Anthony J. Anzalone[1], Stephanie M. Turner[1], Andy T. Asko[1], Joel A. Luedke[2], Andrew Jagim[3], Margaret T. Jones, FACSM[4], Jonathan M. Oliver[1]. [1]*Texas Christian University, Fort Worth, TX.* [2]*University of Wisconsin - La Crosse, La Crosse, TX.* [3]*Lindenwood University, St. Charles, MO.* [4]*George Mason University, Fairfax, VA.* (Sponsor: Margaret Jones, FACSM)

(No relevant relationships reported)

Repetitive head impacts sustained over the course of an American football season, even in the absence of a concussion diagnosis, results in a quantifiable pathophysiological response. Further, long-term exposure to repetitive head impacts may lead to neurological impairment, including the development of neurodegenerative disease. Prophylactic treatment with the omega 3 fatty acids (n-3FA) eicosapentaenoic (EPA) and docosahexaenoic (DHA) attenuates the pathophysiological response to head trauma in rodent models. **PURPOSE:** The purpose of this study was to examine the effect of n-3FA supplementation on a blood biomarker of head trauma over the course of an American football season. **METHODS**: Two National Collegiate Athletic Association American football teams volunteered for the study. Thirty-one athletes (n = 31) on one team ingested a highly bioavailable, proprietary formulation (Mindset®), containing n-3FA, including DHA (2,000 mg), EPA (560 mg), and 320mg docosapentaenoic acid (MS- Ω), over the course of an entire season. Thirty-three athletes (n = 33) from the other team served as the control. Neurofilament light (Nf-L), a biomarker of axonal injury, was measured in blood samples obtained prior to the start of the season (T1), at the end of pre-season camp (T2), and over the course of the season (T3 - T6). Standardized magnitude based inference was used to define outcomes of interest. **RESULTS:** Relative to the control group (12.4 ± 5.3 pg•mL⁻¹), MS-Ω very likely attenuated Nf-L measured at the conclusion of Fall camp (8.9 ± 4.5 pg•mL⁻¹) (mean; ×/÷90% confidence limits; 1.5; ×/÷1.2 fold), a period of significant contact. Further, the attenuation relative to placebo was likely maintained at T3 (1.3; ×/÷1.2 fold), T4 (1.3; ×/÷1.2 fold), T5 (1.3; ×/÷1.3 fold), and T6 (1.2; ×/÷1.3 fold) corresponding to sampling time points during the competitive season. **CONCLUSION:** These data indicate that over the course of the season the head trauma sustained by American football athletes does result in a quantifiable pathophysiological response as measured by a biomarker of axonal injury. Further, administration of MS-Ω may impart neuroprotective qualities as evidenced by lower levels of Nf-L.

A Pre-Workout Supplement Does Not Improve 400 M Sprint Running or Bicycle Wingate Test Performance in Recreationally Trained Individuals

Gregory A. Brown, FACSM[1], Brianna Jackson[2], Brian Szekely[3], Trevor Schramm[4], Brandon S. Shaw[5], Ina Shaw[5]. [1]*the University of Nebraska at Kearney, Kearney, NE.* [2]*AT Sill University, Mesa, AZ.* [3]*Georgia Southern University, Statesboro, GA.* [4]*Southern College of Optometry, Memphis, TN.* [5]*University of Zululand, Kwazulu-Natal, South Africa.*

(No relevant relationships reported)

Pre-workout supplements are often consumed as a drink and are purported to delay the onset of fatigue, increase exercise performance, and are marketed to recreational and competitive athletes. Pre-workout supplements typically contain caffeine and other ingredients that are supposed to act as stimulants. However, previous research has been inconclusive on the effects of pre-workout nutritional supplements on exercise performance. **PURPOSE:** The purpose of this project was to evaluate the effects of a commonly used pre-workout supplement on 400 m sprint running and bicycle ergometer Wingate test performance in recreationally trained college age participants. **METHODS**: For the Wingate testing, 60 minutes after consuming a pre-workout supplement or a similarly flavoured placebo eight recreationally trained college aged males engaged in a 30-second bicycle Wingate ergometer test. For the 400 m sprint running, 60 minutes after consuming a pre-workout supplement or a similarly flavoured placebo 16 college aged participants (9 male and 7 female) engaged in two 400 m running sprints on an indoor track with the sprints separated by 10 minutes of passive rest. **RESULTS**: During the Wingate testing there were no differences in peak power (848.85 ± 210.26 W, 866.92 ± 212.99 W), decline in power (48.6 ± 12.2%, 45.0 ± 11.3%), or change in blood lactate concentrations (8.9 ± 5.4 mmol/L, $8.4 \pm$

Abstracts were prepared by the authors and printed as submitted.

4.3 mmol/L) between the placebo and pre-workout, respectively. During the 400 m sprint running, there were no differences in time for the first (78.1 ± 16.1 sec, 80.0 ± 15.0 sec) or second (79.8 ± 13.8 sec, 80.0 ± 14.2 sec) trials for men between the placebo and pre-workout, respectively. During the 400 m sprint running, there were no differences in time for the first (97.3 ± 11.0 sec, 93.9 ± 10.4 sec) or second (96.4 ± 11.5 sec, 95.1 ± 12.4 sec) trials for women between the placebo and pre-workout, respectively. **CONCLUSION**: In spite of containing ~120 mg of caffeine and other purported stimulants, the present data indicate that consuming a common pre-workout supplement does not improve 400 m sprint running or bicycle Wingate test performance, or alter glycolytic metabolism, in recreationally trained individuals. The lack of ergogenic effect could be due to insufficient caffeine content combined with lack of stimulatory effects from the other ingredients.

2933   Board #216   June 1 3:30 PM - 5:00 PM

Acute Effects Of A Multi-ingredient Pre-workout Supplement On 5-km Running Performance In Recreationally-trained Athletes

Taylor Musgjerd[1], Nora Johnston[2], Andrew Jagim[3], Clayton Camic[4]. [1]University of Wisconsin-La Crosse, La Crosse, WI. [2]University of Northern Colorado, Greeley, CO. [3]Lindenwood University, St. Charles, MO. [4]Northern Illinois University, DeKalb, IL. (Sponsor: John Porcari, FACSM)
(No relevant relationships reported)

PURPOSE: The purpose of the present study was to examine the effects of an acute dose of a multi-ingredient, thermogenic, pre-workout supplement on 5-km running performance and subjective measures of fatigue.
METHODS: Twenty aerobically-trained, college-aged males (n = 10, mean ± SD = 80.8 ± 6.1 kg) and females (n = 10, 64.5 ± 6.6 kg) completed two 5-km running races for time. During the first session, the subjects were randomly assigned to ingest the supplement or placebo 30 minutes prior to running a 5-km run as fast as possible. The supplement contained multiple ingredients including caffeine anhydrous (150 mg), beta alanine (1.6 g), arginine AKG (1.0 g), as well as tyrosine, L-carnitine, green coffee bean extract, and velvet bean extract at unspecified quantities. The placebo was a non-caloric mix that was matched for flavor and consistency. Subjects also completed a 5-point Likert scale (1 = low, 5 = high) questionnaire to determine feelings of fatigue immediately prior to ingesting the substance (baseline), 30 minutes post-ingestion (immediately pre-race), and 5 minutes post-race. For the second session, subjects ingested the opposite substance (supplement or placebo) and underwent the same testing procedures (including time of day) as the first session. Race times were compared between the supplement and placebo conditions using a paired-samples *t*-test. In addition, a two-way ANOVA with repeated measures was used to compare the feelings of fatigue among the conditions (supplement vs. placebo) at the common time points (baseline, pre-race, post-race).
RESULTS: The results indicated there was no significant ($P > 0.05$) difference in 5-km race time between the supplement (23.62 ± 2.08 min) and placebo (23.51 ± 1.97 min) conditions. For the feelings of fatigue, there was no significant condition x time interaction or main effect for condition, but there was a main effect for time. Specifically, the marginal means (collapsed across conditions) for fatigue were significantly ($P < 0.05$) greater post-race (3.3 ± 0.8) than at baseline (2.3 ± 0.7) and pre-race (2.4 ± 0.6).
CONCLUSIONS: The findings of the present investigation indicated that the pre-workout supplement provided no ergogenic effect on 5-km race time or feelings of fatigue when administered on an acute basis in recreationally-active males and females.

2934   Board #217   June 1 3:30 PM - 5:00 PM

Effects of Multi-Ingredient Ergogenic Supplement Consumption on Performance Adaptations to High-Volume Resistance Training

Michael Wong, Dean Directo, Adam Osmond, Edward Jo. *Cal Poly Pomona, Pomona, CA.*
(No relevant relationships reported)

Consumption of various nutritive supplements in isolation have shown to enhance resistance training (RT) adaptations. What remains unclear is the efficacy by which consumption of a multi-ingredient ergogenic supplement (MIES) comprised of branched-chain amino acids, beta-alanine, creatine, glutamine, and black pepper fruit extract facilitates improvements in skeletal muscle performance during RT. PURPOSE: To investigate the effects of a MIES containing the above ingredients on performance adaptations to high-volume periodized RT. METHODS: Thirty-nine recreationally trained males and females were recruited for this randomized, double-blind, placebo-controlled investigation. Subjects were assigned to either a placebo (PLA) (n=16) or experimental MIES group (MIES) (n=23) in a randomized, counterbalanced manner. All subjects completed a 6-week periodized resistance training program consisting of 3 sessions per week with 48 hours of rest between each session. MIES and PLA consumed one serving of the MIES and placebo, respectively, immediately post-

workout and before sleep on training days, and two servings during rest days. Subjects underwent laboratory assessments for maximum upper and lower body strength and power. A 2 (group) x 2 (time) repeated measures analysis of variance (ANOVA) was used to detect main effects and/or interaction. A Tukey's post hoc test was used for pairwise comparisons. Significance was set at p<0.05. RESULTS: 1RM for each exercise improved pre-post training in both MIES (Back Squat= +26.0%, p<0.001; Bench Press= +20.4%, p<0.001; Deadlift= +26.3%, p<0.001) and PLA (Back Squat= +27.1%, p<0.001; Bench Press= +15.6%, p<0.001; Deadlift= +18.4%, p<0.001), but no group x time interactions were found. There was also a significant improvement pre-post training for all dynamic lower body power output measures in both groups with no significant group x time interaction. There were no between-group differences for average daily training volume each week and across the entire training period. CONCLUSION: Supplementation of the experimental MIES in conjunction with high-volume RT failed to improve RT-induced performance adaptations when compared to a placebo group.

The Effects Of A Multi-ingredient Ergogenic Supplement On Body Composition Following High-volume Resistance Training

Dean Directo, Michael Wong, Adam Osmond, Edward Jo. *Cal Poly Pomona, Pomona, CA.*
(No relevant relationships reported)

In addition to resistance training (RT) methodology, nutrient intake remains a critical factor for the support of skeletal muscle metabolism, performance, and adaptation. Despite the traditional debate regarding the ideal type, timing, and quality of nutrients for recovery and/or performance, the consumption of exogenous substances like branched-chain amino acids (BCAA), beta-alanine, creatine, glutamine and various plant-based compounds, like piperine have previously shown to support performance, recovery, or metabolic adaptations in skeletal muscle. This has largely enabled the use of multi-ingredient ergogenic supplements (MIES) that incorporate a single blend of these substances with the intent of obtaining a synergistic ergogenic effect. What remains unclear is the efficacy by which a MIES blend of such ingredients facilitates the adaptive changes in body composition during a high-volume RT regimen. PURPOSE: To investigate the effects of a proprietary MIES comprised of BCAA, beta-alanine, creatine hydrochloride, glutamine, and black pepper fruit extract on body composition during 6 weeks of high-volume RT. METHODS: Male and female subjects completed a 6 week RT program 3 days a week with 48 hours of rest between each session. EXP (n=16) and Placebo (PLA) (n=23) groups consumed one serving of the experimental MIES or placebo, respectively immediately post-workout and before sleep on training days, and two servings during rest days. Body composition was measured pre- and post-training via Dual Energy X-Ray Absorptiometry. RESULTS: EXP (+1.7 ± 0.3 kg, p<0.001) and PLA (+1.5 ± 0.2 kg, p<0.001) demonstrated an increase in total body mass. EXP demonstrated a greater increase in lean mass than PLA (EXP= 2.1 ± 0.3 kg vs. PLA= 1.1 ± 0.3 kg) (p=0.03). Fat mass was significantly greater in EXP (-0.4 ± 0.2 kg vs. PLA= +0.4 ± 0.2 kg) (p=0.02). EXP exhibited a decrease in body fat percentage (1.2 ± 0.3 % units) (p=0.01) while PLA showed no change. Post-training body fat percentage was lower in EXP than PLA. There were no between-group differences for average daily training volume each week. CONCLUSION: Supplementation of MIES comprised of BCAA, beta-alanine, creatine hydrochloride, glutamine, and black pepper fruit extract may enhance body composition changes during high-volume RT.

Cannabis Use Habits In Relation To Timing Of Physical Activity

Jonathon K. Lisano, Kristina T. Phillips, Jeremy D. Smith, Laura K. Stewart. *University of Northern Colorado, Greeley, CO.*
(No relevant relationships reported)

PURPOSE: To describe cannabis use in individuals who use the drug relative to when they participate in physical activity (PA). **METHODS**: Physically active individuals (N=72; males n= 42; females n= 30; average age of 27 years), recruited using the snowball technique, completed a series of self-report questions through Qualtrics designed to describe participants use of cannabis products in relation to their PA. Cannabis use questions were based on the Daily Sessions, Frequency, Age of Onset, and Quantity of Cannabis Use Inventory (DFAQ-CU). **RESULTS:** Respondents reported 417 ± 451 minutes of PA per week, with 74.5% of respondents using cannabis in conjunction with PA at least 1-time per week. Cannabis use was reported in combination with a total of 28 different physical activities. The physical activities most commonly reported included hiking, running, resistance training, yoga, and cycling. Half of participants (51%) reported using cannabis within 1-hour of beginning PA, and 45% reported using most often within 1-hour after finishing PA. Only 4% of respondents reported using cannabis most often during PA. Almost half (47%) of participants that reported using cannabis products before PA were using the *Cannabis Sativa* strain, while 39% of respondents that reported using cannabis

after PA used the *Cannabis Indica* strain. Common perceptions of the effects of cannabis use if used before PA included improved focus, "getting into the zone," pain prevention, and increased pleasure. The most frequent reasons for using cannabis products after PA were to relax, aid in recovery, and stimulate appetite. The majority of participants (69%) reported feeling that cannabis products had a positive effect on their performance. Fewer respondents (29%) felt like there was no effect of cannabis on their performance and only 2% of respondents felt that cannabis use had a negative effect on their PA performance. **CONCLUSION:** Findings from this study showed that cannabis is used before, during and after a wide variety of activities. Participants most often used *Cannabis Sativa* before PA and *Cannabis Indica* after PA. Almost all respondents felt that using cannabis products did not negatively affect their performance.

An Examination of Supplement Use in Volunteer Firefighters

Melitza Ramirez[1], Brittany S. Hollerbach, 66502[1], Sara A. Jahnke[2], Christopher M. Kaipust[3], Katie M. Heinrich[1]. *[1]Kansas State University, Manhattan, KS. [2]National Development and Research Institutes, Leawood, KS. [3]University of Texas Houston, Houston, TX.*

(No relevant relationships reported)

Firefighter personnel are trained to respond to emergencies and are essential to community safety. Though dietary supplementation use can improve overall health and performance, limited information exists on supplement use among firefighters. Understanding supplement use may aid in health and physical performance. **PURPOSE**: To explore supplement use in volunteer firefighters. **METHODS**: A national sample of 363 volunteer firefighters (aged 18-77, 38.1 ± 12.5 years, 79.3% male, 95% Caucasian) in a wellness program were surveyed on their frequency and reasons for supplement use over the past six months. Questions asked about supplements such as multivitamins/minerals, individual vitamins (e.g. Vitamin C, Vitamin D), individual minerals (calcium, iron), performance enhancers (glutamine, CoQ10), sports bars/gels, and energy drinks. Stata version 15 was used for data analysis. **RESULTS**: Of those reporting supplement use, 78 reported using only one supplement, while 277 reported using multiple supplements. Performance enhancers were used by 31 participants (8.5%) at least twice a week; reasons for consumption included increased physical performance, improved overall health, and to prevent health problems. Multivitamin/mineral supplements were consumed by 132 firefighters (36.4%) at least twice a week; reasons for consumption included improved overall health, prevent health problems, and increase heart health (cholesterol/blood pressure). Sports bars/gels were used by 86 firefighters (23.7%) at least twice a week; reasons for sports included increased physical performance, improved overall health, and to lose weight. Energy drinks were consumed by 124 firefighters (34.2%) at least twice a week; reasons for consumption included increased physical performance, cognitive function, and relaxation/stress/mental health. **CONCLUSIONS**: Overall, most firefighters who reported supplement use did so for improvements in overall health and to prevent health problems. Interestingly, firefighters in this study reported higher overall supplement usage than other tactical athlete populations (i.e, military personnel: 55-61%). Future investigations should examine the usage and effectiveness of performance enhancing supplements on health and occupational performance in firefighters.

2938   Board #221   June 1 3:30 PM - 5:00 PM

Use Of Analgesics For Exercise-associated Pain In Collegiate Athletes

Christi Brewer. *Eastern Washington University, Cheney, WA.*

(No relevant relationships reported)

Pharmacoepidemiological research has reported prevalent use of analgesics in several populations, while experimental research has reported the ability of analgesics to inhibit reparative processes in skeletal muscle. Use could be of particular detriment to athletes. **PURPOSES:** To examine prevalence of use analgesics for exercise-associated pain (EAP), patterns and behaviors associated with use, and predictors of use in a sample of Division I male and female athletes. **METHODS:** A valid and reliable 16-item self-report questionnaire previously used to examine analgesic use in recreationally-active college students was modified to include items pertaining to phase of competitive season, injury status, and number of weekly conditioning sessions (C) and team practice sessions (P). Athletes were verbally invited to participate during training sessions. Analgesic use EAP was the primary outcome variable. Secondary outcome variables included patterns of use (weekly, daily frequencies) and behaviors associated with use (likeliness to follow label instructions), with behavioral items rated on a 5-point Likert scale. Descriptive statistics and frequencies were calculated for all items, and logistic regression was used to evaluate the ability of 3 variables (sex, C, P) to predict use. **RESULTS:** Males (n=28) and females (n=41) across a range of sports participated. The majority (97.1%) were in- or post-season, performing 3.9 ± 1.9 C and

5.5±1.4 P sessions weekly. Twenty-nine percent reported being injured and under care of a health professional. Seventy-four percent (73.9%) reported analgesic use for EAP. Thirty-six percent (36.2%) reported use of a combination of analgesics, and 29% used ibuprofen. Most reported use 2 or 3 days per week (33.3%) and 1 or 2 times per day (62.3%). Thirty-five percent self-determined use, and 31.9% reported a combination of self-determined and directed use. Thirty-four percent (34.7%) reported being *very likely* or *extremely likely* to follow label instructions. No individual variables were revealed as significant predictors of analgesic use (sex, p=0.89; C, p=0.33, P, p=0.16). The omnibus test was also non-significant (p=0.28). **CONCLUSION:** Analgesic use is prevalent in collegiate athletes; however, data seem to indicate conservative use and tendency to follow label instructions.

Specific Bioactive Collagen Peptides in Combination with Resistance Training Improve Body Composition in Untrained Subjects

Steffen Oesser[1], Denise Zdzieblik[2], Michael Schunck[1], Daniel König[2]. *[1]Collagen Research Institute, Kiel, Germany. [2]University of Freiburg, Freiburg, Germany.*

(No relevant relationships reported)

It is generally accepted that the combination of resistance exercise and protein supplementation increases fat free mass (FFM) and leads to a reduction in fat mass (FM). However, the question of the optimal type and amount of protein is still under discussion. It was recently demonstrated that bioactive collagen peptide (BCP) intake significantly improves the body composition of sarcopenic men (Zdzieblik et al.(2015) *Br J Nutr*) **PURPOSE** To determine the efficacy of a collagen peptide supplementation in combination with resistance training on the body composition in untrained subjects. **METHODS**
The effect of post-exercise supplementation of specific BCP (BODYBALANCE®) on FFM and FM was tested on 182 untrained women and men aged 46 ± 9 years. The study participants underwent 60 minutes of resistance training three times per week, and were daily treated with 15g BCP or a placebo over a period of 12 weeks. Changes in FFM and FM were measured by DEXA scans and by BIA at the beginning of the study and after 12 weeks. Changes between the study groups in FFM and FM were tested using the unpaired Student's T-test. The studies were conducted with the approval of the Ethics Committee of the Medical Faculty of the University of Freiburg, Germany. All participants gave written informed consent. **RESULTS** The results revealed a significant (p=0.002) increase in FFM after BCP compared to placebo. FFM gain was more than doubled (2.00 ± 0.25 kg) than in individuals who only did the training exercise (0.99 ± 0.19 kg). In addition, FM was significantly (p=0.035) reduced after BCP supplementation by -3.0 ± 0.37 kg compared to placebo (-2.0 ± 0.32 kg). Moreover, study participants who received BCP showed a significant increase in muscle strength of 5.4% compared to placebo treatment. **CONCLUSIONS** Bioactive collagen peptides appear to offer an interesting option for optimized sports nutrition. The results demonstrated that the intake of BCP supports the effect of resistance training, as indicated by a more improved body composition and an increase in muscle strength.

30 Days of Probiotic Supplementation: The Effect Up On Athletes Immunity After a Marathon Race

Geovana SF Leite[1], Edgar Tavares[2], Helena AP Batatinha[1], Ayane S. Resende[1], Marilia C. Seelaender[1], Ricardo A. Fock[1], José C R Neto[1], Ronaldo V T dos Santos[2], Antonio H. Lancha Junior[1]. *[1]University of São Paulo, São Paulo, Brazil. [2]Federal University of São Paulo, São Paulo, Brazil.*

(No relevant relationships reported)

Prolonged strenuous exercise cause an acute increase in leukocytes, including lymphocytes, neutrophils and monocytes. Evidences have suggested that probiotics can enhance athletes' immunity. **PURPOSE:** Investigate the effect of a probiotic supplementation on white blood cells count after a marathon race. **METHODS:** Eight male athletes that participated in a marathon race were randomly assigned to either a probiotic group (PR=4;37.3±5.8 yr,89.2±14.5Kg,time trial 4:04 hrs ±23min) or placebo (PL=4 36.3±8.5 yr,81.8±9.5Kg, time trial 4:53hrs±75min)in a double-blind design. PR was supplemented with sachet containing *Lactobacillus Acidophilus* and *Bifidobacterium Lactis(*10×10^9UFC/d) during 30 days while PL received sachet with maltodextrin(5g/d). It was collected blood samples before the supplementation period (baseline), one day before the marathon (BM), one hour after the race (AR), and 7 days after the marathon(7[th]after)for white blood cells differential count. The data was analyzed using ANOVA with repeated measures and a Bonferroni's *post-hoc*, *p*< 0.05. **RESULTS**: Leukocytes, Neutrophils and Monocytes presented a significant increase AR (**Leu:** PR=13.28±2.63,PL=14.26±4.20mm³; **Neu:**PR=11.20±2.94,PL=12.62±4.27 mm³;

Mono:PR=1.02±0.30,PL=0.95±0.24mm³)when compared to other moments(**Leu:**Baseline: PR=6.47±1.41,PL=5.58±0.56;BM:PR=5.60±0.94, PL=6.01±0.60; 7[th]after:
PR=5.55±0.59, PL=5.57±0.14;
Neu: Baseline:PR=3.13±1.01,PL=3.27±0.72;BM:PR=3.19±0.97,PL=3.66±0.84;7th afterPR=2.89±0.39,PL=3.13±0.30mm³;
Mono: BaselinePR=0.61±0.16,PL=0.52±0.18;BM:PR=0.47±0.03,PL=0.50±0.12;7th after:PR=0.50±0.09,PL=0.48±0.11 mm³)
in both groups with no differences between groups. Regarding lymphocytes cells at the baseline, the probiotic group has presented higher levels when compared to the placebo group (PR=2.53±0.45; PL=1.46±0.21 mm³). In addition, AR, PR has exhibited a significant decrease in the lymphocytes count when compared to the baseline (AR: PR=1.03±0.42 mm³), as well as PL (PL=1.20±0.22 mm³).
CONCLUSION: Thirty days of *Lactobacillus Acidophilus* and *Bifidobacterium Lactis(*10x10⁹ UFC) supplementation have no difference when compared to placebo in leukocytes, neutrophils, monocytes and lymphocytes.
Support by CNPq, CAPES/PROEX.

Short-Term Medium Chain Triglyceride Consumption Does Not Affect Executive Cognitive Function in Healthy Adults.

Laura Q. Jimenez[1], Jay Feldman[2], Brian Arwari[2]. *¹Longwood University, Farmville, VA. ²University of Miami, Coral Gables, FL.*
(No relevant relationships reported)

PURPOSE: The present study was conducted to examine the effects of acute medium-chain triglyceride (MCT) consumption on behavioral cognitive function during a task often linked to rapid decision making and reaction time in sport.
METHODS: Thirty recreationally active college students (M=19, F=11) aged 18-25 participated in this study, which consisted of two experimental days, in a double-blind, randomized-order, crossover design. During each laboratory visit, subjects consumed a fruit smoothie, mixed with an MCT supplement, consisting primarily of coconut oil, or a placebo (the same smoothie, without the supplement). Executive cognitive function testing (using a modified Flanker task) was performed two hours later. To prevent any latent effects of the MCT supplement, trials were separated by at least 72 hours. Dependent variables included accuracy and reaction time on the executive cognitive function task.
RESULTS: Paired-sample T-tests were conducted for Flanker task accuracy and reaction time. MCT consumption did not affect response accuracy (M_{MCT}(SD)=91(11)%, M_{CON}=93(8)%; p=0.36) or reaction time (M_{MCT}(SD)=412(60) ms, M_{CON}=417(53)ms; p=0.71). Further separating the data into sub-sections, including the interference scores between congruent and deviant response accuracies (M_{MCT}(SD)=12(13)%, M_{CON}=17(20)%; p=0.22), and the interference scores between congruent and deviant reaction times (M_{MCT}(SD)=-36(37)ms, M_{CON}=-46(39)ms; p=0.29), also did not yield any significant results.
CONCLUSIONS: Acute medium-chain triglyceride (coconut oil) consumption did not appear to benefit or harm executive cognitive function when taken up to two hours before a cognitive trial, beyond the effects associated with carbohydrate supplementation (in the form of a fruit smoothie), especially if consumption did not lead to gastrointestinal distress. This implies that physical activities relying on rapid decision making and reaction time are unlikely to be affected by a single bolus of MCTs. Future research should investigate potential supplementation effects over longer periods of time, or in clinical populations that may benefit from MCT consumption.

2942   Board #225   June 1 3:30 PM - 5:00 PM

28-Days Hydrogen-Rich Water Supplementation Affects Exercise Capacity in Mid-Age Overweight Women

Sergej M. Ostojic, Darinka Korovljev, Valdemar Stajer, Dejan Javorac. *University of Novi Sad, Novi Sad, Serbia.*
(No relevant relationships reported)

Molecular hydrogen (H_2) improves body composition, metabolic profiles and mitochondrial function in overweight women, yet no studies so far evaluated the effectiveness of H_2 for improving exercise capacity in this population.
PURPOSE: To examine the effects of 28-days supplementation with 1 L per day of hydrogen-rich water (HRW) on exercise capacity and quality of life in overweight mid-age women. **METHODS**: Twelve women (age 53.8 ± 13.0 years, BMI 28.8 ± 3.3 kg/m², VO_{2max} 22.3 ± 3.7 ml/kg/min) participated in this randomized, placebo-controlled, cross-over, repeated-measure interventional study. All participants were allocated in a double-blind design to receive two randomly assigned trials: first group received 1 L per day of HRW (supplying ~ 9 ppm of H_2), while the second group received placebo (tap water). Participants were evaluated at baseline, and following 28 days of intervention. The primary endpoint was the change in cardiorespiratory endurance (VO_{2max}) assessed at baseline and at 28 days follow-up. Secondary outcomes included change from baseline to end of treatment in values for work capacity, impact

of weight on quality of life (IWQoL), and hematological biomarkers. Participants were asked to maintain their usual lifestyle, dietary intake and not to use other dietary supplements during the study. **RESULTS:** HRW intervention significantly improved VO_{2max} as compared to placebo at 28-day follow-up (26.2 ± 4.8 ml/kg/min *vs.* 24.2 ± 4.1 ml/kg/min; $P = 0.03$). Differences were found for time to exhaustion and total work completed during an incremental exercise, with HRW resulting in improvement of both variables as compared to placebo ($P < 0.05$). IWQoL scores and hematological markers were not affected by either intervention ($P > 0.05$). **CONCLUSION:** Results indicate that HRW can be used as an alternative hydration formulation to positively affect exercise performance in mid-age overweight women.

2943   Board #226   June 1 3:30 PM - 5:00 PM

Single versus Split Dose of Iron Optimizes Haemoglobin Mass Gains at 2,106m Altitude

Rebecca Hall[1], Peter Peeling[2], Walter T. P. McCluskey[1], Dan Bergland[3], Trent Stellingwerff, FACSM[1]. *¹Canadian Sports Institute Pacific, Vancouver & Victoria, BC, Canada. ²University of Western Australia, Crawley, Australia. ³Hypo2 High Performance Center, Flagstaff, AZ.* (Sponsor: Dr Trent Stellingerff, FACSM)
(No relevant relationships reported)

Purpose: To determine if a split daily 200mg elemental iron dose (2x100mg) is superior to a single daily iron dose (1x200mg) for optimal haemoglobin mass (Hbmass) gains at altitude, while minimizing gastro-intestinal (GI) discomfort. **Methods:** Twenty-six elite male and female runners attended a 3.1±0.3week training camp at 2,106m altitude in Flagstaff, AZ. A two-group design, randomized and stratified to baseline Hbmass, sex and ferritin, was implemented as: 1) split dose of 2 x 100mg daily (AM & PM; SPLIT) vs; 2) single dosing of 1 x 200mg daily (PM only, SINGLE) elemental iron (ferrous fumarate). Two participants were excluded (baseline ferritins <30μ/mL; n=24 for final analysis). Hbmass measures (via the carbon monoxide rebreathing technique) and venepuncture draws were completed upon immediate (± 2 days) arrival and departure of the camp for ferritin, hepcidin and erythroferrone (ERFE) analysis. Validated food frequency (FFQ), GI, menstrual blood loss (MBL) and training questionnaires were implemented throughout the camp. Univariate analysis was used to compare Hbmass outcomes; accounting for the covariates of dietary iron intake, menstrual blood losses and training volume. The alpha-level was set at p<0.05. Data are reported as means ± standard deviation.
Results: Both groups significantly increased Hbmass post-camp, but SINGLE was significantly higher than SPLIT (SINGLE: 867.3±47.9g, SPLIT: 828.9±48.9g, p=0.048). GI scores were worse (greater) in SINGLE for weeks 1 & 2 combined (SINGLE: 18.0±6.7 points, SPLIT: 11.3±6.9 points, p=0.025), however, GI tolerance improved in SINGLE, and the between group difference was no longer apparent by week 3 (p=0.335). ERFE significantly decreased in both groups (~28.5%), however, no between group differences existed (p>0.05). Hepcidin showed a tendency to decline (~33.5%), with no difference between groups (p>0.05). There were no between group differences in FFQ, MBL or average daily training outcomes (p>0.05).
Conclusion: A single nightly 200mg dose of elemental iron (ferrous fumarate) was superior to a split dose for optimizing changes in Hbmass at 2,106m altitude in elite runners over a 3.1±0.3week training camp. Observed differences may be due to a greater acute hepcidin response in the SPLIT group, however, more research is required to explore the mechanism.

2944   Board #227   June 1 3:30 PM - 5:00 PM

Antioxidant Supplementation Attenuates Muscle Performance Adaptations In Young Women: A Randomized Placebo-controlled Trial

Maurílio T. Dutra[1], Sávio Alex[1], Alyson F. Silva[1], Nathalia B. Sales[1], Marco A. Dourado[1], Andrew Fonseca[1], Filipe D. Lima[1], Lee E. Brown, FACSM[2], Martim Bottaro[1]. *¹University of Brasília, Brasília, Brazil. ²California State University at Fullerton, Fullerton, CA.* (Sponsor: Lee E. Brown, FACSM)
(No relevant relationships reported)

Strength training (ST) is widely known to promote acute and chronic adaptations that result in increased muscle performance and hypertrophy. It has been argued that antioxidant supplementation could affect these adaptations by neutralizing oxidative stress. However, chronic interventions analyzing the effects of ST combined with antioxidant vitamins are scarce, and available results are ambiguous. **PURPOSE:** To investigate the effects of ST combined with vitamin C and E supplementation on muscle performance and thickness. **METHODS:** This was a double-blinded placebo-controlled randomized study. Forty-two untrained women (23.8 ± 2.7 years, 58.7 ±

11.0 kg, 1.63 ± 0.1 m) were allocated into three groups: 1) vitamins (VG, *n*=15), 2) placebo (PG, *n*=12), or 3) control (CG, *n*=15). Participants of VG and PG underwent a periodized ST program, twice a week, for 10 weeks. VG supplemented with vitamin C (1g/day) and E (400IU/day) while PG consumed placebo pills. At the beginning and end of the training period, knee extensor peak torque (PT) and total work (TW) were measured on an isokinetic dynamometer and quadriceps *femoris* muscle thickness (MT) was assessed by ultrasound. Mixed factor ANOVA analyzed data. **RESULTS:** A significant group*time interaction for PT (F = 13.4, *P* = .000), TW (F = 6.0, *P* = .005) and MT (F = 4.0, *P* = .03) was observed. Both VG (37.2 ± 5.4 *vs* 40.3 ± 5.6 mm) and PG (39.7 ± 5.2 *vs* 42.5 ± 5.6 mm) increased MT after the intervention (*P* < .05) with no differences between groups. Also, both VG (146.0 ± 29.1 *vs* 170.1 ± 30.3 N.m) and PG (158.9 ± 22.4 *vs* 182.7 ± 23.2) increased PT after training (*P* < .05). However, a significant group effect (F = 5.2, *P* = .01) showed that only PG presented a significant difference *vs* CG (*P* = .01). In addition, both VG (2068.3 ± 401.2 *vs* 2295.5 ± 426.8 J) and PG (2165.1 ± 369.5 *vs* 2480.8 ± 241.3 J) increased TW after the intervention (*P* < .05). However, a significant group effect (F = 5.1, *P* = .01) showed that only PG presented a significant difference *vs* CG (*P* = .01). **CONCLUSION:** Chronic antioxidant supplementation may attenuate muscle performance improvement, but not muscle growth, in untrained young women after 10 weeks of ST.

Vitamin D Supplementation Improves Health Related Quality of Life in Children with Sickle Cell Disease

Kelly A. Dougherty[1], Chiara Bertolaso[2], Joan I. Schall[3], Kim Smith-Whitley[4], Virginia A. Stallings[4]. *[1]Stockton University, Galloway, NJ. [2]University Hospital Umberto I, Sapienza University, Rome, Italy. [3]The Children's Hospital of Philadelphia, Philadelphia, PA. [4]The Children's Hospital of Philadelphia and University of Pennsylvania, Philadelphia, PA.*
(No relevant relationships reported)

Sickle cell disease has a detrimental impact upon health-related quality of life (HRQL). No study has determined if vitamin D supplementation can improve HRQL in this population using the pediatric Patient-Reported Outcomes Measurement Information System (PROMIS). **PURPOSE**: To assess the impact of vitamin D supplementation on HRQL over a 12-week period in 5- to 17-year-old African American children with (n=21) and without (n=23) type SS sickle cell disease (SCD-SS). **METHODS**: Subjects were randomized to oral daily doses (4000 vs. 7000 IU) of cholecalciferol (vit D$_3$) and evaluated at 6 and 12 weeks for changes in vit D status (serum 25 hydroxyvitamin D (25(OH)D)) and HRQL using PROMIS pediatric short forms. For PROMIS assessment of item response theory-based T-scores (population mean of 50 and SD of 10) in the depressive symptoms, fatigue, and pain domains, a higher T score indicates a worse outcome and in the mobility, peer relationships, and upper-extremity function domains a lower T scores indicate a worse outcome. **RESULTS**: The mean 25(OH)D at baseline was 19.2±7.2 in subjects with SCD-SS and 22.3±9.3 in healthy subjects. After 12 weeks of supplementation, the mean increase in 25(OH)D was 25.6±22.3 ng/mL in subjects with SCD-SS and 20.5±17.5ng/mL in healthy subjects (both P<0.05). In subjects with SCD-SS by 12-wks (n=20), significant (all P<0.05) reductions in pain (54.4 ± 13.3 vs. 48.4 ± 14.8), fatigue (51.7 ± 11.4 vs. 46.4 ± 14.0) and depressive symptoms (43.1 ± 8.1 vs. 39.1 ± 7.3) and improvement in upper-extremity function (45.9 ± 10.9 vs. 51.2 ± 8.7) were observed, with no difference (both P>0.05) in mobility (53.1 ± 6.2 vs. 55.7 ± 5.4) or peer relationships (56.9 ± 7.1 vs. 57.8 ± 11.0). In healthy subjects by 12 weeks, there were no differences (P>0.05) in pain (48.6 ± 8.7 vs. 48.9 ± 7.3), depressive symptoms (41.5 ± 8.2 vs. 39.9 ± 9.4), mobility (57.8 ± 3.3 vs. 57.5 ± 3.7) or peer relationships (56.0 ± 7.3 vs. 56.1 ± 9.2), but significant (both P<0.05) reductions in fatigue (40.3 ± 10.3 vs. 36.3 ± 10.0) and improvement in upper-extremity function (50.6 ± 8.8 vs. 53.2 ± 6.4). **CONCLUSIONS**: Daily high-dose vitamin D supplementation for African American children with and without SCD-SS improved HRQL. Supported by K12 (KL2RR024132), K23 (K23HL114637), (UL1TR000003), CHOP RAG Pilot Grant, GI Research and Education Fund, and Nutrition Center.

Vitamin D$_3$ Supplementation on Immune Functions and Upper Respiratory Track Infection in Male Taekwondo Athletes

Hyun Chul Jung[1], Myong Won Seo[2], Sukho Lee[3], Sung Woo Kim[2], Jong Kook Song[2]. *[1]University of Louisiana at Monroe, Monroe, LA. [2]Kyung Hee University, Yong-In, Korea, Republic of. [3]Texas A&M University-San Antonio, San-Antonio, TX.*
(No relevant relationships reported)

Vitamin D plays an important role for immune functions. Insufficient serum 25(OH)D concentration during winter season may be associated with increased risk of upper respiratory tract infection (URTI) in athletes. **PURPOSE**: This study was aimed to determine the effects of vitamin D$_3$ supplementation on immune functions and URTI in male taekwondo athletes. **METHODS**: Twenty-five male taekwondo (TKD)

athletes, aged 19-22 years with vitamin D deficiency (25(OH)D; 12.3±2.78 ng/ml), participated in this study. They were randomly assigned to receive 5,000 IU/day of vitamin D$_3$ capsule (N=13) or placebo (N=12) during 4 weeks of winter training. Blood samples were collected two times (pre- and post-tests) to analyze serum 25(OH)D concentration. Saliva samples were collected three times (1st, 2nd, and 4th week) to analyze the salivary immunoglobulin A (SIgA) and lactoferrin concentrations. URTI symptoms were reported daily during 4 weeks of training. Repeated measures ANOVAs were performed and significant level was set at *p*<.05. **RESULTS**: The serum 25(OH)D concentration increased by 255.6% in supplementation group, but this level did not change in placebo group (F=247.50, p<.001). SIgA (F=23.00, *p*<.001) significantly increased in both groups during the study period, but salivary lactoferrin level (F=5.79, p=.011) increased only in placebo group at the 2nd week of training. URTI symptoms significantly decreased only in supplementation group (F=5.456, p=.005) throughout the study. **CONCLUSIONS**: The present study found that high dose of vitamin D$_3$ supplementation (5,000 IU/day) increased the serum 25(OH)D concentration to sufficient level (40.1±6.79 ng/ml), and decreased URTI symptoms during winter training. Our findings suggest that vitamin D$_3$ supplementation during winter training may provide potential benefits for preventing URTI in male taekwondo athletes with vitamin D deficient.

Impact of a Carbohydrate Mouth Rinse on Muscle and Functional Power in Older Adults.

Logan E. Chaffin[1], Kayla Holder[1], Chioma Ichoku[1], Gabriel K. Harris[2], Srikant Vallabhajosula[1], Stephen Bailey, FACSM[1]. *[1]Elon University, Elon, NC. [2]North Carolina State University, Raleigh, NC.* (Sponsor: Dr. Stephen Bailey, FACSM)
(No relevant relationships reported)

People over the age of 70 have decreased muscular power and reduced functional ability. Carbohydrate mouth rinse (MR) has been effective at producing an increase in power-like activities in young healthy athletic populations. **PURPOSE:** The purpose of this study is to assess the effect of a carbohydrate MR on functional measures of power in an older population. **METHODS:** Twelve subjects (5 males, 7 females; Age= 77±3 years) completed 2 experimental sessions under different MR conditions (Placebo (PLAC), 6.4% glucose (CHO)). Subjects completed the timed-up and go (TUG) and hand grip tests immediately after and 10 minutes after application of the MR. During the sit-to-stand phase of the TUG subjects initiated movement with both feet placed on force platforms. **RESULTS:** No differences were found in the TUG as a result of the MR condition immediately (PLAC=9.16±0.34 sec, CHO=9.26±0.33 sec) after or 10 minutes (PLAC=8.98±0.36 sec, CHO=9.11±0.34 sec) after MR. Similar results were found for the hand grip test immediately (PLAC=68.8±5.5 lbs, CHO=68.8±5.7 lbs) after and 10 minutes (PLAC=69.4±5.9 lbs, CHO=73.8±5.8 lbs) after MR. In contrast, impulse (PLAC=352±36 Ns, CHO=409±39 Ns; p=0.01) and power (PLAC=85±9 N-m sec^{-1}, CHO=99±10 N-m sec^{-1}; p=0.02) generated during sit-to-stand were greater immediately after CHO MR as compared to PLAC MR. This result did not persist 10 minutes after MR. **CONCLUSIONS:** CHO MR improved impulse and power during the sit-to-stand phase of the TUG; however, functional performance of the TUG and hand grip was not changed as a result of MR. These results suggest that CHO MR transiently increases muscle power in normal subjects above 70 years of age.

Greater Fitness is Associated with Reduced Injury Risk in Specialized Military Men

Lisa M. Hernández[1], Stephanie D. Coffin[1], Marcus K. Taylor, FACSM[2]. *[1]Leidos, San Diego, CA. [2]Naval Health Research Center, San Diego, CA.* (Sponsor: Marcus K. Taylor, PhD, FACSM)
(No relevant relationships reported)

Recent literature has shown that cardiorespiratory fitness (CRF) and strength deficits are associated with greater musculoskeletal injury (MSKI) risk. When combined, the Functional Movement Screen (FMS) and lower quarter Y-Balance test (YBT) are powerful indicators of MSKI risk in athletes and military personnel. As the premier combat force for countering explosive hazards, U.S. Navy Explosive Ordnance Disposal (EOD) operators must perform optimally in the most austere environments. To safeguard health and mission success, it is critical to assess factors that influence MSKI risk in this elite group.

PURPOSE: To assess the relationships between measures of fitness and injury risk in EOD operators.
METHODS: Fifty-one active duty men (age 35.6 ± 1.0 yr) were evaluated for body fat percentage (BF%) using dual-energy x-ray absorptiometry, CRF (maximum volume of oxygen uptake [VO_{2max}]), muscular strength (one-repetition max [1-RM] back squat and bench press), and injury risk assessments (FMS, YBT). A quartile split for VO_{2max} established the bottommost, low, high, and topmost VO_{2max} groups. ANOVA and Pearson product-moment correlations were used to evaluate fitness and injury risk associations.
RESULTS: Means ± SE were as follows: BF% = 17.9 ± 0.5, VO_{2max} = 47.0 ± 0.9 ml/kg/min, time on treadmill (TT) = 12.2 ± 0.2 min, time of ventilatory threshold (VT) = 6.2 ± 0.2 min, FMS total score = 15.8 ± 0.3, and YBT left composite (LC) = 99.0 ± 1.0% and right composite (RC) = 98.6 ± 1.0%. Mean FMS scores were different between quartiles (F[3,47] = 5.182, $p < .01$), where the bottommost VO_{2max} group had the lowest scores. YBT was also different between quartiles: LC (F[3,47] = 3.704, $p < .05$) and RC (F[3,47] = 2.899, $p < .05$), where the high VO_{2max} group had the greatest values. Associations with FMS were BF% ($r = −.33, p < .05$), TT ($r = .35, p < .05$), and VT ($r = .30, p < .05$). Correlations with LC and RC were BF% ($r = −.37$ for both, $p < .01$) and TT ($r = .37-.46, p < .01$). No associations with 1-RM were observed.
CONCLUSION: This study is consistent with accruing data that indicate more fit individuals have a lower injury risk. While strength is a critical element of overall fitness, CRF and BF% may better predict MSKI risk. Due to their unique and arduous operational demands, the EOD operator can further reduce injury risk by maintaining peak physical condition.

Adrenal Stress and Performance during Military Survival Training

Tunde K. Szivak[1], Elaine C. Lee[2], Cathy Saenz[3], Brian C. Focht, FACSM[3], Jeff S. Volek, FACSM[3], Carl M. Maresh, FACSM[3], William J. Kraemer, FACSM[3]. [1]*Merrimack College, North Andover, MA.* [2]*University of Connecticut, Storrs, CT.* [3]*The Ohio State University, Columbus, OH.*
(No relevant relationships reported)

PURPOSE: The purpose of this research study was to evaluate neuroendocrine and physical performance responses in sailors and Marines undergoing U.S. Navy Survival, Evasion, Resistance and Escape (SERE) training.
METHODS: 20 men (Age: 25.3 ± 3.6 years; Height: 178.1 ± 6.1 cm; Weight: 83.7 ± 12.6 kg) took part in the study. Men were further split into high fit (n =10) and low fit (n = 10) subgroups based on physical fitness test scores. Blood samples were obtained at three timepoints (T1: baseline, T2: stress, T3: recovery), and were analyzed for plasma epinephrine, plasma norepinephrine, plasma dopamine, serum cortisol, serum testosterone, and plasma neuropeptide Y. Vertical jump and handgrip tests were performed at T1 and T2.
RESULTS: For the group as a whole (n = 20), stress hormone concentrations were significantly elevated at T2, with a concomitant reduction in testosterone concentrations. NPY concentrations did not increase at T2, but decreased significantly at T3. Subjects maintained performance on the vertical jump and handgrip tests from T1 to T2. Significant between group differences were observed in norepinephrine (high fit: 3530.64 ± 2146.54 pmol•L-1, low fit: 4907.16 ± 3020.85 pmol•L-1) and NPY (high fit: 169.3 ± 85.89 pg•mL-1, low fit: 123.02 ± 88.86 pg•mL-1) responses at recovery (T3).
CONCLUSIONS: This study revealed that despite differential catecholamine and NPY responses during recovery, the SERE training course resulted in significant increases in stress hormone concentrations in all subjects regardless of physical fitness level, with no reductions in physical performance measures.

Differences between U.S. Army Trainees and Active Duty Soldiers in Performing Physically Demanding Occupational Tasks

Maria C. Canino, Bruce S. Cohen, Stephen A. Foulis, Peter N. Frykman, Jan E. Redmond, Edward J. Zambraski, Marilyn A. Sharp. *U.S. Army Research Institute of Environmental Medicine, Natick, MA.*
(No relevant relationships reported)

The training implemented during initial entry training (IET) for combat arms trainees (up to 16 weeks) is designed to sufficiently optimize performance of physically demanding occupational tasks. Trainees must be physically capable of performing the tasks within their jobs to the minimal acceptable performance standard, as delineated by U.S. Army Training and Doctrine Command. **PURPOSE**: To compare U.S. Army trainees to active duty soldiers performing physically demanding occupational tasks. **METHODS**: 192 U.S. Army male combat arms trainees (TRs) at the end of their IET and 369 active duty male combat arms soldiers (ADs) both performed the sandbag carry (SBC), casualty drag (CD) and move under direct fire (MUF) tasks. During the

SBC, subjects wore personal protective equipment (PPE; ~32 kg) while lifting and carrying 16 pre-filled 18-kg sandbags a distance of 10m to build a fighting position (4 long x 2 wide x 2 high) as fast as possible (min). For the CD, subjects wore PPE and a weapon while dragging a 123-kg simulated casualty 15m as fast as possible (60-sec time limit). Time was recorded and later calculated as velocity (m·s⁻¹). During MUF subjects wore PPE and a weapon to perform a series of combat rushes covering 100m as fast as possible (min). The MUF course cycled between one prone and two kneeling positions, each 6.6 m apart. Univariate ANCOVA (height and body mass as covariates) were used to compare differences in performances on the three tasks between TRs and ADs. **RESULTS**: 94% of TRs and 99% of ADs performed the three tasks to the minimal acceptable performance standards. ADs performed significantly faster than TRs on SBC (AD: 1.73 ± 0.29 min, TR: 2.09 ± 0.46 min; p<0.01) and CD (AD: 1.14 ± 0.28 m·s⁻¹, TR: 0.80 ± 0.30 m·s⁻¹; p<0.01) with no differences in MUF performance (AD: 2.24 ± 0.15 min, TR: 2.27 ± 0.22 min; p=0.09). **CONCLUSIONS:** Although majority of the TRs met the minimal acceptable performance standards on the three tasks, ADs performed the SBC and CD faster. This could be due to ADs having more experience performing the tasks. While further training occurs at TRs first duty station, TRs may benefit from additional occupational task training during IET. *The views expressed in this abstract are those of the authors and do not reflect the official policy of the Department of Army, Department of Defense, or the U.S. Government.*

Effect of a Simulated Tactical Occupation Stressor on Physiological Strain Index and Blood Pressure

Cody E. Morris[1], Lee J. Winchester[1], Andrew J. Hussey[1], Ariel S. Tomes[1], Wesley A. Neal[1], Damon M. Wilcoxen[1], MiRanda N. Anderson[1], William J. Bradshaw[1], Dana N. Lucas[1], Harish Chander[2], Scott W. Arnett[1]. [1]*Western Kentucky University, Bowling Green, KY.* [2]*Mississippi State University, Mississippi State, MS.* (Sponsor: Scott Lyons, FACSM)
(No relevant relationships reported)

PURPOSE: As a firefighter performs in live-fire suppression, it is critical to understand to the degree their physiological stress is exacerbated by the physical work they are required to conduct to reach a potential victim of an emergency. The purpose of this study was to evaluate physiological strain index (PSI) in response to a simulated firefighting occupation workload.
METHODS: Ten healthy male adults participated in this study. While wearing proper testing attire, participants completed a simulated fire stair climb (SFSC) by completing two consecutive 3-min workloads on a Matrix C7xe ClimbMill (Matrix Fitness USA, Cottage Grove, WI, USA) at a stepping rate of 60 steps/min. The participants completed this protocol under four conditions, with some conditions including the wearing of a 34.04 kg (75 lbs) weighted vest to simulate the wearing of personal protective equipment (PPE) typically worn by a firefighter. Some conditions involved the inclusion of a color-word interference test (CWIT) as a distracting mechanism. PSI was evaluated by continuously monitoring HR and core temperature by using CorTemp® ingestible thermometers and radio receiver (HQ, Inc., Palmetto, FL). PSI was calculated using a previously published and validated equation (Moran et al., 1998). Blood pressure was measured pre-exercise, following initial 3 min workload, and following completion of total workload.
RESULTS: A repeated-measures ANOVA showed that there was a significantly different PSI when comparing conditions ($p = 0.001$). A significantly elevated PSI per min was exhibited during all six minutes of exercise for both the weighted vest and weighted vest + CWIT conditions compared to exercise conditions without the vest. Systolic blood pressure also exhibited a significantly different degree of elevation in the same manner ($p = 0.006$).
CONCLUSIONS: Based on the results of the current study, it appears that the wearing of a weighted vest to simulate PPE significantly elevates PSI above what would be expected by the exercise alone. These findings suggest that firefighters are potentially at a substantial degree of physiological stress from the exercise and weight of gear alone. Further work should be conducted to further evaluate the usefulness of PSI as a means to monitor firefighters during actual or simulated fire suppression.

2952   **Board #235**   **June 1 3:30 PM - 5:00 PM**
Effect of a Simulated Tactical Occupation Stressor on Perceived Exertion and Blood Lactate

Wesley A. Neal[1], Cody E. Morris[1], Lee J. Winchester[1], Andrew J. Hussey[1], Ariel S. Tomes[1], Damon M. Wilcoxen[1], MiRanda N. Anderson[1], Dana N. Lucas[1], Harish Chanders[2], Scott W. Arnett[1]. [1]*Western Kentucky University, Bowling Green, KY.* [2]*Mississippi State University, Mississippi State, MS.* (Sponsor: Scott Lyons, FACSM)
(No relevant relationships reported)

PURPOSE: Findings by Marcora et al. (2009) and Zering et al. (2016) suggest that perceived exertion can be elevated during an exercise bout of a familiar intensity if it is

followed by a task requiring substantial cognitive attention. The purpose of this study was to evaluate rating of perceived exertion (RPE) and markers of physiological stress in response to a simulated firefighting occupation workload.
METHODS: Ten healthy male adults participated in this study. While wearing proper testing attire, participants completed a simulated fire stair climb (SFSC) by completing two consecutive 3-min workloads on a Matrix C7xe ClimbMill (Matrix Fitness USA, Cottage Grove, WI, USA) at a stepping rate of 60 steps/min. The participants completed this protocol under four conditions, with some conditions including the wearing of a 34.04 kg (75 lbs) weighted vest to simulate the wearing of personal protective equipment (PPE) typically worn by a firefighter. Some conditions involved the inclusion of a color-word interference test (CWIT) as a distracting mechanism. RPE was measured each minute during exercise using Borg's 15-point (6 - 20) scale (Borg, 1982; Borg, 1998). Lactate was measured following initial 3 min workload and following completion of total workload.
RESULTS: A repeated-measures ANOVA showed that there was a significantly different RPE when comparing conditions (p < 0.0005). A significantly elevated RPE per min was exhibited during all six minutes of exercise for both the weighted vest and weighted vest + CWIT conditions compared to exercise conditions without the vest. A repeated-measures ANOVA showed that there was a significantly different blood lactate when comparing conditions (p < 0.0005).
CONCLUSIONS: Based on the results of the current study, it appears that the wearing of a weighted vest to simulate PPE significantly elevates RPE above what would be expected by the exercise alone. Blood lactate levels mirrored these results. These findings suggest that firefighters are potentially at a substantial degree of perceived stress from the exercise and weight of gear alone.

2953   Board #236   June 1 3:30 PM - 5:00 PM

Effect of a Simulated Tactical Occupation Stressor on Immune System Markers of Physiological Stress and Inflammation

Ariel S. Tomes[1], Cody E. Morris[1], Lee Winchester[1], Andrew J. Hussey[1], Wesley A. Neal[1], Damon M. Wilcoxen[1], MiRanda N. Anderson[1], William J. Bradshaw[1], Dana N. Lucas[1], Harish Chander[2], Scott W. Arnett[1]. *[1]Western Kentucky University, Bowling Green, KY. [2]Mississippi State University, Mississippi State, MS.* (Sponsor: Scott Lyons, FACSM)
(No relevant relationships reported)

PURPOSE: Walker et al., 2015 reported that increases in immune system markers [interleukin-6 (IL-6), C-reactive protein (CRP)] occur simultaneously with each increase in core temperature. A substantial physiological and psychological disturbance experienced by firefighters could potentially lead to a depression in immune system function. The purpose of this study was to evaluate specific immune system markers in response to a simulated firefighting occupation workload.
METHODS: Ten healthy male adults participated in this study. While wearing proper testing attire, participants completed a simulated fire stair climb (SFSC) by completing two consecutive 3-min workloads on a Matrix C7xe ClimbMill (Matrix Fitness USA, Cottage Grove, WI, USA) at a stepping rate of 60 steps/min. The participants completed this protocol under four conditions, with some conditions including the wearing of a 34.04 kg (75 lbs) weighted vest to simulate the wearing of personal protective equipment (PPE) typically worn by a firefighter. Some conditions involved the inclusion of a color-word interference test (CWIT) as a distracting mechanism. Salivary cortisol (CORT) was measured at baseline, following initial 3 min workload, and following completion of total workload. CRP was evaluated at baseline and one hour following the completion of each workload.
RESULTS: A repeated-measures ANOVA showed that there was a significantly different blood lactate when comparing conditions ($p < 0.0005$). Both Conditions 2 and 4 exhibited a significantly higher BL ($p < 0.05$) than Conditions 1 and 3. There were not shown to be any significant differences ($p > 0.05$) as a result of the SFSC between Conditions 2 and 4 or any differences between Conditions 1 and 3 in regards to BL. Neither CORT ($p = 0.116$) or CRP ($p = 0.700$) was shown to be significantly different across conditions or from baseline.
CONCLUSIONS: Based on the results of the current study, it appears that the wearing of a weighted vest to simulate PPE significantly elevates BL above what would be expected by the exercise alone. This illustrates the significant increase in exercise intensity while wearing the simulated PPE. However, the degree of exercise employed was not enough (with or without the weighted vest) to elicit any substantial changes in inflammatory markers.

2954   Board #237   June 1 3:30 PM - 5:00 PM

Effect of a Simulated Tactical Occupation Stressor on Reaction Time

Andrew J. Hussey[1], Cody E. Morris[1], Lee J. Winchester[1], Ariel S. Tomes[1], Wesley A. Neal[1], Damon M. Wilcoxen[1], MiRanda N. Anderson[1], William J. Bradshaw[1], Dana N. Lucas[1], Harish Chander[2], Scott W. Arnett[1]. *[1]Western Kentucky University, Bowling Green, KY. [2]Mississippi State University, Mississippi State, MS.* (Sponsor: Scott Lyons, FACSM)
(No relevant relationships reported)

PURPOSE: Further work needs to be conducted on the effects exercise or physical exertion has on the body in regards to reaction time (RT). This becomes especially important to occupations who must complete a strenuous physiological workload while making potential life-and-death decisions that require a quick response. The purpose of this study was to evaluate RT in response to a simulated firefighting occupation workload.
METHODS: Ten healthy male adults participated in this study. While wearing proper testing attire, participants completed a simulated fire stair climb (SFSC) by completing two consecutive 3-min workloads on a Matrix C7xe ClimbMill (Matrix Fitness USA, Cottage Grove, WI, USA) at a stepping rate of 60 steps/min. The participants completed this protocol under four conditions, with some conditions including the wearing of a 34.04 kg (75 lbs) weighted vest to simulate the wearing of personal protective equipment (PPE) typically worn by a firefighter. RT was evaluated by employing a color-word interference test (CWIT) to evaluate how quickly the participant could react to distracting or incorrect visual stimuli to provide a response. The ability to answer quickly as well as accurately was assessed during the CWIT.
RESULTS: A repeated-measures ANOVA showed that there was a significantly different overall RT ($p = 0.001$) during the SFSC while wearing the weighted vest being significantly worse than baseline ($p = 0.016$). This difference was mirrored in RT during correct responses ($p = 0.025$) exhibiting a slowed RT while wearing the weighted vest ($p = 0.106$). CWIT accuracy ($p = 0.159$) or RT during incorrect responses ($p = 0.630$) was not shown to be significantly different from baseline.
CONCLUSIONS: Based on the results of the current study, it appears that the wearing of a weighted vest to simulate PPE significantly impairs RT. These findings suggest that the decision-making ability of tactical-style occupations could be hampered in response to such a workload-induced physiological stress, exposing themselves and potential victims they are attempting to help to further harm.

2955   Board #238   June 1 3:30 PM - 5:00 PM

Heart Rate Reserve: An Objective Measure of Soldiers' Physical Exertion During Field Operations

Leif Hasselquist, Clifford L. Hancock, Carolyn K. Bensel. *Natick Soldier Research, Development, and Engineering Center, Natick, MA.*
(No relevant relationships reported)

Physiological monitoring can be accomplished in a military field environment using wearable technologies, but information is limited on physical exertion measures that are most useful for military applications, such as mission planning and protective equipment evaluations.
PURPOSE: Determine sensitivity of percentage heart rate reserve (%HRR) to variations in carried load using experimenter- and self-paced military tasks.
METHODS: 38 Army male soldiers [M (SD): Age = 24.2 (4.1); Wt. = 80.7 kg (12.5); Ht. = 1.76 m (.07); $\dot{V}O_{2Peak}$ = 50.3 ml/kg/min (5.4)] volunteered for a 6-session study conducted under an IRB-approved protocol. Wearing a heart rate monitor, they executed 3 trials (1 trial/session) of an experimenter-paced, 4.83-km foot march (FM) at a 4.83 km·h^{-1} speed and 3 trials (1 trial/session) of a self-paced, maximum effort run of an obstacle course (OC) carrying a different military load (randomized) on each trial (FM: 8.8, 47.2, 50.7 kg; OC: 8.8, 28.1, 31.5 kg). Maximum heart rate (MHR) was obtained in the final 20 s of $\dot{V}O_{2Peak}$ testing. Resting HR (RHR) was recorded in the final 20 s of a 5-min period of sitting prior to trial initiation. The highest HR in a trial (MHR$_{trial}$) was also identified. %HRR was calculated as [(MHR$_{trial}$ – RHR)/(MHR – RHR)] x 100. Separate repeated measures ANOVAs (Subjects x Load) were applied to FM and OC %HRR and completion time.
RESULTS: On the FM, completion time was not significantly affected by load, $F(1.15, 42.6) = 2.68$, $p =.105$, $\eta p^2 = .067$, [M (SD) in min: 59.68 (1.06), 59.37 (1.08), 60.52 (3.74) for loads 1-3], but %HRR increased significantly with each load increase, $F(1.66, 61.44) = 112.17$, $p < .001$, $\eta p^2 = .752$ [M (SD) in %: 54.15 (10.45), 76.15 (11.53), 82.32 (8.10) for loads 1-3]. On the OC, completion time increased significantly with each load increase, $F(2, 74) = 132.25$, $p < .001$, $\eta p^2 = .781$ [M (SD) in min: 4.34 (0.61), 5.58 (1.05), 6.23 (1.11) for loads 1, 2, & 3], but %HRR did not show a significant load effect, $F(1.51, 55.95) = 1.03$, $p = .347$, $\eta p^2 = .027$ [M (SD) in %: 91.02 (5.23), 91.97 (5.13), 91.18 (6.02) for loads 1-3].

Abstracts were prepared by the authors and printed as submitted.

CONCLUSIONS: %HRR distinguished among external loads carried on an experimenter-paced task (FM). %HRR did not vary with load on a self-paced maximal effort task (OC) but, in conjunction with completion times, %HRR provided critical data on soldiers' physical exertion.

2956   Board #239   June 1 3:30 PM - 5:00 PM

Effect of Long-term Elite Military Training and Operations on Hormonal Profile

Andrew E. Jensen[1], Laura J. Arrington[2], Lorraine P. Turcotte, FACSM[1], Karen R. Kelly[3]. [1]University of Southern California, Los Angeles, CA. [2]Leidos, Inc., San Diego, CA. [3]Naval Health Research Center, San Diego, CA.
(No relevant relationships reported)

Chronic exposure to multifactorial stress, such as that endured by elite military operators, may lead to overtraining syndrome and negatively impact hormonal regulation. In acute settings (<6 mos), military training has been shown to lead to hormonal dysfunction; however, less is known about the consequences of long-term military training. **PURPOSE:** The purpose of this study was to determine the chronic effects of military operations and training on the hormone profile of elite military operators. **METHODS:** Active-duty elite US military operators (n = 65, age = 29.8 ± 1.0 yrs, height = 178.4 ± 0.7 cm, weight = 85.1 ± 2.0 kg) concomitantly engaged in rigorous physical training were recruited to participate in the study. Basal plasma concentrations of luteinizing hormone (LH), total testosterone (TT), free testosterone (FT), sex-hormone binding globulin (SHBG), cortisol, thyroid stimulating hormone (TSH), triiodothyronine (T3), and thyroxine (T4) were obtained between 0600-1000 hrs. Data were analyzed for correlations and compared against normative reference values; all data are presented as mean ± SE. **RESULTS:** Mean LH, TT, FT, SHBG, cortisol, TSH, T3, and T4 for all subjects were: 3.4 ± 0.2 IU $\cdot$ L^{-1}, 13.5 ± 0.9 nmol $\cdot$ L^{-1}, 28.2 ± 1.2 pmol $\cdot$ L^{-1}, 94.2 ± 6.4 nmol $\cdot$ L^{-1}, 441.3 ± 26.4 nmol $\cdot$ L^{-1}, 3.5 ± 0.7 mIU $\cdot$ L^{-1}, 150 ± 9.0 ng $\cdot$ dL^{-1}, and 7.8 ± 0.2 µg $\cdot$ dL^{-1}, respectively. There was a significant positive correlation between TT and cortisol ($R^2 = 0.07$; $y = 0.0093x + 9.4364$; $P < 0.05$). In addition, 43% of the participants (n = 28) had TT below age-based normative reference ranges. Those with lower than normal TT (8.2 ± 0.3 vs. 17.6 ± 1.3 nmol$\cdot$L^{-1}; $P < 0.01$), also had lower FT (24.4 ± 1.9 vs. 31.1 ± 1.4 pmol $\cdot$ L^{-1}, $P < 0.01$), cortisol (367.4 ± 39.1 vs 497.2 ± 33.2 nmol$\cdot$ L^{-1}; $P < 0.05$) and T3 (121.1 ± 5.4 vs. 164.0 ± 14.3 ng $\cdot$ dL^{-1}; $P < 0.01$). **CONCLUSION:** These results indicate that military operations and training may place a large burden on the operators and depress or alter the hypothalamic pituitary, adrenal, gonadal and thyroid axes. Further research need be conducted to determine what, if any, consequences these differences may cause.

Psychological Hardiness And Success On The Occupational Physical Assessment Test In Army Combat Arms Recruits

Bruce Cohen, Stephen Foulis, Maria Canino, Jan Redmond, Edward Zambraski, Marilyn Sharp. USARIEM, Natick, MA.
(No relevant relationships reported)

In January 2017, the U.S. Army employed the Occupational Physical Assessment Test (OPAT) to determine the physical readiness of recruits (RCs) prior to initial entry training (IET). The OPAT consists of the standing long jump (SLJ), seated power throw (SPT), strength deadlift (SDL), and interval aerobic run (IAR). Recruits who meet the top OPAT level (i.e., black) qualify for heavy physically demanding jobs, such as combat arms (i.e., infantry, artillery, etc). Psychological readiness, measured by hardiness, has been shown to predict recruit success. **PURPOSE**: To examine the relationship between psychological hardiness and physical readiness (OPAT) in combat arms RCs. **METHODS:** Within the first week of IET, 945 U.S. Army male combat arms RCs performed the OPAT and completed the Dispositional Resilience Scale - Military (DRS-II-M) questionnaire, a validated 24-item, 5-point Likert scale (1 = definitely false to 5 = definitely true) measure. DRS-II-M provides three positive (control, commitment and challenge) and three negative (alienation, powerlessness and rigidity) hardiness dimensions. RCs were divided into two groups; those who achieved the OPAT black level (n=636) (SLJ $\geq$ 160 cm, seated power throw $\geq$ 450 cm, SDL $\geq$ 160 lb, and IAR $\geq$ 43 shuttles) versus those who did not (n=309). Two-tailed independent sample t-tests were used to compare hardiness across groups. **RESULTS:** RCs achieving black level scored significantly higher than those who did not on positive hardiness dimensions summed averages (SA) (12.65 ± 1.29 vs 12.43 ± 1.47; p = 0.015) and significantly lower on negative hardiness SA (6.35 ± 1.39 vs 6.63 ± 1.43; p = 0.004). Within the individual measure dimensions, black-level RCs scored higher on challenge (4.15 ± 0.58 vs 4.05 ± 0.62; p = 0.013) and control (4.35 ± 0.47 vs 4.25 ± 0.51; p = 0.003) averaged factors (AF) of positive hardiness and lower on alienation (1.53 ± 0.68 vs 1.63 ± 0.69; p = 0.033) and powerlessness (1.57 ± 0.62 vs 1.70 ± 0.66; p = 0.003) AF of negative hardiness. **CONCLUSIONS:** RCs who score high on the OPAT also have increased hardiness suggesting they will be successful in meeting the

---

psychological and physical demands of combat arms jobs. *The views expressed in this abstract are those of the authors and do not reflect the official policy of the Department of Army, Department of Defense, or the U.S. Government.*

Evaluation Of Occupational Heat Strain Under Dry And Humid Conditions With Equivalent WBGT

Jeffrey B. Powell, Yongsuk Seo, Amanda Strauch, Raymond Roberge, Jung-Hyun Kim. NIOSH/CDC/NPPTL, Pittsburgh, PA. (Sponsor: Dr. Edward Sinkule, FACSM)
(No relevant relationships reported)

PURPOSE
American Conference of Governmental Industrial Hygienist's (ACGIH) Threshold Limit Value (TLV), based on Wet Bulb Globe Temperature (WBGT), is a commonly used tool to prevent occupational heat stress (core body temperature (Tc) elevation within +1°C or $\leq$ 38 °C). This study examined the hypothesis that a level of heat stress would be equivalent to different combinations of ambient temperature and relative humidity should it be matched to the equivalent in terms of WBGT.
METHODS
All subjects provided informed consent approved by the NIOSH IRB. Eight healthy men (Age: 23±2 yrs.) wearing a cotton work coverall with a hardhat and work gloves underwent four cycles of an intermittent work-rest (15 min each, total 2 hours) under two ambient conditions characterized as either dry (45.5°C, 15% RH) (DRY) or humid (31°C, 84% RH) (HUM), but both equivalent to 30°C WBGT. The work was performed via a cycling exercise at a fixed rate of 350 watts metabolic heat production while the rest was given as sitting on a chair and removing gloves and headgear, with hydration *ad lib*. Tc, skin temperature (Tsk), Thermal sensation (TS), and Rating of Perceived Exertion (RPE) were measured during exercise.
RESULTS
Measurement of Tc, TS, and RPE were not significantly different between DRY and HUM conditions. There was also no difference in Tc elevation (DRY: 0.8±0.4°C, HUM: 0.7±0.3°C) within the upper limit of TLV. However, Tsk was significantly higher in DRY condition than HUM during exercise (p≤0.05). The average amount of water intake was not significantly different between DRY (1187.5±258.8 ml) and HUMID (901.5±323.6 ml) throughout trials (P>0.05).

		Baseline	1st Exercise	2nd Exercise	3rd Exercise	4th Exercise
Tc (°C)	DRY	37.0 ± 0.4	37.0 ± 0.3	37.2 ± 0.2	37.4 ± 0.3	37.7 ± 0.3
	HUM	36.9 ± 0.4	37.1 ± 0.4	37.2 ± 0.4	37.4 ± 0.4	37.7 ± 0.4
Tsk (°C)	DRY	34.5 ± 0.7	36.1 ± 0.3	36.4 ± 0.4	36.3 ± 0.6	36.3 ± 0.7
	HUM	33.9 ± 0.5	35.3 ± 0.3	35.4 ± 0.5	35.3 ± 0.5	35.2 ± 0.5
TS	DRY	7.1 ± 0.2	9.2 ± 0.6	9.8 ± 0.7	9.8 ± 0.5	10.0 ± 0.8
	HUM	7.4 ± 0.5	9.1 ± 0.7	9.4 ± 0.9	9.6 ± 0.9	9.6 ± 0.9
RPE	DRY	6.1 ± 0.4	9.4 ± 1.2	10.1 ± 1.5	10.4 ± 1.8	10.5 ± 1.7
	HUM	6.1 ± 0.4	9.3 ± 1.3	10.1 ± 1.7	10.1 ± 1.8	9.9 ± 1.6

CONCLUSION
These data demonstrated that a level of heat stress is similar under different ambient temperature and RH when matched the same in WBGT. However, it is speculated that a prolonged working time (e.g. 4 to 8 hour work shift) would likely surpass the upper limit of ACGIH's TLV.

Combat Exposure Blunts Sympathetic Response to Acute Exercise Stress in Explosive Ordnance Disposal Personnel

Marcus K. Taylor, FACSM, Shiloah A. Kviatkovsky, Lisa M. Hernández. Naval Health Research Center, San Diego, CA.
(No relevant relationships reported)

Electrodermal activity (EDA) is a valid proxy of sympathetic nervous system activity during exercise and thus possesses the translational potential for studying the effects of acute and chronic stress. **PURPOSE**: To evaluate the effect of combat exposure (CE) on the EDA response to acute exercise stress in chronically stressed military men. **METHODS:** Thirty-six healthy military men (mean age: 37.0±6.9 yr) completed a graded exercise test to assess maximal oxygen consumption (VO$_{2max}$). EDA was recorded at baseline and during exercise (25, 50, 75, 100% VO$_{2max}$) and recovery. A tertile split of CE levels established three exposure groups: low CE (n=12), medium CE (n=12), and high CE (n=12). A 3 (group) × 6 (stage) repeated-measures analysis of variance evaluated EDA changes across stages of exercise, as well as between CE

levels. **RESULTS:** Baseline EDA values for high, medium, and low CE did not differ ($p>0.05$). From 25% to 100% VO_{2max}, mean percent changes in EDA from baseline were +85.2 to +121.6%, with a subsequent decline in seated recovery (+105.8%) ($p<0.001$, $\eta_p^2 =0.28$). An interaction between CE and exercise workload was observed ($p=0.022$, $\eta_p^2 =0.13$). Specifically, low CE displayed a steep linear increase in EDA from 25% to 100% VO_{2max}, followed by a steady decrease into recovery. In contrast, the high CE EDA response was blunted, with a peak occurring at 75% VO_{2max}, after which it declined through 100% VO_{2max}. The medium CE EDA response mirrored low CE until 75% VO_{2max} and then declined through seated recovery. **CONCLUSION:** Dose-dependent effects of CE were demonstrated on EDA response to exercise stress. The low-CE pattern is consistent with the literature characterizing healthy plasma catecholamine responses during exercise stress, as well as with our prior research illustrating EDA responses in aerobically fit individuals. High-CE individuals, by contrast, exhibit a less adaptive response. Collectively, these findings imply that CE disrupts the sympathetic response to acute exercise stress.

Factors Impacting Field March Performance of U.S. Service Academy Cadets

Todd A. Crowder[1], Scott K. Rapuano[2]. [1]*US Military Academy, West Point, NY. [2]3rd Infantry Division, Fort Stewart, GA.*
(No relevant relationships reported)

Field march performance (FMP) is an important skill of ground combat forces. Aerobic ability, "GRIT", overall strength & perhaps lean body mass are important factors influencing FMP. **PURPOSE:** Investigate factors impacting FMP in a military school selection process of U.S. Service Academy cadets. **METHODS:** 230 relatively fit subjects participated in a one-day military school selection tryout culminating with an ~8.5 mile FMP carrying ~35-lb load on terrain including several elevation changes each of at least ~500 feet. Specific multiple regression & frequency distribution analysis involved investigating the factors influencing the top & bottom 10% FMP (n = 46) of the larger sample. **RESULTS:** Analysis revealed that service academy career run time was the most potent factor impacting FMP; multiple R = .79, adjusted R^2 = .62. Threshold measures appear present; 12:30 or faster 2MR (13 vs 0 subjects) and 2:38 or faster on an indoor obstacle course test (IOCT; 15 vs 2 subjects) reside in the Top 10% fastest FMP group. Body mass (adjusted R^2 = -.02) and pull-ups (adjusted R^2 = .02; a questionable surrogate for strength) did not impact FMP. Descriptive data:

Group n = ()	HT in	BM lbs	PU Reps	SU Reps	Pullups Reps	2MR Secs	2MR-YR Secs	APFT Pts	APFT-YR Pts	FMP Min	IOCT Day Secs	IOCT-YR Secs
ALL (230)	71 (2.8)	180 (22.6)	74.1 (12.1)	69.5 (11.5)	11.2 (4.2)	821.4 (60.1)	793 (51.9)	270.6 (31.0)	316 (32)	122.5 (14)	216.4 (30.7)	NA*
Top 10% FMP (23)	70.6 (2.7)	178.6 (20.6)	74.4 (11.1)	75.5 (9.0)	12.0 (4.1)	781.2 (47.3)	752 (42.1)	290.8 (26.4)	335 (29.4)	100.9 (5.1)	199.7 (26.5)	156.3 (14.4)
Bottom 10% FMP (23)	70.6 (2.3)	177.6 (15.9)	65.5 (8.3)	62.0 (9.1)	8.7 (3.2)	879.2 (64.9)	841.1 (48.7)	241.3 (24.1)	291.5 (25.1)	149.7 (8.8)	241.6 (36.4)	181 (15.6)

*Data unavailable, institutional data reveals mean IOCT time of ~180 secs.
DISCUSSION: With 35-lb load, body mass & pull-ups did not influence FMP, whereas aerobic ability was the most potent factor. A postulated "GRIT" factor, attaining a performance badge on the IOCT (<2:38 min:sec); although a high incidence of success attainment (15/23 top 10% vs 2/23 bottom 10%), did not increase the variance in a two-factor regression model. **CONCLUSIONS:** In the present study, more robust strength measures were unfortunately not attained and future research should examine these and other physiological parameters. For soldiers desiring success on an 8.5 mile FMP with a 35-lb load, achieving & maintaining a career 2MR of at least 12:30 appears to enhance FMP and lead to a more enhanced physical profile related to military school selection criteria.

Change in Measures of Moral Function Following Acute Bouts of Marine Corps Martial Arts Training

Jacob A. Siedlik[1], John P. Vardiman[2], Jake A. Deckert[3], Trent J. Herda[3], Joseph P. Weir, FACSM[3], Aaron W. Clopton[3], Philip M. Gallagher[3]. [1]*Creighton University, Omaha, NE.* [2]*Kansas State University, Manhattan, KS.* [3]*University of Kansas, Lawrence, KS.*
(No relevant relationships reported)

The Marine Corps Martial Arts Program (MCMAP) is designed to be delivered in an environment characterized by periods of intense physical activity and psychological stress. The purpose of the program is to prepare Marines for the stress and complex ethical decisions encountered in the modern-day battlefield. However, how multifactorial stressors effect ethical decision-making processes is not well understood. **PURPOSE:** To quantify changes in ethical decision-making following MCMAP training. **METHODS:** Fifty-five, active duty, newly enlisted U.S. Marines (Males: n =

37; age = 19 ± 1 yr; height = 176 ± 7 cm; mass = 74 ± 7 kg; Females: n = 18; age = 20 ± 2 yr; height = 164 ± 6 cm; mass = 61 ± 6 kg) volunteered for this investigation. Nine cohorts were recruited over a 2-year period with each cohort observed 3 times with 3 weeks between each visit. Serial blood samples for cortisol, norepinephrine (NE), and epinephrine (EPI) were collected before training and during the recovery period (Immediate Post IP), 15, 30, 45 and 60min). Endocrine measures were quantified using summary measures and analyzed with RMANOVAs. To quantify moral function, the Moral Functioning Continuum (MFC) was adapted from the Continuum of Injurious Acts. The MFC represents a hierarchy from less severe to more severe aggressive actions. The subjects responded on a continuum as to whether they consider acts in hypothetical situations as legitimate or appropriate with scores assessed before training, IP, 30, and 60 min. Moral function variables were analyzed using a multilevel regression models. **RESULTS:** There were no significant differences observed for the summary or baseline endocrine measures. Moral Intention exhibited an acute response to training with significantly impaired decision making observed immediately post training. Moreover, both Moral Intention and Moral Judgment worsened over the visits suggesting a chronic impairment related to time in training. **CONCLUSION:** We have identified a functional change in ethical decision-making following acute bouts of MCMAP. We would suggest future work not only examine the transient changes in decision making in response to an acute stressor, but also examine how time in service changes the individuals ethical decision-making process.

Prediction of Lower Extremity Musculoskeletal Injuries for Naval Special Warfare Operators: A Machine Learning Approach

Kim Beals, Karen A. Keenan, Nicholas J. Kissel, Lucas Mentch, Wuxin Yang, Bradley C. Nindl, FACSM, Qi Mi. *University of Pittsburgh, Pittsburgh, PA.* (Sponsor: Bradley C Nindl, FACSM)
(No relevant relationships reported)

Lower extremity (LE) musculoskeletal injuries (MSI) are a common and costly occurrence in US NAVY Sea, Air, and Land (SEALs) Operators. Understanding the risk factors associated with LE MSI is an important step in designing injury prevention programs. **PURPOSE:** To develop a robust mathematical model to predict LE MSI in SEAL Operators. **METHODS:** 285 subjects (age: 26 ± 5 yrs, height: 179 ± 7 cm, weight: 85 ± 9 kg) participated in testing, including: LE muscular strength and flexibility; balance; body composition; anaerobic power/capacity; and aerobic capacity (VO2max). Medical charts were reviewed for LE MSI 365 days following laboratory testing. The correlated variable sets were identified using Hierarchical Clustering Analysis (HCA). Important features then were selected from the clusters and modeled with regression trees wherein output (predictions) were interpreted as the probability of injury for each individual. To classify observations, a decision threshold was defined that minimized the false positive rate (FPR) conditional on a true positive rate (TPR) of approximately 90% whenever all available variables were utilized. Individuals with predicted probabilities above this threshold were classified as injured. Variables selected in the final models were chosen in a forward fashion, with individual predictors that reduced the FPR without significantly lowering the TPR added to the model. The procedure stopped when no remaining predictor variables were able to produce a model that outperformed the current iteration. **RESULTS:** LE MSI rate was 13/285 or 4.5%. Each cluster of feature sets from HCA consisted of variables mostly from the same laboratory test category. The final regression tree model contained knee flexion and left knee extension strength (normalized to body weight), fat-free mass (kg), and hamstring flexibility, as the best predictors (TPR of 92.3% and FPR of 2.9%). **CONCLUSION:** Knee strength, fat-free mass, and hamstring flexibility were important risk factors identified in the machine learning algorithm that accurately classified SEAL Operators with LE MSKI. Alternative high prediction models also can be created using this modeling framework on different variable sets. **Supported by ONR N00014-11-1-0929**

Abdominal Circumference Measurements in a US Navy Active Duty Population

Katherine M. Wilson[1], Douglas M. Jones[1], Matthew P. Mandel[1], Rebecca S. Weller[2], Melissa D. Laird[3], Jay H. Heaney[3]. [1]*Leidos, San Diego, CA.* [2]*Innovative Employee Solutions, San Diego, CA.* [3]*NHRC, San Diego, CA.*
(No relevant relationships reported)

Abdominal obesity is a major risk factor for multiple diseases including Type II diabetes, hypertension, heart disease, and stroke. One of the quickest and most economical means of measuring abdominal obesity is abdominal circumference (AC). There are four sites most commonly measured for AC; iliac crest (IC), mid-abdominal (between IC and lowest rib), umbilicus (UMB), and the smallest region of the waist. Circumference at the IC is the current site used by the US Navy for those sailors who

do not pass height and weight standards. However, use of a more easily defined site, such as the UMB, may improve reliability, especially on sailors whose IC may be difficult to palpate.

Purpose: The purpose of this study was to determine if obtaining circumference at the UMB is a valid measure for AC in the US Navy active duty population.

Method: UMB and IC circumference measurements were taken on 115 subjects, (79 male and 36 female), using a retractable tape measure on the skin. Trained researchers took measurements at end of expiration with the tape parallel to the floor while ensuring tape tension did not cause indentation of the skin. Three measurements were taken at both sites per individual by the same researcher. Averages were calculated and used for analysis.

Results: Mean circumference for males was 35.3 ± 3.8 inches at UMB and 35.7 ± 3.6 inches at IC. Mean circumference for females was 33.8 ± 4.1 inches at UMB and 35.3 ± 3.8 inches at IC. There was a high correlation between UMB and IC measurements ($r^2 = .981$ and $.966$ for males and females, respectively). For intra-rater reliability, interclass correlation coefficients (ICC) for the three measurements for males were ICC = .996 at both UMB and IC. For females correlations were ICC = .992 at UMB and .986 at IC.

Conclusion: High correlation between sites suggests UMB can be a valid substitute for IC when measuring AC. The high ICC for both sites supports reproducibility of AC measures at these sites. The ease of locating the UMB eliminates the need to palpate correct IC measurement site. Based on these results, use of the UMB as the Navy standard to obtain an AC measurement may be preferable as it can be less intrusive and more easily located.

2964 Board #247 June 1 3:30 PM - 5:00 PM

Evaluation of The US Navy's Physiological Heat Exposure Limits during Deployment in The Persian Gulf

Douglas M. Jones[1], Katherine M. Wilson[1], Eric Duckworth[1], Magnus Perkins[2], Melissa Laird[3], Jay H. Heaney[3]. *[1]Leidos Inc., San Diego, CA. [2]USS Nimitz, Bremerton, WA. [3]Naval Health Research Center, San Diego, CA.*
(No relevant relationships reported)

The U.S. Navy uses Physiological Heat Exposure Limits (PHEL curves) to reduce heat stress casualties aboard naval vessels. The PHEL curves, established in the 1960s, have not been examined over several decades of advancements in shipboard technology. PHEL curves ranging from I to VI (low to high metabolic work), are assigned to each job which, in combination with ambient workspace conditions, determine allowable stay times in a particular workspace. Due to advancements in shipboard design, it is probable that the metabolic rate while performing certain shipboard duties has changed, which could reduce the accuracy of current PHEL assignments.

PURPOSE: To compare predicted and measured metabolic rates of scullery personnel aboard an aircraft carrier deployed in the Persian Gulf.

METHODS: Eight military personnel (age: 22 ± 2 yrs, ht: 165 ± 6 cm, wt: 71.8 ± 11.9 kg) assigned to shipboard scullery work (designated PHEL V) had their metabolic rate predicted based on established PHEL guidance. They then performed routine scullery work for the duration of their shift while measurements of oxygen consumption (VO_2), heart rate (HR), and core temperature (T_{core}) were collected for 3-4 hours. Measurements were collected again during a second shift to determine consistency of metabolic rates. Predicted and measured VO_2 recordings, converted to watts (W), were then compared to determine accuracy of existing PHEL curve assignments.

RESULTS: VO_2 measurements between the first and second shifts were not different (229 ± 33 vs 225 ± 31 W; p =.72), suggesting that duties performed were consistent. However, the predicted metabolic rates of the current PHEL assignments were significantly higher than those actually measured (240 ± 22 vs 227 ± 28 W; p = .03). Mean T_{core} of scullery personnel during both shifts was $37.4 \pm 0.2°C$, with the highest T_{core} recorded at 38.3°C. Mean HR was 96 ± 12 bpm, equivalent to $49 \pm 6\%$ of age-adjusted maxHR.

CONCLUSION: Findings from this limited data set identify a discrepancy between current PHEL curve assignments and measured metabolic rates in scullery personnel, likely resulting from task automation. Further work on this issue is warranted, as discrepancies between predicted and actual work rates could alter workspace allowable stay times and reduce the frequency of required workspace heat stress monitoring.

2965 Board #248 June 1 3:30 PM - 5:00 PM

Fitness and Body Composition Characteristics of Special Weapons and Tactics Team Members of Law Enforcement

Rafael A. Alamilla[1], Javier D. Romero[1], Kong Tu[1], Christina N. Cooper[2], Gary W. Berwick III[1], Matthew C. Jackson[1], Guillermo Escalante[1], Nicole C. Dabbs[1], Jason Ng[1]. *[1]California State University, San Bernardino, San Bernardino, CA. [2]California State University, Long Beach, San Bernardino, CA.* (Sponsor: Bryan Haddock, FACSM)
(No relevant relationships reported)

The job demands of members in Special Weapons and Tactics (SWAT) teams of law enforcement agencies involve heavy exertion, yet it remains uncertain whether this special population has adequate fitness levels to sustain high intensity work efforts. **PURPOSE:** To examine the fitness and body composition characteristics of SWAT members. **METHODS:** Fourteen healthy men (mean $\pm$ SD; age = 33.1 ± 5.7 y, height = 180.7 ± 5.4 cm, mass = 90.6 ± 10.0 kg) from SWAT teams of local law enforcement agencies completed five health-related fitness assessments. These included 1) a total body dual-energy x-ray absorptiometry (DEXA) scan to determine lean body mass (LBM), fat mass (FM), bone mass (BM), percent body fat (%body fat), bone mineral density (BMD), and a BMD T-score; 2) a one-repetition maximum (1RM) test of upper body strength on a bench press; 3) a graded exercise test on a treadmill to measure maximum oxygen uptake (VO_{2max}); 4) a YMCA submaximal bench press test to measure upper body muscular endurance; and 5) the Canadian trunk forward flexion test to measure hamstring flexibility. **RESULTS:** Participants had an LBM of 70.1 ± 7.2 kg, FM of 17.2 ± 5.5 kg, BM of 3.7 ± 0.6 kg, %body fat of $18.7 \pm 4.7\%$, a BMD of 1.3 ± 0.1 g·cm^{-2}, and a T-Score for BMD of 1.06 ± 1.15. Absolute and relative 1RM on the bench press were 120.9 ± 14.5 kg and 1.35 ± 0.22 kg·kg^{-1}, respectively. VO_{2max} was 47.9 ± 5.5 ml·kg^{-1}·min^{-1}. Participants completed 52 ± 15 repetitions on the YMCA submaximal bench press test. Distance reached on the Canadian trunk forward flexion test was 30.7 ± 5.7 cm. **CONCLUSION:** According to ACSM normative data for 30-39-year-old males, participants' body fat percentage is classified as fair. According to normative data from the World Health Organization, this population displayed a higher-than-average BMD T-score compared to other 30-year-old men. Participants demonstrated very good to excellent levels of cardiorespiratory fitness, muscular strength, muscular endurance, and flexibility, suggesting their fitness levels are appropriate for the vigorous exertions involved in this occupation. This information is beneficial for fitness professionals who train the tactical population. Partially Supported by NIGMS Training Grant GM083883

2966 Board #249 June 1 3:30 PM - 5:00 PM

Body Composition Indices to Classify Activity Level in Air Force Men and Women

Guy D. Leahy[1], Todd A. Crowder[2], Jerry L. Mayhew[3]. *[1]Kirtland Air Force Base, Kirtland AFB, NM. [2]United States Military Academy, West Point, NY. [3]Truman State University, Kirksville, MO.*
(No relevant relationships reported)

The search continues for a simple, accurate means of classifying the best body build and/or composition of active duty military personal. Various branches of the military consider body composition assessment an integral part of determining combat readiness. Heretofore, branches of the military have relied on a tape measure test to estimate body fat (%fat), which has not proven entirely successful. Recent interest has increased in body composition ratios to discern proportions of muscle and fat to identify personnel with greater military-task performance potential. **PURPOSE:** To evaluate the ability of selected body composition ratios to differentiate among activity level groups of active duty Air Force personnel. **METHODS:** Air Force men (n = 604) and women (n = 343) were evaluated for body composition using air displacement plethysmography (BodPod®, Life Measurement) to identify fat mass (FM), fat-free mass (FFM) and %fat. Participants were stratified into 4 age groups, determined by decade, with individuals <20 yrs (n = 13) combined with the 20-29 yr-old group and into 4 activity groups (sedentary, low active, active, and very active). Height and weight were used to calculate BMI = kg/m^2. Fat-free mass index (FFMI) and fat mass index (FMI) were determined by evaluating each component relative to height (m^2). Body type was estimated from the ratio of FFMI:FMI. **RESULTS:** An activity category x age group (4×4) MANOVA was performed on each sex. In men, BMI, FMI, and %fat were significantly different (p<0.001) among activity groups and age groups, with no significant interactions. In women, BMI, FMI, and %fat were significantly different (p<0.007) among activity groups. Among age groups, FFMI, %fat, and body type were significantly different. No interactions were significant. Discriminant analysis identified FM as the best discriminator of activity group in each sex, but the success rate of each category was <10%. **CONCLUSION:** Body composition indices do not appear to offer a simple solution to identifying military

personnel with the proper proportion of FFM to FM commensurate with active duty status in either sex. Additional research may need to concentrate on the relationship between body composition indices and physical performance tasks.

Morphological Characteristics Associated with Successful and Non-Successful Performance on Occupationally Specific, Operationally Relevant Physical Tasks

Neal Baumgartner[1], Matthew F. Gruse[1], William F. Wilson[2]. *[1]US Air Force Exercise Science Unit, San Antonio, TX. [2]US Air Force Personnel Center Analysis Branch, San Antonio, TX.*

(No relevant relationships reported)

The US Air Force has expanded its research and development efforts of occupationally specific, operationally relevant (OSOR) physical fitness tests and standards. Knowledge of factors affecting success on OSOR physical tasks can provide valuable information for selection, training and operations. **PURPOSE**: We compared the morphological characteristics associated with success and non-success on operational physical tasks to inform targeted selection processes and training programs for physically demanding career fields. **METHODS**: A bona fide occupational requirements physical demand analysis was conducted for six Battlefield Airmen career fields. Analysis identified operationally-required critical physical tasks, which provided the basis for developing physical task simulations (PTSs). Career field senior leaders and experience operators reviewed PTS data to determine an operationally relevant minimum effective time (MET) for task success. Measures of morphology (stature, body mass, body mass index, and fat-free mass, fat mass, and relative body fat from both bioelectric impedance and skinfolds) and performance on 14 PTSs were recorded ($n = 171$, 62 female; age, 28.5 ± 5.6 yrs). Performance was successful if the subject both completed the PTS and met the MET. **RESULTS**: Successful performers were significantly different than non-successful performers for all morphological characteristics measured (stature 176.7 cm - 167.8 cm, body mass 82.3 kg - 70.8 kg, body mass index 26.3 kg/m2 - 25.1 kg/m2, fat-free mass 69.6 kg - 55.2 kg, fat mass 12.7 kg - 15.7 kg, and relative body fat 15.2% - 22.2%) across nearly all PTSs. Number of PTSs significance ($p < .01$) reached equals: stature 14 of 14 PTSs, body mass 13, body mass index 10, fat-free mass 14, fat mass 10, and relative body fat 11. **CONCLUSION**: The study showed that significant differences in morphology exist between US Airmen who successfully complete and those that do not complete operational physical tasks inherent to physically demanding military occupations such as USAF Battlefield Airmen.

Validity of Critical Velocity Regression Equation to Estimate Weighted Sprint Performance

Nathan D. Dicks[1], Tammy V. Joe[1], Kyle J. Hackney[1], Robert W. Pettitt, FACSM[2]. *[1]North Dakota State University, Fargo, ND. [2]Rocky Mountain University of Health Professions, Provo, UT.* (Sponsor: Robert W. Pettitt, FACSM)

(No relevant relationships reported)

The maximal aerobic steady-state has been estimated for running using the critical velocity (CV) concept. The CV metric has been associated with occupational and combat-specific performance measures. Tactical professionals are often burdened with load carriage that takes the form of duty gear, equipment, weapons, body armor, and protective gear. Thus, a model of high-intensity interval training (HIIT) prescribed using the CV concept to specifically increase CV would be of considerable use for improving tactical performance. **PURPOSE:** We investigated the validity of a recently developed equation for predicting sprinting times of various tactical loads based upon performance of a running 3-min all-out exercise test (3MT). **METHODS:** 13 recreationally trained participants completed the running 3MT to determine CV and finite running capacity for running velocities exceeding CV (D'). Two subsequent counterbalanced loaded sprints of 800 and 1000 m distances with 20 and 15% of their body mass, respectively, were evaluated. Estimated times (t, sec) for running 800 and 1000 m with a tactical load was derived using t = $(D - D')$/CV, where the CV was adjusted for added load using the following regression equation: original CV + (-0.0638 x %load) + 0.6982, D was 800 or 1000 m, and whole percentage load was ~15 or 20% of the participant's body mass. **RESULTS:** From the 3MT, CV (3.80 $\pm$ 0.5 m/s^{-1}) and D' (200 ± 49.88 m) values were determined. The typical error of predicting actual time for the 800 and 1000 m loaded sprints was 5.6 and 10.1 s, with corresponding ICCs of 0.95 and 0.87, and coefficient of variations of 2.9 and 4.3%. The regression model (188.7 ± 25.4 s) underestimated actual (195.2 ± 22.4 s) sprint times for the 800 m distance with ~20% load carriage (t = 2.96, p = 0.01). Similarly, estimated (229.5 ± 27.1 s) underestimated actual (244.9 ± 24.2 s) sprint times for the 1000 m distance with ~15% load carriage (t = 3.95, p < 0.01). The effect size differences between estimate and actual sprint times were small (0.27) and moderate (0.60) for 800 and 1000 m, respectively. **CONCLUSION**: The adjustment to CV

through the regression equation yields small to moderate overestimates of maximal loaded sprint times for distances of 800 and 1000 m. Whether such errors remain pervasive for prescribing HIIT is unclear and is a research problem worth exploring.

Effects of Wrist Cooling on Recovery from Exercise-Induced Heat Stress with Firefighting Personal Protective Equipment

Monique D. Dudar, Ronald Caruso, Emily Schlicht, Kelsey Denby, Alexs A. Matias, Stephen J. Ives. *Skidmore College, Saratoga Springs, NY.*

(No relevant relationships reported)

Enhancing recovery from firefighting is paramount due to the high cardiovascular strain associated with firefighting compounded by the encapsulating personal protective equipment (PPE), which can result in severe fatigue and/or cardiac incidents. Recent work suggests that wrist cooling via DhamaSPORT^{tm} band might enhance recovery from live firefighting, but work in a controlled setting with measures of core temperature is needed. **PURPOSE:** To determine the effects of the DhamaSPORT^{tm} cooling band on recovery from Exercise-Induced Heat Stress associated with wearing PPE. **METHODS:** In 11 male participants (23 ± 5 years old, 176 ± 4 cm tall, 84 ± 12 kg mass, BMI 27 ± 3 kg/m^2) we measured heart rate (HR), core temperature (T_{CO}), thermal sensation (TS), and rating of perceived exertion (RPE) during 30 min of walking exercise (3 mi/hr, 5% grade) in full PPE and SCBA (~20kg), and in a single blind, counterbalanced, crossover design, we assessed the recovery from exercise with a DhamaSPORT^{tm} cooling band placed on their wrist but only activated during one trial (control vs. cool). Pre-exercise, and at recovery, heart rate variability (HRV; log transformed root mean square of successive differences; LnRMSSD) and fatigue (visual analog scale; VAS) were recorded. **RESULTS:** At rest no differences were observed between trials for HR, HRV, VAS, TS, or T_{CO}. During exercise, HR (145 ± 22 vs. 148 ± 19 bpm), T_{CO} (37.8 ± 0.3 vs. 37.8 ± 0.3 °C), TS (6.4 ± 0.8 vs. 6.5 ± 0.4), or RPE (4.9 ± 1 vs. 5.0 ± 1) were not different between trials (all, $p > 0.05$, control vs. cool). Time to 50% recovery (46 ± 41 vs. 43 ± 41 sec) and time to complete recovery (519 ± 275 vs. 624 ± 289 sec) and were not significantly different with the band active (both, $p > 0.05$, control vs. cool). During recovery, there was no significant differences in T_{CO} or HR ($p > 0.05$). At recovery, T_{CO} (37.6 ± 0.3 vs. 37.8 ± 0.3°C, $p = 0.07$), HR (70 ± 10 vs. 75 ± 11 bpm, $p = 0.06$), and fatigue VAS (2.9 ± 2.0 vs. 2.5 ± 2.5, $p = 0.08$) tended to be lower, while HRV (LnRMSSD; 4.1 ± 0.9 vs. 4.2 ± 0.6), and TS (3.7 ± 0.8 vs. 3.8 ± 0.8) were relatively similar with the band active ($p > 0.05$, control vs. cool). **CONCLUSION**: Use of the DhamaSPORT^{tm} cooling band after exercise-induced heat stress might enhance recovery of core temperature, fatigue, and HR, without notable impact on heart rate variability or thermal sensation. Supported by: DhamaUSA.

Longitudinal Changes in Dynamic Balance Ability Among Firefighter Recruits: A Multivariate Analysis Perspective

David J. Cornell[1], Stacy L. Gnacinski[2], Kyle T. Ebersole[1]. *[1]University of Wisconsin - Milwaukee, Milwaukee, WI. [2]Drake University, Des Moines, IA.* (Sponsor: Terry J. Housh, FACSM)

(No relevant relationships reported)

Research has demonstrated a link between dynamic balance ability, assessed via the star excursion balance test (SEBT), and musculoskeletal injury (MSKI) risk. Previous research also suggests that changes in health and fitness occur among firefighter recruits as they progress from their training academy to active-duty service. However, similar longitudinal changes in dynamic balance ability have yet to be examined. **PURPOSE:** To observe longitudinal changes in dynamic balance ability among firefighter recruits. **METHODS:** 27 male firefighter recruits enrolled in the same training academy volunteered to participate in the current study (mean $\pm$ SD, age = 29.9 ± 4.1 yrs; height = 179.8 ± 4.6 cm; body mass = 87.2 ± 9.7 kg). SEBT data were collected at the beginning (W1) and end (W14) of their firefighter training academy, as well as at the end of their probationary period (W38). SEBT reach distances were normalized to limb length and averaged between right and left reaches in the anterior (SEBT$_{ANT}$), posterolateral (SEBT$_{PL}$), posteromedial (SEBT$_{PM}$) directions. α = 0.05 determined statistical significance for all analyses. **RESULTS:** An omnibus RM MANOVA revealed a significant and large effect of time on dynamic balance ability ($F_{6,100} = 13.463$, $\Lambda = 0.306$, $\eta^2_p = 0.447$, $P < 0.001$). Results of the *post hoc* RM

ANOVAs demonstrated significant main effects of time on $SEBT_{ANT}$ ($F_{2,52}$ = 29.280, $P < 0.001$), $SEBT_{PL}$ ($F_{2,52}$ = 12.856, $P < 0.001$), and $SEBT_{PM}$ ($F_{2,39.754}$ = 4.460, P = 0.026) reaches. Follow-up pairwise comparisons further revealed that from W1 to W14, $SEBT_{PL}$ and $SEBT_{PM}$ significantly increased, while a significant change was not observed in $SEBT_{ANT}$. From W14 to W38, significant decreases were observed in all three SEBT reach directions. From W1 to W38, a significant decrease was observed in $SEBT_{ANT}$, but no significant changes were observed in the $SEBT_{PL}$ and $SEBT_{PM}$. **CONCLUSIONS:** Results indicate that this firefighter recruit training academy yielded significant improvements in dynamic balance ability, particularly in $SEBT_{PL}$ and $SEBT_{PM}$ reach directions. However, these adaptations were lost before recruits finished their probationary period. Job challenges may influence the capability for new firefighters to maintain the improvements in dynamic balance ability gained during their recruit training academy, increasing their MSKI risk.

Physical Activity Intensity Of Brazilian Militar Firefighters During A 24h On-duty Period

Leonardo Correa Segedi[1], Daniel Saint Martin[2], Edgard Koenig Soares[2], Maciel Rosenkranz Nogueira[1], Keila Elizabeth Fontana[2], Gilliard Lago Garcia[2], Maria Korre[3], Guilherme Eckhardt Molina[2], Denise L. Smith[4], Stefanos N. Kales[3], Luiz Guiherme Grossi Porto[5]. [1]University of Brasília and Brasília Fire Department and GEAFS, Brasília, Brazil. [2]University of Brasília and GEAFS, Brasília, Brazil. [3]Havard T.H Chan School of Public Health, Boston, MA. [4]Departament of Health and Exercise Sciences, Skidmore College, Saratoga Springs, NY. [5]University of Brasilia and Havard T.H. Chan School of Public Health, Boston, MA and GEAFS, Brasília, Brazil.

(No relevant relationships reported)

Firefighters' job activities expose firefighters to multiple physical stressors. In Brasilia Fire Department wildland firefighters are a specialized group that perform primarily wildland fire suppression and other tasks, such as recues. **PURPOSE**: To evaluate the physical activity (PA) intensity of wildland firefighters during a routine 24-hour on-duty period. **METHODS**: We evaluated 26 wildland firefighters, aged 34.6±6 years, with BMI 25.3±2.9 kg/m² and VO_{2max} of 45.9±3.9 mL(kg.min)$^{-1}$. Each participant wore an Polar® heart rate (HR) transmitter with an ActiGraph accelerometer for HR data storage during a 24-hour period. Maximum HR (MHR) was estimated by Tanaka formula. PA intensity was defined in HR zones: very heavy (≥ 94% of MHR); heavy (77% - 93% of MHR); moderate (64% - 76% of MHR) and light (≤ 63% of MHR). Absolute and relative time spent in each zone were compared between those who participated or not on at least one episode of wildland fire suppression (Mann-Whitney test). Volunteers reported main duties on a written log. **RESULTS:** 17 participants (65.3%) accumulated at least 30min/day of moderate to vigorous physical activity (MVPA). 50% of the volunteers responded to wildland fires and classified those activities as light (31%) or moderate intensity (69%). Absolut and relative time in each HR zone were similar between those who responded or not to wildland fires (p>0.05). 21 (81%) reached the HR of heavy intensity and 12 (46%) the very heavy one. Table 1 shows descriptive data.

Table 1: median (min - max) time of HR in different physical activity intensities (n = 26).

	Absolute (min)	Relative (%)
Light	1083.8 (562.5 - 1315.0)	95.5 (86.9 - 99.9)
Moderate	23.9 (3.3 - 140.6)	2.3 (0.3 - 11.1)
Heavy	15.7 (0.0 - 65.8)	1.3 (0.0 - 5.6)
Very heavy	0.0 (0.0 - 35.0)	0.0 (0.0 - 4.5)
Wear time	1180.5 (639.0 - 1323.0)	

Conclusion: Firefighters spent most of their time in light activities, including sedentary and resting periods. However, >80% of the volunteers interspersed the light activities with periods of MVPA. No firefighter reported any heavy demand during the monitored days. New studies including firefighters' activities during huge wildland fires are needed.

Firefighting Influences Cognitive Performance: The Heart of the Matter

Tina A. Greenlee[1], Daniel R. Greene[2], R. Mia Kaim[3], Annmarie Chizewski[3], Kathryn M. Rougeau[4], Gavin P. Horn[5], Steven J. Petruzzello, FACSM[3]. [1]The Geneva Foundation, San Antonio, TX. [2]Augusta University, Augusta, GA. [3]University of Illinois at Urbana-Champaign, Urbana, IL. [4]Oakland University, Rochester, MI. [5]Illinois Fire Service Institute, Champaign, IL.

(No relevant relationships reported)

Firefighters (FFs) work in hazardous, volatile environments with considerable physical and mental demands that might influence cognitive performance. The nature and extent of such influence requires examination. PURPOSE: Determine the influence of a night-burn FF drill on new-recruit FFs' perceptual sensations (thermal, respiratory, effort), physical workload (heart rate; HR), and cognitive performance (modified Flanker task), while identifying individual risk factors. METHODS: New-recruit, male FFs (N=28; 24.96 ± 4.2 yrs) participated in a live-fire night-burn drill (48:54±03:46 mins) as part of a 6-wk training program. This involved emergency response, fire attack, and search and rescue. Aerobic fitness was estimated from 1.5-mi run time. Cognitive behavioral performance on a modified Flanker task and perceptual states (thermal sensation, RPE, respiratory distress, feelings, felt arousal, fatigue, anxiety) of each FF were measured on a separate baseline day, as well as pre- and post-firefighting (Post-0, End). HR was continuously recorded throughout. RESULTS: After accounting for baseline, M HR during drill predicted variance in post-task affect (state anxiety: 24.5%, P= 0.01); TS: 18.1%, P= 0.025; FS: 14.6%, P= 0.046); VAS nervousness: 17.4%, P= 0.028). M HR during drill also predicted cognitive performance Post-0 for Flanker Accuracy on all trials (16.8%, P= 0.033). FS change from Pre to Post-0 also explained Accuracy for all trials (14.4%, P= 0.047). 1.5-mi run time predicted variance in Post-0 Flanker SD for all trials (20.2%, P= 0.016). VAS fatigue change from Pre to Post-0 also explained Flanker SD (16.5%, P= 0.032). CONCLUSIONS: Simple, on-line tracking of HR may be able to help incident commanders recognize FFs who, indicated by greater relative HR during emergency response, may have diminished decision-making capacity on the fireground. Other factors (e.g., trait anxiety, dispositional resilience) may influence physical effort put forth in an emergency scenario and may put certain FFs at higher risk for making errors. Future research should determine trainability of such factors in order to enhance performance and, ultimately, safety for FFs. Manifestation of such changes in cognitive performance, in terms of decision making during a live-fire emergency, needs further investigation.

2973   Board #256   June 1 3:30 PM - 5:00 PM

Firefighting Exercises, Heat Stress, And The Cardiovascular System In Recovery

Sarah Bergstrom[1], Summer Cook, FACSM[1], Robert Kenefick, FACSM[2], Timothy Quinn, FACSM[1]. [1]University of New Hampshire, Durham, NH. [2]U.S. Army Research Institute of Environmental Medicine, Natick, MA. (Sponsor: Timothy Quinn, FACSM)

(No relevant relationships reported)

Sudden cardiac death is a common cause of mortality in the firefighting (FF) community. This population has many lifestyle and health risk factors that contribute to cardiovascular disease development; therefore, it is necessary to focus on cardiovascular variables and heat stress in this population. **PURPOSE:** To examine multiple cardiovascular variables in a firefighting cohort during recovery from firefighting exercises to investigate the relationships between recovery time and heat stress as well as body temperatures and indices of arterial stiffness. **METHODS:** A 20-minute exercise bout consisting of aerobic and resistance exercise was performed by 15 healthy career firefighters (age=32.0±7.2 y; ht=1.8±0.1 m; wt=92.7±18.4 kg; VO_{2max} = 40.8±6.5 ml kg^{-1} min^{-1}) while wearing personal protective equipment (PPE). Two conditions were studied: HOT=40°C, 30% humidity; CON=16°C, 78% humidity). Electrocardiography, arterial stiffness, HR, blood pressure, core (T_c), skin (T_{sk}), and temperature gradient (T_{grad}) measurements were obtained pre, during, and 5,10,20,40,60 min post-exercise. Subjects sat for a 60-min recovery while measurements were taken. A repeated measures MANOVA was used to test for differences between the conditions and over time. **RESULTS:** HR was not different at rest between conditions (p=0.577). HOT HR was higher than CON at 5 and 10 min into recovery (p= 0.003, p=0.009). HOT HR was higher than pre (70±14bpm) throughout recovery (80±12bpm;p<0.05). Aortic Augmentation Index (AIx) showed a time effect at 5, 20 min of recovery (p=0.019, p=0.005). Subendocardial Viability Ratio (myocardial perfusion) did not change in either condition over time. The T_{grad} showed a time effect with CON T_{grad} lower than pre throughout exercise and HOT T_{grad} lower than pre throughout exercise and 5 min into recovery (p<0.05). **CONCLUSION:** The increased HR and convergence of T_c and T_{sk} seen in this short bout of exercise and in one stage of recovery with relatively mild heat stress suggest a need for further investigation in this population and PPE. Specifically, it is necessary to relate body temperature and arterial

stiffness as cardiovascular risk factors while performing multiple bouts of exercise with shorter recovery times in higher environmental temperatures while wearing PPE to better simulate live FF.

2974   Board #257   June 1 3:30 PM - 5:00 PM

Effectiveness Of Cold, Wet Towels As A Cooling Modality For Fireground Rehab

Rebeccah L. Stansbery, Lindsey N. Russo, David Hostler, FACSM. *University at Buffalo, BUFFALO, NY.* (Sponsor: Dave Hostler, FACSM)

(No relevant relationships reported)

Firefighters experience a rise in body temperature during exertion. The use of active cooling modalities during fireground rehab is necessary to lower elevated core body temperatures in order to avoid heat stress related incidents. The use of cold, wet towels placed around the head and neck are listed as an effective cooling modality in the NFPA standard in spite of limited evidence of effectiveness. **PURPOSE**: We tested the hypothesis that the thermal transfer of cold, wet towels placed around the head and neck would be ineffective at promoting recovery of core body temperature when compared to forearm immersion in 10°C water.
METHODS: Fourteen healthy subjects (6 female) aged 22.1 ± 1.6 y completed two separate experimental trials counterbalanced for cooling modalities of cold, wet towels (CT) and forearm immersion (FI). Subjects wore full firefighter turnout gear while completing two rounds of a firefighting-based exercise circuit in 40°C and 60% relative humidity. Five minutes following exercise completion, subjects were cooled for 30 min with the assigned modality in the hot, humid environment. Heart rate, core body temperature, blood pressure, and perceptual scales were recorded at various time points from baseline through the completion of active cooling.
RESULTS: Heart rate (CT: -6.54 ± 6.86 bpm, FI: -28.36 ± 10.37 bpm, p< 0.01) and core temperature (CT: -0.05 ± 0.17 °C, FI: -0.60 ± 0.50 °C, p<0.01) decreased more during FI. At the end of the cooling period, ratings of perceived recovery (p<0.05), thermal sensation (p<0.01), thermal comfort (p<0.01), and sweating sensation (p<0.01) improved for both cooling modalities but favored forearm immersion.
CONCLUSIONS: Cold, wet towels placed around the head and neck following exertional heat stress did not provide adequate recovery of heart rate or core temperature in a hot humid setting.

2975   Board #258   June 1 3:30 PM - 5:00 PM

The Effect of Personal Protective Equipment on Firefighter Occupational Performance

Ashley Y. Lesniak[1], Haley Bergstrom[2], Jody L. Clasey[2], Arnold J. Stromberg[2], Mark Abel[2]. *[1]Lynchburg College, Lynchburg, VA. [2]University of Kentucky, Lexington, KY.*

(No relevant relationships reported)

PURPOSE: To determine the effect of load carriage (LC) and the self-contained breathing apparatus (SCBA) on occupational performance of structural firefighters. METHODS: Twenty-one professional male structural firefighter recruits (Age: 28.6 ± 4.3 yr; Height:178.6 ± 7.2 cm; Body mass: 94.1 ± 15.4 kg; Body fat: 17.8 ± 8.4%) participated in the study. Occupational physical ability was assessed by time to complete a simulated fire ground test (SFGT). The SFGT was composed of a stair climb, charged hose drag, equipment carry, ladder raise, forcible entry, search, and victim rescue. Subjects performed 2 familiarization trials and 3 trials of a SFGT in different conditions: physical training clothes only (PT), wearing turnout gear and an SCBA (but not breathing through the SCBA (LC)), and wearing turnout gear and breathing through the SCBA (SCBA). RPE was also measured. Heart rate, blood lactate, and perceived exertion were assessed during the SFGT. Repeated measures ANOVAs were used to identify differences among trials. To describe within group changes, relative difference scores were calculated as follows: % difference = (([experimental trial outcome – PT outcome] / PT outcome) x 100). RESULTS: The SCBA trial took 44.5 ± 15.5% longer (345.9 ± 43.7s; p<.001) and the LC trial took 38.3 ± 12.6% longer (331.2 ± 39.3s; p<.001) than the PT trial (241.0 ± 33.3s). The SCBA trial took longer than the LC trial (p = .046). Heart rate and lactate measures were not different between trials. RPE was higher in the SCBA trial (6.7 ± 1.7) and LC (6.3 ± 1.5) compared to the PT trial (4.6 ± 1.8; p<.001). CONCLUSION: Load carriage and the respirator elicit a large decrement in occupational performance. Performance in PT clothes is not an accurate depiction of performance in load carriage. Firefighters and practitioners must identify safe and effective training strategies to prepare firefighters for the occupational demands of load carriage and respirator use.

2976   Board #259   June 1 3:30 PM - 5:00 PM

The Influence Of Wildland Fire Operations On Adipose Tissue, Skeletal Muscle And Lipids

Michelle M. Johannsen[1], Grant Galvin[1], Colin Campbell[1], Carl J. Murphy[1], Brent C. Ruby, FACSM[2]. *[1]University of Alaska - Fairbanks, Fairbanks, AK. [2]University of Montana, Missoula, MT.* (Sponsor: Robert H. Coker, FACSM)

(No relevant relationships reported)

Wildland fire suppression requires extended work shifts in arduous settings that may include high ambient temperatures, altitude or compromised air quality. The physiological demands of the job have been well characterized with total energy expenditure (EE) often exceeding 5,000 kcal/day. **PURPOSE:** The purpose of this study was to evaluate changes in cross-sectional area of the muscles of the upper thigh (XT), body composition, and blood lipids over a 5-month fire season. **METHODS:** Wildland firefighters (N=27, 25 M, 2 F, 27±1 years, N=15 hotshots, N=12 type II crew) were recruited from the Fairbanks, AK area prior to the 2017 fire season. Total and regional lean tissue mass (LTM) and fat mass (FM) were quantified from dual x-ray absorptiometry (DXA), while XT was calculated from magnetic resonance imaging (MRI). Pre- and post-season ≥3-hour fasted blood samples were collected for measures of total cholesterol (CHOL), high (HDL) and low-density lipoproteins (LDL). Results were analyzed using paired t-tests, presented as means±SEM and considered significant at p<0.05. **RESULTS:** The 27 participants averaged a total of 63±10 days on wildfire assignments. There was an increase in total body mass (78.5±2.5 kg and 79.7±2.4 kg) and body mass index (23.9±0.5 and 24.5±0.5) from pre- to post season, respectively; (N=27). There was also an increase in total FM (12.4±1.9 kg and 13.9±1.0 kg), arm FM (1.4±0.1 kg and 1.5±0.1 kg), leg FM (4.1±0.4 kg and 4.7±0.3 kg), and visceral FM (318±47 g and 419±48 g) from pre- to post-season, respectively; (N=27). Total LTM, arm LTM, and leg LTM (N=27), were unchanged. MRI analysis revealed no changes in XT over the fire season (N=27). Of the 27 participants that completed DXA and MRI scans, 18 completed blood sampling. There was an increase in CHOL (160±8 and 176±8) and LDL (83±6 and 96±9 mg/dL) from pre- to post-season, respectively (N=18). HDL remained unchanged. **CONCLUSION:** Increased FM and blood lipids may reflect the occupational consequences of seasonal wildland fire operations. Despite previously reported high levels of EE in this cohort, these concomitant alterations in adipose tissue and blood lipids may indicate the detrimental influence of dietary and/or environmental factors.

2977   Board #260   June 1 3:30 PM - 5:00 PM

Prediction Of Heat Strain Using Trunk Posture While Wearing Personal Protective Clothing: A Pilot Study

Yongsuk Seo, Tyler D. Quinn, Patrick Yorio, Ali Aljaroudi, Aitor Coca, Jung-Hyun Kim, Raymond J. Roberge, Jon Williams. *National Institute for Occupational Safety and Health, Pittsburgh, PA.* (Sponsor: Edward J. Sinkule, FACSM)

(No relevant relationships reported)

PURPOSE: Many occupations, such as firefighting and emergency healthcare response, require the use of personal protective equipment (PPE) in hot and humid environments. Increased core body temperature (Tco) and muscular fatigue from hyperthermia may result in alteration to the biomechanics of walking, which can be measured to estimate the level of heat strain. The purpose of this study was to determine if trunk posture is related to hyperthermia while walking on a treadmill with PPE. **METHODS**: Five healthy men walked on a treadmill in three conditions while wearing healthcare worker (HCW) PPE (1: 30 minutes walking at 3.0 mph and 0% grade, 20°C and 50% relative humidity (RH); 2: 30 minutes walking at 3.0 mph and 0% grade, 27.5°C and 60% RH; and 3: 30 minutes walking at 3.0 mph and 0% grade, 32.5°C and 70% RH). Trunk posture [degrees of trunk flexion (+) or extension (-)], Tco, and heart rate (HR) were measured continuously throughout exercise. **RESULTS**: Average end exercise Tco for all conditions was 37.3±0.6°C. Trunk posture (0.52±5.6) displayed a significant positive relationship with age (22±3 years) (r = 0.29) and Tco (r = 0.21) along with the control variable HR (126.1±28.4 beats/min) (r = 0.41). Trunk posture was significantly negative related to BMI (25.1±2.4 kg/m²) (r = -0.28) and height (178.7±7.2 cm) (r=-0.28). Generalized Estimating Equations revealed that Tco was significantly and positively related to trunk posture while controlling for the other covariates (B = 6.47, p <0.001). Age was shown to moderate the relationship between Tco and trunk posture (Tco * age, B = 3.34, p <0.001). **CONCLUSIONS**: A significantly positive relationship was found between Tco and the magnitude of trunk flexion in hyperthermia. This relationship was shown to be moderated by age. Trunk posture measurement may be useful in predicting fall potential and magnitude of heat strain in individuals wearing PPE while exercising or working in hot and humid environments.

Comparison between Six Hours of Continuous Walking to Six Hours of Intermittent Walking

Charli D. Aguilar, Nathaniel G. Bodell, Jeffrey Montes, Elizabeth A. Tanner, Andrea Woita, Jessica Knurick, James W. Navalta, FACSM. *University of Nevada Las Vegas, Las Vegas, NV.* (Sponsor: Dr. James Navalta, FACSM)

(No relevant relationships reported)

INTRODUCTION: Studies have shown that employee productivity and satisfaction decline with number of hours worked [1,2]. However, most of these studies looked at sedentary career fields when many careers require long hours of standing and/or walking.
PURPOSE: The purpose of this study was to determine if repeated breaks from walking has an effect on productivity and satisfaction.
METHODS: 23 healthy adults (11 males, 12 females) mean age of 22.5 ± 3.4 years volunteered to participate in the study. Participants were split into two groups. Continuous walkers, (n=11) who walked around a standard 400 outdoor meter track at a self-selected pace for 6 hours with one 10 minute break at 3 hours. Intermittent walkers (n=12), who walked for 50 minutes followed by a 10 minute break, repeated 6 times. Heart rate (HR), Blood pressure (BP), laps, and feeling scale were analyzed at Pre-walking, Midpoint, and Post walking. Dependent variables were analyzed utilizing a 2 (group) x 3 (time) ANOVA with repeated measures on time. Significance was accepted at the p<0.05 level.
RESULTS: Continuous group walked significantly more laps total and more laps per hour (mean 58.8 ± 5.93 vs. 46.9 ± 4.21 mean total laps, $p < 0.01$). However, there was no difference in number of laps per relative hours walked (9.8 ± 0.98 vs. 9.4 ± 0.84 laps/hr, $p = 0.894$). Although a decline in feeling scale from hour one to hour 6 was observed, it was not similar for both groups (Continuous p=0.039, Intermittent p=0.032). No significant differences were observed between groups in HR, Systolic BP or Diastolic BP.
CONCLUSIONS: Individuals walked the furthest distance when walking continuously. Six hours may not be enough time to see a significant decline in walking performance measures. The test environment may have been more enjoyable than a usual work environment.

Pilot Project: Energy Expenditure Comparison of Active Dance Video Games Pauses in Work Place

Andrée-Anne A. Parent, Joséphine Sans, Alain-Steve Comtois. *Université du Québec à Montréal, Montréal, QC, Canada.*

(No relevant relationships reported)

Health programs incorporating physical activity components in office space work environments are encouraged to reduce sedentary/sitting down time that has recently been shown to be detrimental to employee health. **PURPOSE**: The aim of this pilot project is to compare energy expenditure of three methods to play dance active video games to reduce employee sedentary time and explore the possibilities and limitations to using this video game type as part of an employee based health program. **METHODS**: A total of 8 desk based worker participants (men, 26 ± 5 years) were recruited to perform 3 types of active video game dances using original instructions and a modification to allow individuals with limitations to play. The 3 dances were Party Rock Anthem, Land of 1000 Dances, and No limit (JustDance, Ubisoft, Montreal). The modifications were to play with a motion capture device (Kinect, Microsoft, USA), with a controller device (PSMove, Sony, Jp), and with a controller device in a sitting position (PSMove, Sony, Jp).The energy expenditure was measured by oxygen uptake using a portable metabolic analyser (K4b2, Cosmed, It) and the heart rate by a heart rate monitor (v800, Polar, Fi). **RESULTS**: The group average METS with Kinect vs PS vs sitting position during the Party Rock Anthem was 6.3 ± 0.8, 5.5 ± 1.2, and 3.0 ± 0.8 METS (p<0.001). The group average METS on Kinect vs PS vs sitting position during Land of 1000 Dances was 7.4 ± 1.6, 6.1 ± 1.4, and 3.6 ± 1.4 METS (p<0.001). Finally, the group average METS on Kinect vs PS vs sitting position during No limit was 6.8 ± 1.3, 5.8 ± 1.3, and 3.5 ± 1.1 METS (p<0.001)**. CONCLUSIONS**: Knowing that now these games are available using only a cell phone as a controller and a simple computer with internet, it seems feasible to use these video games to reach the minimum ACSM guidelines in a health program for an office company, even when modified for physically limited employees. However, a significant difference between the different types of play and individual needs must be considered in a workplace health program. Furthermore, additional research needs to be done to measure the impact of implementing physical active work breaks on personnel fitness changes and retention.

An Analysis of the Physical Demands of National Ambulance Resilience Unit (NARU) Roles

Sam D. Blacker[1], Mark P. Rayson[2], Ella Walker[1], Carla Rue[1], Jane E.S Thompson[1], Jullianne Doherty[1], Stephen D. Myers[1]. *[1]University of Chichester, Chichester, United Kingdom. [2]Mark Rayson Consulting Limited, Bristol, United Kingdom.*

(No relevant relationships reported)

PURPOSE: The National Ambulance Resilience Unit (NARU) works on behalf of each National Health Service (NHS) Ambulance Trust in England to strengthen national resilience and improve patient outcome in challenging pre-hospital scenarios. NARU personnel are trained to deal with hazardous or difficult situations and mass casualty incidents. The aim of this study was to quantify the physically demanding tasks undertaken by NARU personnel. METHODS: The study was completed in two phases. In Phase 1, 10 subject matter experts from a range of NHS Ambulance Trusts participated in a two-day researcher led workshop to define the most physically demanding tasks performed by NARU personnel. In Phase 2, 34 participants (29 men and 5 women, stature 1.77 ± 0.08 m, body mass 84 ± 14 kg, estimated VO_{2max} 39 ± 7 mL·kg^{-1}·min^{-1}) performed scenarios of the tasks defined in Phase 1, with measurements of heart rate, speed of movement, load carried, and weights and forces of objects moved. Data are expressed as mean ± standard deviation. RESULTS: Eleven criterion tasks were defined in Phase 1: Swift Water Rescue, Re-board Boat, Unload Vehicle and Set-up Decontamination Unit, Clinical Decontamination (CD), Movement in Gas Tight Suits, Marauding Terrorist Firearms Attack (MTFA) , Over Ground Rescue, Unload Incidence Response Unit Vehicle, Above Ground Rescue, Over Rubble Rescue, and Subterranean Rescue. The shortest tasks were the Swift Water Rescue and Re-board Boat at ~1 min, with resultant heart rates of 76 ± 10 and 61 ± 14 %HR$_{max}$, respectively. The longest tasks were the CD and MTFA (~120 min) resulting in heart rates of 65 ± 11 and 73 ± 11 %HR$_{max}$, respectively. The greatest forces exerted were during equipment lifting and carrying (e.g. 167 kg by 6 people) and dragging of casualties (e.g. single person 88 kg casualty and stretcher drag). CONCLUSION: All five components of fitness (aerobic endurance, anaerobic endurance, muscular strength, muscular endurance and mobility) are required to successfully perform the criterion tasks undertaken by NARU personnel. These data can be used to inform interventions to enhance physical performance and develop physical employment standards for specialist ambulance responders. ACKNOWLEDGEMENT - This work was conducted in collaboration with the National Ambulance Resilience Unit in the United Kingdom.

Vitamin D Status in Elite South African (SA) Rugby Union Players: A Pilot Study

Pierre L. Viviers, FACSM[1], Jeandré Viljoen[1], Glen Hagemann[2], Alan Kourie[2], Danielle Roberts[2], Wayne Derman[1]. *[1]Stellenbosch University, Stellenbosch, South Africa. [2]Sharks Medical Centre, Durban, South Africa.*

(No relevant relationships reported)

Evidence suggests that poor vitamin D status (VIT-D) has negative implications for the health, well-being and performance of athletes. To date, little is known about athletes from the Southern Hemisphere. **PURPOSE:** i) To assess vitamin D levels in elite SA Rugby Union players (RU); and ii) to ascertain whether a relationship exists between vitamin D status and seasonal climatic variation, dietary intake or skin type. **METHODS:** In this longitudinal observational study, a cohort of elite RU players were screened to determine factors related to their VIT-D status including: i) serum 25-hydroxyvitamin D [25(OH) D], ii) comprehensive dietary analysis and iii) a Fitzpatrick skin type classification questionnaire (evaluating genetic predisposition, reaction to sun exposure and tanning habits). Initially, forty-one players completed the summer assessment, whereas only 17 were available for follow-up 6 months later during the winter. **RESULTS:** The mean s-[25(OH)D] was 62.0 ± 22.4 ng/mL^{-1} (95% CI: 50.5, 73.5) for the summer period, while at time point 2 the mean s-[25(OH)D] was 38.4 ± 11.2 ng/mL^{-1} (95% CI: 32.6, 44.2). Analysis of paired data revealed that 88% (2/17) of players displayed adequate s-[25(OH)D] during summer with the remaining 12% (2/17) of cases showing signs of insufficiency. During winter, 82% (14/17) had adequate s-[25(OH)D] while 6% (1/17) and 12% (2/17) of players displayed concentrations indicative of insufficiency and deficiency. No association was found between reported dietary intake and s-[25(OH)D]. A negative correlation (p=0.05) was found for summer s-[25(OH)D] and the Fitzpatrick skin type score. **CONCLUSIONS:**

Both VIT-D insufficiency and deficiency were low in SA RU athletes. Seasonal differences in VIT-D and skin score were demonstrated, likely due to changes in the length of sunlight exposure that effects endogenous VIT-D production.

Effects of Training Camp on Hematological Variables in Athletes with Sickle Cell Trait

Michael E. Owens[1], Haoyan Wang[1], Nathan P. Lemoine, Jr.[1], Jack Marucci[1], Shelly Mullenix[1], Arnold G. Nelson, FACSM[1], Ralph R. Castle[1], Brian A. Irving[1], Guillaume Spielmann[1], Jennifer Rood[2], Timothy S. Church[2], Brian Harrell[3], Neil M. Johannsen[1]. [1]*Louisiana State University, Baton Rouge, LA.* [2]*Pennington Biomedical, Baton Rouge, LA.* [3]*Baton Rouge General Sports Medicine, Baton Rouge, LA.* (Sponsor: Arnold G. Nelson, FACSM)

(No relevant relationships reported)

PURPOSE: To explore the hematological differences in African-American athletes with sickle cell trait (SCT) and healthy controls (CON) before preseason camp and the changes that occur after preseason training. METHODS: Sixteen (n=8 SCT; n=8 position matched, CON) NCAA Division 1 athletes (12 football, 2 each women's soccer and volleyball) had blood drawn before and after preseason camp and analyzed for Hb electrophoresis (Hb-A, Hb-A2, Hb-S, and Hb-F), complete blood count with differential, chemistry panel 26, and prothrombin time, activity and international normalized ratio (INR). RESULTS: Baseline total Hb was similar between SCT and CON (mean±SD; 14.2±1.3 vs. 14.1±0.9g/dL, resp; P=0.87), but as expected, Hb-A was lower and Hb-A2 and Hb-S were higher in SCT than CON (P<0.001 for all). Baseline neutrophils were higher (4.43±1.29 vs. 3.28±0.93cellsx10^3/mL, P<0.005) and lymphocytes tended to be lower (1.56±0.45 vs. 1.99±0.39cellsx10^3/mL; P=0.09) amongst SCT compared to CON, respectively. Baseline amylase (99.4±25.4 vs. 72.9±18.8u/L; P=0.03), uric acid (6.8±1.7 vs. 5.5±0.8mg/dL; P=0.08), and creatinine (1.2±0.2 vs. 1.0±0.2mg/dL; P=0.07) were higher in SCT compared to CON. All Hb measures in SCT were similar after camp compared to baseline (P>0.33 for all). Baseline and position adjusted change in neutrophils were similar between SCT and CON (mean, 95%CI; -0.09, -2.06 to 1.89 vs. 0.36, -1.61 to 2.34cellsx10^3/mL, resp; P=0.77). Similarly, the adjusted change in lymphocytes was not different between SCT and CON (0.53, 0.01 to 1.05 vs. 0.15, -0.37 to 0.67, resp; P=0.40), however, total lymphocyte counts increased in SCT over time (P<0.05). Creatinine responses differed between SCT and CON (-0.05, -0.12 to 0.02 vs. 0.05, -0.03 to 0.12; P=0.05) and potassium decreased a greater extent in SCT (-0.44, -0.6 to -0.3 vs. -0.2, -0.3 to -0.1; P=0.05) after camp. CONCLUSION: Despite major hematological differences due to SCT, very few changes occur during the exhaustive, preseason camp at sea level. *Funded in part by the Robert and Patricia Hines Endowed Professorship in Kinesiology, LSU, and unrestricted funding provided in part by a gift to the Tiger Athletic Foundation.*

Body Composition Changes in Male Collegiate Lacrosse Players from Preseason to Post Season

Caroline Varlotta[1], Hallie Zwibel[2], Joanne DiFrancisco-Donoghue[3]. [1]*New York Institute of Technology college of Osteopathic Medicine, Old Westbury, NY.* [2]*New York Institute of Technology College of Osteooathic Medicine, Old Westbury, NY.* [3]*New York Institute of Technology College of Osteopathic Medicine, Northport, NY.* (Sponsor: Gerard P Varlotta, FACSM)

(No relevant relationships reported)

Body composition changes differ in all sports due to specific training. In the off season most teams participate in strength training programs, however during the competitive season, training is often replaced with team sport training. Lacrosse players in previous studies showed better performance with decreased body fat percentage and increased lean body mass. However, its common during the competitive season to show an increased expenditure with more frequent practices and no adaptation to diet, which can lead to a decrease in lean body mass (LBM) along with rapid body fat percent loss in the competitive season. These changes can increase chances of injury, decrease performance, and slow recovery.
Purpose: To examine body composition changes in male collegiate lacrosse players from preseason to post season
Methods: We examined 18 male NCAA Division II collegiate lacrosse players (age 19.6±1.72) pre -competitive season, and post -season (January and May). Subjects completed a body composition assessment using dual-energy X-ray absorptiometry.
Results: Using descriptive statistics and a 2 way t-test, there was a decrease in overall total mass of 8.7 lbs. (179.9±33.2 vs 171.2±28.2, *p*=0.42). Body fat % decreased by 2.5% (21.1±7.6 vs. 18.6±6.7, *p*=0.58). Lean body mass increased by 1.5 lbs. (133.9±16.44 vs. 135.3±15.3).

Conclusion: Although these results were not significant, there was a decrease in % body fat and a minimal increase in lean body mass from pre to post season in Division II male lacrosse players. These changes do not demonstrate negative energy balance throughout the competitive season as previous research suggests.

Stress Urinary Incontinence in Female Powerlifting: A Survey

John Petrizzo, Rori Alter-Petrizzo, John Wygand, FACSM, Robert M. Otto, FACSM. *Adelphi University, Garden City, NY.* (Sponsor: John Wygand, FACSM)

(No relevant relationships reported)

Stress urinary incontinence (SUI), usually defined as involuntary leakage from the urethra, synchronous with exertion/effort, or on sneezing or coughing with an incidence rate of 4-35% in the general population has an unknown incidence with female powerlifters. **PURPOSE:** The purpose of this anonymous online survey was to identify trends related to SUI in female powerlifters who do not otherwise have risk factors for or symptoms of SUI in their daily lives. **METHODS:** Female powerlifters between the ages of 18-35 who have successfully been competing for at least two years on a National level or higher, are nulligravida, and have no history of SUI symptoms with ADLs, as well as no history of kidney disease, bladder disease, diabetes mellitus, pelvic floor, bladder, or rectal prolapse were eligible to participate. Solicitation scripts were posted on both USA Powerlifting and the United States Powerlifting Association's Facebook pages. 51 competitive female powerlifters completed the survey (ht. 162.6 ± 7.0 cm, body mass 71.4 ± 13.7 kg, waist 77.2 ± 8.3 cm, and hip 100.3 ± 10.0 cm). **RESULTS:** 74.5% (38) of participants indicated that they have experienced SUI while training the power lifts. Only 7.8% (4) who reported suffering from SUI while lifting indicated that they spoke to their doctors about the condition. 35.3% (18) indicated that they had not tried anything to help them manage their symptoms. 68.6% (35) indicated that they experience SUI while performing the deadlift while 49% (25) reported experiencing SUI while performing the squat. No participants reported experiencing SUI while performing the bench press. Additionally, 31.4% (16) reported experiencing symptoms while performing sets of 2-3 reps while 21.6% (11) subjects reported experiencing symptoms only while performing singles. 56.9% (29) reported that their symptoms were worse while wearing a weightlifting belt. Finally, 35.3% (18) reported that their symptoms of SUI while lifting causes them distress or anxiety. **CONCLUSION:** SUI is a significant issue for female powerlifters that may cause distress and anxiety when training and competing. SUI is more prevalent during heavy lower body lifting and may be made worse when wearing a weightlifting belt. This information can be useful to coaches and lifters when trying to manage the symptoms of SUI.

Differential Sweat And Urine Electrolyte Reponses In Collegiate Football Players With Sickle Cell Trait

Nathan P. Lemoine, Jr[1], Michael E. Owens[1], Haoyan Wang[1], Jack Marucci[1], Shelly Mullenix[1], Derek Calvert[1], Arnold Nelson, FACSM[1], Ralph R. Castle[1], Brian Irving[1], Guillaume Spielmann[1], Jennifer Rood[2], Timothy Church[2], Brian Harrell[3], Neil Johannsen[1]. [1]*Louisiana State University, Baton Rouge, LA.* [2]*Pennington Biomedical Research Center, Baton Rouge, LA.* [3]*Baton Rouge General Sports Medicine, Baton Rouge, LA.* (Sponsor: Arnold Nelson, FACSM)

(No relevant relationships reported)

Purpose: To determine the effects of sickle cell trait (SCT) on hydration status and body temperature regulation in collegiate football players during 17 days of pre-season training.
Methods: Twelve players were recruited to two groups: 6 with the SCT and 6 position-matched control players (CON). Body weight was measured and urine collected pre- and post-practice to examine urine color, specific gravity (USG), and electrolytes (Na^+, K^+, and Cl^-). Sweat was collected using gauze covered by a waterproof patch on the lower back. Each player ingested a core temperature pill 4-6 hours prior to practice. Ambient and black globe temperatures and humidity were collected pre-and post-training to assess wet-blub globe temperature (WBGT).
Results: Mean WBGT was 28.6±3.1°C (24.1-33.5°F). Average weight loss was -1.1±1.0kg (mean±SE). Weight loss, maximal core temp and heat storage (change in core temperature per hour) were similar in CON and SCT (P>0.05). However, SCT had significantly higher sweat sodium and chloride levels (Na^+: 60.79±7.18 mmol/L; Cl^-: 51.57±6.49 mmol/L) compared to CON (Na^+: 47.54±7.17mmol/L; Cl^-: 40.53±6.48 mmol/L; P<0.001 for both). CON had higher post-training USG (1.028±0.007) than SCT (1.018±0.007; P<0.001). Urine electrolytes were significantly higher for CON than SCT in all pre and post measurements (Pre Na^+:164.06±8.74 mmol/L vs. 100.31±9.10 mmol/L; Pre-K^+: 52.84±4.43 mmol/L vs. 36.50±4.59 mmol/L; Pre-Cl^-: 151.36±8.50 mmol/L vs. 87.61±8.80 mmol/L and Post-Na^+:118.47±8.79 mmol/L vs. 70.26±9.07 mmol/L; Post-K^+: 62.74±4.61 mmol/L vs. 35.48±4.73 mmol/L, Post-

Abstracts were prepared by the authors and printed as submitted.

Cl⁻: 99.06±5.14 mmol/L vs. 51.78±5.59 mmol/L, respectively; P<0.001 for all).
Conclusions: Sweat electrolyte levels were higher in the SCT group whereas urine electrolytes and USG were higher in CON for all measures. Future research should investigate whether the dissimilarities in sweat and urine electrolytes in SCT are meaningful and result in altered sodium or fluid balance concerns.
Funded in part by the Robert and Patricia Hines Endowed Professorship in Kinesiology, LSU, and unrestricted funding provided in part by a gift to the Tiger Athletic Foundation.

Cardiometabolic Changes During The Hormonal Transition Of A Male-to-female Athlete: A Case Study

Shannon L. Wilson[1], Andrew C. D'Lugos[1], Theresa M. Jorgensen[1], Joanna Harper[2], Corrie M. Whisner[1], Jared M. Dickinson, FACSM[1], Glenn A. Gaesser, FACSM[1], Siddhartha S. Angadi, FACSM[1]. *[1]Arizona State University, Phoenix, AZ. [2]Providence Portland Hospital, Portland, OR.*
(No relevant relationships reported)

PURPOSE: To assess the cardiovascular changes during estrogen treatment for gender reassignment in an aerobically trained, male-to-female transgender athlete.
METHODS:Subject is a biologically male distance runner (age 27) that initiated gender reassignment. Social male-to-female transition was completed prior to testing. The following assessments were performed: anthropometry, DXA (dual energy x-ray absorptiometry) scan (1st, 3rd, and 4th visit only), resting echocardiogram, treadmill-based VO2peak, resting carotid-femoral pulse wave velocity (cf-PWV), resting peripheral/central blood pressures and augmentation index (normalized at heart rate of 75 bpm; AIX@75). Baseline assessments were made during two separate visits completed prior to estrogen treatment (visits were averaged). Subsequent assessments were made at 2 and 6 weeks following the initiation of the estrogen treatment (10 mg estradiol valerate s.c. once per week).
RESULTS:

	Baseline	2 weeks	6 weeks
BMI	18.5	19.8	19.6
Total body fat	18.80%	21.80%	22.50%
Visceral body fat	143 g	274 g	230 g
Absolute VO$_2$	3.3	3.3	2.9
Relative VO$_2$	58.7	55.8	50.3
SBP	118	111	109
DBP	73	71	65
cSBP	106	99	96
cDBP	74	71	65
cf-PWV	6.7	6.2	6.2
AiX@75	4.75	-13	-6

RHR: Resting heart rate; SBP: Systolic blood pressure; DBP: Diastolic blood pressure; cSBP: Central systolic blood pressure; cDBP: central diastolic blood pressure; cf-PWV: carotid femoral pulse wave velocity; Aix@75: Augmentation index normalized at a heart rate of 75

	Baseline	2 Weeks	6 weeks
EF (%)	58.74	60.66	62.29
SV (ml)	87.36	90.34	89.96
LVESV (ml)	61.14	58.58	54.45
LVEDV (ml)	148.73	148.92	147.92
LVSD (cm)	3.36	3.37	3.35
LVDD (cm)	5.3	5.31	5.33

EF: Ejection fraction; SV: Stroke volume; LVESV: Left Ventricular End Systolic Volume; LVEDV: Left Ventricular End Diastolic Volume; LVSD: Left Ventricular systolic diameter;LVDD: Left Ventricular diastolic diameter.**CONCLUSIONS**: : Body composition and cardiorespiratory physiology are altered during the immediate weeks of male-to-female estrogen therapy

Low Energy Availability Associated With Lower BMD And Bone Stress Injury Site In Female Athletes

Bryan Holtzman[1], Allyson L. Parziale[1], Katherine M. Cooper[1], Erin Flynn[1], Adam S. Tenforde[2], Kathryn E. Ackerman, FACSM[1]. *[1]Boston Children's Hospital, Boston, MA. [2]Spaulding National Running Center, Cambridge, MA.* (Sponsor: Kathryn E. Ackerman, FACSM)
(No relevant relationships reported)

Low energy availability (LEA) is a risk factor for impaired bone health and bone stress injury (BSI). Additionally, those with BSI at trabecular-rich bone sites are at higher risk for low BMD vs. those with BSI at only cortical-rich sites.
PURPOSE: To evaluate the association of LEA with BMD and site of BSI in female athletes.
METHODS: 1000 female athletes (ages 15-30 years) presenting to a sports medicine clinic completed a 400+ question survey covering topics related to relative energy deficiency in sport (RED-S), including female athlete triad risk factors and athletic activity. Comprehensive chart review was completed to identify athletes with history of BSI and available dual energy x-ray absorptiometry (DXA). LEA was defined as meeting ≥ 1 criterion: self-reported history of eating disorder/disordered eating (ED/DE), high score on the Brief Eating Disorder in Athletes Questionnaire (BEDA-Q), and/or high score on the Eating Disorder Screen for Primary Care (ESP). Athletes with BSI of the pelvis, femoral neck, sacrum, and/or calcaneus were categorized into the trabecular-rich BSI group; all others were categorized into the cortical-rich BSI group. Associations between EA status, BSI location, and DXA were assessed by chi-squared or t-test analysis (p<0.05).
RESULTS: Of the 1000 patients surveyed, 126 had a history of both BSI and available DXA. Of these patients, 53.2% had LEA. Patients with LEA had lower BMD Z-scores than those with normal EA at the lumbar spine (-0.92±1.06 vs. -0.49±0.98, p=0.022), total hip (-0.27±0.75 vs. 0.29±0.77, p=0.009), and femoral neck (-0.34±0.87 vs. 0.23±0.97, p=0.028). Patients with ≥ 1 trabecular BSI accounted for 21.4% of the sample. In the trabecular-rich BSI group, 70.4% had LEA, while 48.5% of those in the cortical-rich group had LEA (p=0.043). Additionally, those with trabecular-rich BSI had lower BMD than the cortical-rich BSI group at the lumbar spine (-1.19±1.10 vs. -0.58±0.99, p=0.015), but not at other sites assessed by DXA.
CONCLUSIONS: Our findings support the well-established relationship between LEA and impaired BMD. We also found that trabecular-rich BSI is associated with low EA and independently associated with low BMD. Therefore, trabecular BSI may serve as a clinical indicator for further bone health evaluation and assessment for LEA, including ED/DE.

(No relevant relationships reported)

Abstract
Background: Ultraviolet (UV) radiation harms skin causing deadly skin cancer, however many athletes fail to use sun safe practices. No studies have examined the potential threat of a "second sun" created by UV radiation reflected off different outdoor playing surfaces.
Aim: This study hypothesized that athletic surfaces would reflect UV radiation and that this UV radiation would be greatest at lower heights and from smooth light-colored surfaces.
Methods: To evaluate this hypothesis, UVA and UVB radiation and reflected UV radiation were measured with UV dosimeters on different outdoor playing surfaces at various heights.
Results: All surfaces reflected UVA radiation (0.4 - 8% of direct UVA exposure), while only the smooth and light-colored playing surfaces (clay court, light asphalt, and concrete) reflected any UVB radiation (5 - 8%) and only at the lowest measured height. The amount of reflected UVA radiation did not change across heights comparable to typical human stature, but varied between surfaces. Light-colored and/or smooth playing surfaces including concrete, infield dirt, and clay and green courts reflected the most UVA radiation. The lightest-colored and smoothest surface, the spectator stands, reflected by far the most UV radiation, with 22 times the rate of UVA reflection of the least reflective surface, brown turf.
Conclusion: Reflected UV radiation threatens outdoor athletes and spectators. Tennis players, infield baseball and softball players, those who play on concrete surfaces, and coaches and others in the stands are at greatest risk and should be particularly vigilant with sun safety.

Differences In Return To Play Guidelines Using Red-s Cat And Triad Risk Assessment Guidelines For Female Athletes

Allyson L. Parziale[1], Bryan Holtzman[1], Katherine M. Cooper[1], Erin Flynn[1], Adam S. Tenforde[2], Kathryn E. Ackerman, FACSM[1]. [1]Boston Children's Hospital, Waltham, MA. [2]Spaulding National Running Center, Cambridge, MA. (Sponsor: Dr. Kathryn E. Ackerman, FACSM)

(No relevant relationships reported)

The International Olympic Committee (IOC) proposed the term Relative Energy Deficiency in Sport (RED-S) to describe the health and performance consequences beyond the well-established Female Athlete Triad (Triad). Both the IOC and the Triad Coalition have developed return-to-play (RTP) criteria to guide clinical decision making on clearance for participation in sports based on health assessment. **PURPOSE**: To determine the agreement between the RED-S Clinical Assessment Tool (RED-S CAT) and Triad risk assessment criteria (Triad-RA) for sports participation clearance levels for female athletes. **METHODS**: 1000 female athletes (ages 15-30 years) presenting to a sports medicine clinic completed a comprehensive, 400+ question survey covering topics related to RED-S, including Triad risk factors, and sports participation. Clearance level/risk assessment for each athlete was assigned according to each syndrome's model as low (green light), moderate (yellow light), or high risk (red light). Clearance level by each model was compared within each athlete. **RESULTS**: Using the RED-S CAT, 26.6% of athletes were green light (full clearance), 29.7% were yellow light (provisional/limited clearance), and 43.7% were red light (fully restricted). Using the Triad-RA, 30.2% of athletes were low risk, 61.9% were moderate risk, and 7.9% were high risk. Overall the models agreed that 86% of the athletes were at elevated risk (moderate or high). The most discordance occurred for athletes deemed to be at high risk by RED-S CAT, but moderate risk by Triad-RA; these athletes accounted for 37.3% of all subjects. The Triad-RA cleared 8.8% of the sample for full participation that the RED-S CAT categorized as elevated risk; the RED-S CAT cleared 5.2% of the sample for full participation that the Triad-RA categorized as elevated risk. **CONCLUSIONS**: Most female athletes surveyed met elevated risk categories using both RED-S CAT and Triad-RA. The RTP criteria for both syndromes should be further refined for use in primary care settings as part of pre-participation examinations to appropriately categorize athletes needing further medical care and potential restriction from sport.

Game Day Glucose Values For A High School Soccer Player With Type 1 Diabetes: A Case Study

Timothy McKay, Jason R. Jaggers, Kupper Wintergerst. *University of Louisville, Louisville, KY.* (Sponsor: Ann Swank, FACSM)

(No relevant relationships reported)

Sport and exercise can improve cardiovascular health for someone with type 1 diabetes mellitus (T1DM), but it must be performed safely. Blood glucose control in adolescent athletes can be challenging, especially on the day of competition. Because of the hormonal response to stress of a game, blood glucose will be altered even if exerting a similar amount of energy. PURPOSE: The purpose of this case study was to examine average daily glucose for a period of 72- hours starting on and following a non-gameday (NGD) compared with a game day (GD) for a high school soccer player with type 1 diabetes. METHODS: Data from a 15 year old male athlete with T1DM was used for this case study. The athlete wore an accelerometer on his upper left arm during the same time period in which his continuous glucose monitor (CGM) and insulin pump was being observed. Average daily blood glucose from the athlete's CGM was obtained over a 72-hour period on NGD and GD following consent. RESULTS: Paired samples t-tests showed no difference in daily energy expenditure at either time points. Average insulin on GD was slightly higher compared to NGD (36.2 ± 1.48 vs. 28.26 ± 9.85) but did not reach significance. Average daily glucose over the NGD was significantly lower (p < 0.01) compared to GD (128.27 ± 32.72 mg/dL vs. 167.74 ± 58.32 mg/dL). This was confirmed by comparing 3 additional GD with 3 NGD (167 ± 9.62 mg/dL vs. 130 ± 5.71 mg/dL). On the day of competition, the CGM recorded a high of 308mg/dL and a low of 49mg/dL within 24 hours following the game, compared to a high of 227mg/dL and a low of 72mg/dL for the NGD. CONCLUSION: CGM averages displayed competition and post recovery glucose values that were significantly higher compared to those of NGD. The results suggest that hormonal stimuli from competition and the recovery associated with participation in competitive sports can influence glucose fluctuations in athletes with T1DM. This was confirmed by additional analysis that included values from 3 other GD CGM readings.

Impact Of Seasonal Change In Body Composition On Hemoglobin Levels Among Long Distance Runners.

Masaya Tokita[1], Norimitsu Kinoshita[1], Kenta Okuyama[2]. [1]Hosei University, Tokyo, Japan. [2]Shimane University, Shimane, Japan.

(No relevant relationships reported)

PURPOSE: Long distance runners pursue leanness to improve performance. Losing fat mass is achieved by chronic negative energy balance, and it would increase the risk of developing anemia. The purpose of this study was to assess the association between change in %fat and decreases in hemoglobin (Hb) and ferritin levels among long distance runners. **METHODS**: A cohort of 40 Japanese competitive male runners of the same university team was analyzed retrospectively. Blood test and body composition analysis (DXA) were performed twice a year: pre-season in March and peak-season in August. The least significant change in %fat was calculated (LSC: 0.11) and the subjects were dichotomized into 2 groups: change in %fat from pre- to peak-seasons within +/- LSC (constant: CNT, n=14), and change in %fat exceeded LSC (decrease: DCR, n=26). No runners increased %fat. Body compositions were compared by paired t-test between pre- and peak-seasons for each group. Changes of Hb and ferritin were analyzed by 2-way repeated measures ANOVA between CNT and DCR. P<0.05 was considered statistically significant. Written informed consent was obtained from each runner. **RESULTS**: Only fat mass (FM) and %fat were significantly different between CNT and DCR in pre-season (3.4 vs. 4.4 kg and 6.3 vs. 8.1 %, respectively); other variables (age, lean soft tissue mass [LM], Hb, and ferritin) were not (20.3 vs. 19.9 y/o, 51.2 vs. 50.1 kg, 14.9 vs. 15.3 g/dl, and 43.3 vs. 60.7 ng/ml, respectively). Total running mileage (March - July) was not significantly different between CNT and DCR (3193 vs. 3171 km). FM, LM and %fat significantly decreased from pre- to peak-seasons in DCR (3.4 kg, 50.6 kg, and 5.9 %, respectively in peak-season); but not in CNT (3.6 kg, 51.4 kg, and 6.2 %, respectively). Two-way repeated measures ANOVA showed that there was a significant main effect of the seasonal phase of training on Hb (CNT: 14.9 to 14.3 g/dl, DCR: 15.3 to 14.4 g/dl) and ferritin (CNT: 43.3 to 32.9 ng/ml, DCR: 60.7 to 48.5 ng/ml). No significant interaction effect was observed between the seasonal phase of training and the change in %fat. **CONCLUSIONS**: Hb and ferritin significantly decreased from pre- to peak-seasons with or without decrease in %fat among lean runners. It is recommended to conduct blood test periodically for recognition of developing anemia which would impair performance.

Hormonal Responses after Exercise-induced Muscle Damage in Healthy Humans

Anastassios Philippou[1], Roxane Tenta[2], Maria Maridaki, 17237[1], Michael Koutsilieris[1]. [1]National and Kapodistrian University of Athens, Athens, Greece. [2]School of Health Science and Education, Harokopio University, Athens, Greece.

(No relevant relationships reported)

Mechanically overloaded muscle and its subsequent damage are strong stimuli for eliciting acute hormonal changes, and muscle adaptation following exercise-induced muscle damage may involve complex hormonal responses before the completion of muscle regeneration. **PURPOSE**: This study investigated systemic responses of thyroid-stimulating hormone (TSH), free thyroxine (fT4) and prolactin (PRL) for several days after eccentric exercise-induced muscle damage in humans. **METHODS**: Nine healthy men (age 25.7 ± 1.7 years, height 180.4 ± 1.7 cm, body mass 77.2 ± 2.7 kg, body mass index 23.7 ± 0.6) performed 50 maximal eccentric muscle actions using the knee extensor muscles of both legs on an isokinetic dynamometer. Blood samples were withdrawn before and at 6, 48 and 120 hrs post-exercise, and serum levels of TSH, fT4) and PRL were measured by ELISA using commercially available kits. Myoglobin (Mb) concentration and lactate dehydrogenase (LDH) activity were also evaluated as indirect markers of muscle damage. One-way ANOVA was used for statistics. **RESULTS**: Significant alterations in Mb and LDH were observed over time after eccentric exercise (p<0.05-0.001). Serum fT4 levels exhibited a gradual increase reaching statistical significance at 48 and 120 hrs following the muscle damaging exercise (1.20±0.05 ng/dl, 1.29±0.04 ng/dl, and 1.26±0.05 ng/dl, at 6, 48 and 120 hours after exercise, respectively, compared to 1.13±0.02 ng/dl at baseline; mean±SE, p<0.05). Both PRL and TSH showed also a gradual increase up to 33% at 48 hrs and 120 hrs post exercise, respectively, however they failed to reach statistical significance due to a large variability shown between the subjects' responses (PRL: 23.4±3.1 ng/ml, 28.1±4.7 ng/ml, 30.2±4.1 ng/ml and 25.7±4.6 ng/ml; TSH: 1.09±0.14 μIU/ml, 1.27±0.15 μIU/ml, 1.17±0.20 μIU/ml, and 1.33±0.17 μIU/ml, at baseline, 6, 48 and 120 hours post-exercise, respectively, mean±SE, p>0.05). **CONCLUSION**: The late elevated levels of TSH and PRL, and particularly of fT4, during the recovery period after muscle damage may suggest functional interactions between those

hormones and muscle regeneration. Further studies are needed to characterize the mechanisms by which those hormonal responses are triggered and regulated at the systemic level during recovery after exercise-induced muscle damage.

Physical Functioning in Older Breast Cancer Survivors: A 12-Month Randomized-Controlled Trial with 6-month Follow Up.

Mary E. Medysky[1], Sydnee Stoyles[1], Nathan F. Dieckmann[1], Kerri M. Winters-Stone, FACSM[2]. *[1]Oregon Health and Science University, Portland, OR. [2]Knight Cancer Institute, Portland, OR.* (Sponsor: Kerri Winters-Stone, FACSM)
(No relevant relationships reported)

The largest age group of breast cancer survivors (BCS) in the U.S. is comprised of women ages 65+, who are susceptible to age-related decrements in physical function accelerated by cancer treatment toxicities. Though exercise is known to reverse age-related functional limitations, older BCS may be heterogeneous in baseline functioning which may affect the efficacy of exercise to reverse functional declines. **PURPOSE:** Determine the efficacy of each aerobic and resistance training to improve physical function in older BCS, considering baseline physical functioning. **METHODS:** Older, early-stage, BCS (mean age=72), who underwent chemo- or radio-therapy in the previous 2 years were randomized to 12 months of supervised, group aerobic (AER) or resistance (RES) training or control (CON) flexibility exercise, followed by 6 months of home-based training. Physical function was assessed by the Physical Performance Battery (PPB), 5x chair stand time (sec), maximum bench and leg press (kg), and 4-meter usual walk speed (m/sec) tests and self-reported lower-body function with the Late-Life Function and Disability Instrument (LLFDI). A linear mixed effects model was used to assess function after 12 and 18 months on the full sample and only in BCS with PPB scores ≥9. **RESULTS:** 114 BCS were enrolled and randomized to AER (n=37), RES (n=39), or CON (n=38). Within the full sample there was a significant improvement in bench press strength at 12 months (p=0.03) and PPB at 18 months in RES vs CON. After removing participants with low baseline physical functioning (n=79), the following additional significant differences were found between: 1) RES (αmean=2.72±1.7) and CON (αmean=-3.06±2.0) for self-report physical function at both 12 (p=0.04) and 18 months (p=0.005), 2) AER (αmean=0.4±0.0) and CON (αmean=-0.03±0.0) at 12-months for average walk speed and, 3) AER (αmean=0.32±0.3) and RES (αmean=0.50±0.2) at 18 months, for chair time (p=0.05). **CONCLUSIONS:** Although AE and RT are efficacious in improving physical function in older BCS across a range of baseline physical functioning, broader improvements may only be possible among women with better functioning and thus capable of achieving a greater dose of exercise. Older BCS may need to be stratified into groups based on their initial functioning, then matched to appropriate training.

The Relationship Between Six Minute Walk Distance And Dyspnea Symptoms Among Preoperative Lung Cancer Patients

sung-a kong[1], Jaekyung Lee[1], Jinhee Lee[2], Hyeyun Park[2], Juhee Cho[1]. *[1]Sungkyunkwan University, seoul, Korea, Republic of. [2]Samsung Medical Center, seoul, Korea, Republic of.*
(No relevant relationships reported)

Background and Objective: The purpose of this study was to examine the relationship between preoperative 6MWD and symptoms, quality of life in patients who underwent lung resection for primary lung cancer.
Material and Methods: Patients of cohort included were those scheduled to undergo lung cancer surgery, at participating hospitals in the Seoul of South Korea. In total, 364 persons(mean age, 61.51yr) attended from March 2016 to September 2017. Exclusion criteria of a cohorts of lung cancer study included ECOG PS >1 and neoadjuvant therapy, Multiple cancer, recurrent lung cancer. Patients planned for lung cancer surgery filled out a questionnaire and perform before surgery. Cardiorespiratory fitness (CRF) was assessed six minute walk distance using the 6-minute walk test (6MWT). The symptoms was assessed using the mMRC and CAT questionnaires. The quality of life was assessed using the EORTC Quality of Life, Core30 and lung cancer 30 questionnaires. Data from were summarized according to the 6MWT recorded (lower and higher) estimated using 6MWD (cut-point 450m).

Results: Lung cancer patients with low 6MWD (<450m) were more likely to have dyspnea than those with high 6MWD(>450m).
mMRC and CAT score were -0.256 (95% CI -0.387, -0.125), -2.427(95% CI -3.751, -1.104).
Quality of life were general health score 10.456 (95% CI -5.030, 15.882), fatigue score -8.891 (95% CI -14.618, -3.165).
Conclusions: Preoperative 6MWD was significantly associated with preoperative symptoms and QoL in patients who underwent lung resection for malignancies
Key words: Lung cancer, Cardiorespiratory fitness, symptoms

Different of dyspnea and QoL by 6MWD before surgery			
	mMRC score	CAT score	General Health_QoL
6MWD <450m	0.53 (0.52-0.54)	8.10 (7.88-8.30)	58.53 (58.02-59.04)
6MWD >450m	0.24 (0.24-0.25)	5.43 (5.32-5.55)	67.41 (67.14-67.70)

Cognition Improves In Cancer Survivors After A Multi-dimensional Cancer Rehabilitation Program

Hillary Conner[1], Tim Burnham[1], Ralf Greenwald[1], Robert Pritchett[1], Katie Kemble[2]. *[1]Central Washington University, Ellensburg, WA. [2]University of Washington, Seattle, WA.*
(No relevant relationships reported)

Cancer Related Cognitive Impairment (CRCI), or "chemo-brain," has become a recognized problem for cancer survivors;, however, limited evidence exists about concerning interventions that may improve cognition for cancer this population. survivors. Symptoms include: short-term memory loss, decreased concentration, mental "fogginess" and fatigue. These symptoms may contribute to a decrease in quality of life. **PURPOSE:** To measure the effectiveness of a multi-dimensional cancer survivor rehabilitation program on cognition as well as physical and psycho-social functioning. **METHODS:** Sixty-two post-treatment cancer survivors, (7 men, 55 women, 35-77 years) were subjects in a one group, pre-post, quasi-experimental design. Subjects were cleared for exercise prior to participation. The program consisted of two, 90 minute sessions pera week for 12 weeks. Each meeting was divided into 3 sections: an educational activity, cardiovascular endurance training, and a strength and flexibility session. A subset of this group (n= 22) participated in brain exercise games once pera week for 15 minutes. Dependent measures included: the Montreal Cognitive Assessment (MoCA), the General Practitioner assessment of Cognition (GPCOG), aerobic capacity, body fat %, lower body flexibility, handgrip strength, quality of life, Schwartz fatigue scale, and the LASA scale (fatigue, anxiety, confusion, depression, energy and anger). **RESULTS:** The following measures showed statistically significant (p < .05) improvements:. GPCOG increased 6.6%**,** aerobic capacity increased 20.7%, body fat decreased by 1.9%, lower body flexibility improved 14.3%, handgrip strength increased 11.6%. Quality of life increased 10.4%. Fatigue measured by the Schwartz scale decreased 18.5%, LASA scale results: fatigue decreased 36.7%, depression decreased 49.2%, confusion decreased 42.7%, energy increased 23.8%, anger decreased 40.8%, anxiety decreased 30.7%. MoCA increased 4.3% and approached significance (p= .056). **CONCLUSION:** The combination of tools acquired in the cancer rehabilitation program proved effective in improving cognition and reducing symptoms often seen in post-treatment cancer survivors. The mechanism for cognitive improvement cannot be ascertained from the design of this study but may hold promise for future studies.

Skeletal Muscle Blood Flow, Oxygen Extraction and Consumption in Women Receiving Chemotherapy for Breast Cancer

Amy A. Kirkham, David Ian Paterson, Edith Pituskin, Justin Grenier, Esther Yang, Richard B. Thompson. *University of Alberta, Edmonton, AB, Canada.*
(No relevant relationships reported)

PURPOSE: Cardiac muscle injury is a well-recognized side effect of anthracycline chemotherapy and trastuzumab therapy for breast cancer. Preclinical studies have identified parallels in cell damage response and dysfunction between cardiac and skeletal muscle. However, assessment of the effect of treatment on skeletal muscle in patients has been limited to muscle strength.
METHODS: Early stage breast cancer patients receiving chemotherapy including anthracyclines or trastuzumab enrolled into a RCT of a multi-disciplinary team intervention versus usual care. Patients underwent a MRI scan before the first and after the third chemotherapy treatment. A maximal incremental single leg plantar flexion test was performed followed by 15 min of rest. A 4-min steady state test was

then performed at 60% of peak power. Beginning at end-exercise, time-resolved blood flow (popliteal vein, phase contrast MRI) and venous oxygen saturation (S_vO_2, susceptometry-based oximetry using deoxyhemoglobin as an intrinsic contrast agent) were measured with custom methods. These values were used to calculate lower leg VO_2 using the Fick equation with [hemoglobin] (hb) extracted from clinical records and S_aO_2 measured via pulse oximetry.
RESULTS: Twelve patients have completed both scans. Preliminary analyses were of change over time with both groups combined. Peak power did not change (15.7 ± 3.0 to 16.6 ± 3.8 W, p=0.227). After treatment, oxygen carrying capacity of the blood (hb*1.34*S_aO_2) was significantly decreased (median change = -17%, p=0.004) due to reduced hemoglobin (13.5 ± 13 to 11.2 ± 13 g/dL). Exercise blood flow increased (438 ± 119 to 633 ± 167 mL/min, median change=44%; p<0.001) out of proportion to this reduction. S_aO_2 and S_vO_2 did not change appreciably (~98% and 60%, respectively). As a result there was a small but non-significant increase in leg VO_2 (30 ± 9 to 35 ± 13 mL/min, median change = 16%, p=0.165). Exercise mean arterial pressure decreased and heart rate increased after treatment (p=0.007, p=0.017).
CONCLUSIONS: Our preliminary findings indicate that chemotherapy for breast cancer does not reduce oxygen extraction with isolated muscle exercise. Local blood flow increases partly in response to reduced oxygen-carrying capacity of the blood, but mechanisms for the remaining hyperemia response are unknown.

Assessing Body Composition With Dual-energy X-ray Absorptiometry And Bio-electrical Impedance In Breast Cancer Survivors

Kyuwan Lee, Nathalie Sami, Christina Dieli-Conwright, FACSM. *U of Southern California, Los Angeles, CA.* (Sponsor: Christina Dieli-Conwright, FACSM)
(No relevant relationships reported)

PURPOSE: As obesity is recognized as a risk factor for breast cancer recurrence, the assessment of body composition is vital in breast cancer survivors (BCS) to guide appropriate weight management interventions. Dual-energy X-ray absorptiometry (DXA) is a highly valid and accurate method for assessing body composition, however, the use of DXA is limited due to availability and high cost. Bio-electrical impedance analysis (BIA) is an alternative method to estimate body composition due to safety, low cost, and ease of use. The purpose of this study was to verify whether DXA and BIA yield similar results for body composition including: body fat percentage (BFP), lean body mass (LBM) and fat mass (FM) in BCS. We further examined whether our results differed by BMI category.
METHODS: BCS (Stage I-III) who had completed cancer-related treatment within the previous 6 months were included in this study. BFP, LBM and FM were estimated using BIA (InBody 520) and followed immediately by DXA (GE Lunar Prodigy). Testing was performed between 7:00-11:00 AM following a minimum 4-hour fast. BMI categories used were based on the World Health Organization: normal (18.0-24.99 kg/m²), overweight (25.0-29.9 kg/m²), obese (30.0-34.99 kg/m²), and severely obese (>35.0 kg/m²). Agreement between the devices was assessed by Bland-Altman analysis.
RESULTS: Our study population included a total of 89 BCS (52.7±10.4 yr), primarily Hispanic (63.6%), with BMI of 29.2±5.6 kg/m². There was no agreement between the two devices in assessments of BFP (DXA: 44.2±6.2 vs BIA: 40.4±7.8%), LBM (DXA: 39.1±7.6 vs BIA: 42.9±5.9kg) and FM (DXA: 32.4±10.8 vs BIA: 30.6±11.0kg). DXA provided significantly higher estimates of BFP and FM, with a lower estimate of LBM compared to BIA (P<0.001). These findings held true among BCS in the normal (n=28), overweight (n=21), and obese group (n=23). However, there was agreement between the two devices on FM (DXA: 48.7±7.2 vs BIA: 47.9±5.7kg) in severely obese BCS (n=17; P=0.102).
CONCLUSIONS: BIA may underestimate BFP and FM and overestimate LBM, compared to DXA in BCS. However, BIA and DXA provide similar FM in severely obese BCS, suggesting that BIA can be alternative to estimate FM. Future studies are warranted to assess the utilization of these 2 devices in a larger cohort of BCS across BMI categories.

Muscle Strength and Fasting Insulin Levels Following a Combined Exercise Intervention in Breast Cancer Survivors

Nathalie Sami, Kaylie Zapanta, Kyuwan Lee, Christina Dieli-Conwright, FACSM. *University of Southern California, Los Angeles, CA.*
(No relevant relationships reported)

PURPOSE: Breast cancer treatments may lead to elevated fasting insulin levels and gains in fat mass causing insulin resistance in skeletal muscle and subsequent reductions in muscle strength (MST). Exercise is a non-pharmacologic strategy to improve elevated insulin and reduced MST. In particular, combined aerobic and resistance exercise (CE) reduces insulin levels and improves MST, and has been shown to be superior to resistance or aerobic exercise alone at reducing insulin resistance in patients with type 2 diabetes. The purpose of this study was to determine whether fasting insulin levels and muscle strength (MST) can be improved following a 16-week supervised CE intervention in overweight and obese breast cancer survivors (BCS).
METHODS: Sedentary, overweight/obese (BMI >25 kg/m²) BCS (Stage I-III) were randomized to the Control (CON) or the Exercise (EX) groups. EX underwent supervised CE sessions 3 times per week for 16 weeks. CON was asked to maintain their current level of activity. Fasting serum insulin was measured using enzyme-linked immunoabsorbent assays. MST was assessed from 10-RM (repetition maximum) tests of the leg extension (LE) and chest press (CP) to estimate 1-RM values. Repeated measures ANOVA was used to examine the effects of exercise on MST and insulin. Pearson's correlations were performed to examine the association between MST changes for each exercise and insulin.
RESULTS: At baseline, EX (n=48) and CON (n=46) did not differ by age (53.0 ± 10.4 yr), insulin (35.2 ± 15.4 pmol/L), or BMI (33.5 ± 5.5 kg/m²). Post-intervention, insulin was significantly reduced (-13.5 ± 3.1%) and all MST measures (35.9 ± 6.7%) significantly increased in EX compared to CON (*P*<0.01). Significant correlations were found between reduced insulin and improved MST for LE (r=-0.67, p=0.001) and CP (r=-0.81, p=0.01) in EX.
CONCLUSION: A 16-week supervised CE intervention is an effective approach to reduce insulin, and increase MST, and reductions in insulin are associated with improved muscle strength in BCS. Collectively, this supports the utilization of aerobic and resistance exercise as vital components of cancer rehabilitation following completion of cancer treatment.

Sex Differences In Objectively Measured Physical Activity Among Individuals With ACL Reconstruction

Christopher Kuenze[1], Lisa Cadmus-Bertram[2], Karin Pfeiffer, FACSM[1], Caroline Lisee, FACSM[1], Stephanie Trigsted[3], Dane Cook[2], David Bell[2]. *[1]Michigan State University, East Lansing, MI. [2]University of Wisconsin - Madison, Madison, WI. [3]High Point University, High Point, NC.* (Sponsor: Karin Pfeiffer, FACSM)
(No relevant relationships reported)

Females are more likely to experience poor knee-related outcomes and are less likely to return to pre-injury levels of return to sport following ACLR as compared to males of the same age and pre-injury activity level. Evidence has shown that young adults with ACLR participate in significantly less moderate-to-vigorous physical activity (MVPA) as compared to healthy matched. However, it is not clear if an individual's sex is a factor in their determining the likelihood of engagement in healthy levels of MVPA following ACLR. **Purpose:** To examine the effects of sex and ACLR status on the volume of MVPA in which an individual engages as well as the likelihood that an individual will meet national guidelines for weekly MVPA. **Methods:** 31 individuals with a history of ACLR (Sex = 22F/9M, Age = 20.3 ± 1.7 years, BMI = 23.3 ± 2.8kg/m², Time since surgery = 28.2 ± 17.1mo) and 32 healthy individuals (Sex = 22F/10M, Age = 20.8 ± 1.6 years, BMI = 23.3 ± 30kg/m²) enrolled in this study. Objective MVPA in Freedson bouts (min/wk) were assessed with an ActiGraph GT3X-BT accelerometer worn on an elastic belt at the hip over a period of 7 days with a minimum of 4 days of wear with ≥10 hours per day. Wear time (min/day) was validated using recommendations of Choi et al. Between group (ACLR, Healthy) and sex (M/F) differences in MVPA in Freedson bouts were investigated using a 2 (group) x 2 (sex) ANOVA. Fischer's exact test was utilized to assess the sex-based difference in meeting national MVPA recommendations (MVPA > 150 min/wk) among individuals with ACLR. **Results:** Overall, individuals with ACLR (MVPA = 114±95 min/week) participated in less MVPA in Freedson Bouts per week as compared to healthy individuals (MVPA = 212±138 min/wk, *p* = 0.002). Females (MVPA = 184±133min/wk) were more active than males (MVPA = 116±102 min/wk, *p* = 0.02). There was no meaningful interaction between group and sex (*p* = 0.06) but females with ACLR (72.0%) were more likely to meet MVPA guidelines when compared to males (36.3%, *p* = 0.05). **Conclusion:** Individuals with ACLR participate in less MVPA than those with no history of knee injury which is consistent with previous findings. While no interaction was present between sex and history of ACLR, females with ACLR were more likely to meeting MVPA guidelines which may have implications for long term health risks associated with ACLR.

Road Bicycle Saddle Shape Preference and its Potential Determinants

Sewan Kim[1], James E. Peterman[1], Todd M. Carver[2], Garrett Y.D. Getter[2], William C. Byrnes, FACSM[1]. [1]University Colorado Boulder, Boulder, CO. [2]Specialized Bicycle Components, Boulder, CO. (Sponsor: William Byrnes, FACSM)

(No relevant relationships reported)

The saddle is an integral part of riding a bicycle, however research examining determinants of cycling saddle preference/comfort is limited. **PURPOSE:** To determine if trained cyclists can differentiate between road bicycle saddle shapes and whether preferences are related to anatomy and/or cycling position variables. **METHODS:** Cyclists riding 5-12 hr/wk and training for a cycling event participated (21 M and 21 F). Pelvic anatomy (composition plus ischial tuberosity width) and overall body composition were determined by DXA. Cycling position variables were determined using 3D motion capture. Subjects then completed 3 separate saddle evaluations using identical cycling shorts while riding 3 differently shaped saddles (flat, convex widthwise and concave lengthwise). The 1st and 3rd evaluations were identical and occurred in the lab on an ergometer adjusted to the subject's personal cycling position. In a blinded, randomized design, subjects rode each saddle twice for 5 min. A 6-item visual analog comfort questionnaire (0-100 with 100 being extreme comfort) was completed after each bout. For evaluation 2, subjects rode each saddle for 1 wk on their road bike while maintaining normal riding hours with comfort assessed at the end of each week. Upon study completion, subjects chose a preferred saddle, which was collected independent of comfort ratings. **RESULTS:** For evaluations 1 and 3, comfort ratings were not different between saddles or across evaluation sessions. With prolonged testing, significant (p<0.05) differences were observed for overall comfort for convex vs. concave (72.5 ± 18.0 and 61.2 ± 17.9) and flat vs. concave (70.7 ± 19.1 and 61.2 ± 17.9). Evaluation 2 comfort ratings matched preferred saddle choice, but did not improve subjects' ability to differentiate saddles during evaluation 3. No relationships were observed between saddle comfort and any anatomy or cycling position variables. **CONCLUSION:** Trained cyclists in an acute, blinded setting cannot differentiate saddle shapes even when accustomed to the saddle. With longer exposure, cyclists can differentiate saddle shapes and demonstrate a preference that aligns with comfort ratings. However, no relationship was found between measured variables and saddle preference/comfort.

Associations of Intracortical Facilitation and Inhibition of the Soleus with Popliteal Venous Flow

Masafumi Terada, Keisuke Senoo, Kaede Kaneda, Syunya Nonoyama, Tadao Isaka. Ritsumeikan University, Shiga, Japan

The soleus muscle is functionally important to maintain venous return and consequently cardiac output by compressing underlying veins in order to increase blood flow back to the heart. Previous literature has reported that soleus dysfunction may contribute reduced venous retune. Soleus dysfunction have been attributed to altered intracortical excitability within the central nervous system. However, there is little investigation that has examined associations of intracortical facilitation and inhibition of the soleus with venous flow in the popliteal vein. Determining these associations may help to establish neurophysiological mechanisms that cause altered venous return. **PURPOSE:** Determine if intracortical facilitation and inhibition of the soleus are associated with popliteal venous flow. **METHODS:** Ten participants (8M, 2F; 20.3 ± 0.9yrs; 165.0 ± 7.6cm; 61.0 ± 5.4kg) were enrolled in this current study. Paired-pulse transcranial magnetic stimulation was used to assess intracortical facilitation (ICF) and short-interval intracortical inhibition (SICI) in the soleus muscle. Blood flow velocities in the popliteal vein were measured using Dropper ultrasound in a standing position and immediately after five repetitions of maximum voluntary isometric contraction (MVIC) strength of the plantar flexors. Peak velocity and time-averaged maximum velocity (TAMAX) were assessed. Pearson Product Moment Correlations were used to examine associations of ICF and SICI in the soleus with measures of blood flow velocity in the popliteal vein. Significance was set a priori at p<0.05. **RESULTS:** TAMAX immediately after MVIC was moderately correlated with ICF (r=0.63, p=0.03) and SICI (r=0.59, p=0.04). **CONCLUSION:** These findings indicate the potential for associations of intracortical facilitation and inhibition of the soleus with blood flow velocities in the popliteal vein. Further study with a large sample size is needed to examine these associations in specific pathological condition in order to determine the effects of clinical dysfunctions on venous return.

Agreement Of Heart Rate Monitoring With A Smartwatch In Persons Using Wheelchairs

Daniel Moreno, Evan Glasheen, Antoniette Domingo, Brian Panaligan, Jochen Kressler. *San Diego State University, San Diego, CA.*

(No relevant relationships reported)

Purpose: To validate heart rate (HR) from a fitness smartwatch (SW) designed to measure values in wheelchair users against standard heart rate monitoring. Valid HR tracking will be useful tool for monitoring exercise intensities for wheelchair users. **Methods**: 5 wheelchair users (age=50.0 (5.6)), and 3 able-bodied (age=25.3(3.2)) participants completed several tasks; wheelchair treadmill propulsion at 30, 45, and 60 strokes per minute (spm), arm cycle ergometry (ACE) at 45, 60, and 80 revolutions per minute (rpm), and ACE VO2max test at 50rpm with wattage(W) increments of 15/20(female/male) per 3min stage until failure. Participants wore the SW on their dominant hand, and a heart rate monitor strap around their chest. Average steady state HRs from SW and HR strap were compared by Bland-Altman analysis.**Results**: Combined resting HRs from the SW were 78(11) beats per minute (bpm). HR strap recorded 78(11)bpm for resting HR. Bland-Altman analysis showed high agreement between SW and HR strap (mean difference= -.04 bpm, limits of agreement (LoA) ±6 bpm). Mean absolute percent error (MAPE) for resting state was 2.5%. Reported average HRs by SW for treadmill task at 30, 45, and 60spm were 54(44), 76(48) and 62(54) bpm, respectively. HR strap measurement were 76(12), 102(25), and 110 (14) bpm. Poor agreement was seen for the treadmill task at 30spm (-49(-171-73)), 45spm (-25(-116-66)), and 60srpm (-48(-160-65)), with MAPEs of 42.2%, 27.6% and 43.9%, respectively. For ACE, average HRs reported by SW at 45, 60, and 80rpm were 89(12), 88(38), and 101(47)bpm. HR strap measurements were 85(12), 90(18), and 91(15)bpm. Mean differences (LoA) were 5(-74-83), -2(-79-76), and 9(-93-112), with MAPEs of 30.6%, 31.3%, and 43.3%, respectively. Average HRs reported by SW for stages 1, 2, 3, 4 and 5 of ACE VO2max were 82(9), 91(42), 113(112), 85(67) and 41(82)bpm, respectively. HR strap measurements were 83(10), 95(6), 115(7), 143(12), and 169(4)bpm. Good agreement was seen at first three stages -.4(-7-6), 2.2%, -4(-88-79) 21.2%, and -2(-16-12) 3.1%. Agreement declined at higher stages 4 and 5, with -58(-207-92) 38.5% and -128(-283-28) 76.3%, respectively.**Conclusion**: SW shows good validity at measuring HR at rest and only at lower frequencies/stages of ACE based exercises. The SW was poor at tracking HR for the treadmill tasks.

Maturation-Related Change in Neuromuscular Component of Force Production in Trained and Untrained Girls

Rana Fayazmilani*[1], Aynaz Pourmotahari[2]
[1]Faculty member of Shahid Beheshti University, Exercise Physiology, r_milani@sbu.ac.ir
[2] Master Student of Exercise Physiology, Shahid Beheshti University, ai.pourmotahari@mail.sbu.ac.ir

Abstract
Purpose: the main purpose of the present study was to investigate the maturation-related change in neuromuscular components of force production in gymnasts and untrained girls during the maximal voluntary isometric contraction (MVC). **Method**: 60 girls, in two groups of gymnasts and untrained were divided into the three subgroups of preadolescents, adolescents, and adults according to Tanner's scale. All aspects of study were explained and clarified to all subjects. Then, informed consent forms were completed by subjects (in the child's group by their parents). After familiarity and initial measurements, each subject performed three maximal voluntary isometric contractions (MVC) of the knee extensor at five different angles to determine the optimal angle of force production. The rate of force development (RFD) was calculated using the torque data. The EMG signal of the rectus femoris muscle was recorded during the MVC test to measure voluntary activation (RMS). **Results**: The normalization of torque based on body weight eliminated the difference in force between the age groups. These results were similarly observed in the level of RMS and RFD. However, there was a significant difference between the gymnasts and the untrained groups in all variables. **Conclusion**: It seems that the differences in body size are more likely to justify absolute force differences than the neural factors. This is partly supported by the results of RMS and the RFD.
Keywords: Preadolescents, Electromyography (EMG), Rate of Force Development (RFD), Maximum Voluntary contraction (MVC)

Effects Of High Intensity Interval& Eccentric Training On Irisin And Myostatin Levels In Rats

neda khaledi, heidar hadavand, milad azad, farnoosh bidgoli.
kharazmi university, tehran, Iran, Islamic Republic of.
(No relevant relationships reported)

Some myokines such as irisin and myostatin have considerable effects on energy metabolism in addition to the musculoskeletal system. **PURPOSE:** Our aim was to investigate the effects of 9 weeks different training methods on circulating irisin and myostatin.**METHODS**: For this purpose, 20 Sprague Dawley rats with the weight range of (130±30gr) were divided into three groups: control (n=7), high intensity interval training (n=6), and eccentric training (n=7). They were held in the dark: light of 12:12. 48 hours after the last exercise session, protein measurement was performed using enzyme-linked immunosorbent assays (ELISA) test. **RESULTS:** Serum myostatin and irisin levels increased significantly following eccentric but they decreased following high intensity interval training. **CONCLUSIONS**:Despite these differences both myokines indicated significant relationship following 9 weeks of eccentric and high intensity interval training. Given the markedly increase in circulating myokines after eccentric training sessions these data suggest that eccentric training is probably more effective to stimulate skeletal muscle metabolic regulation.

Changes In Vitamin D Status Before And After Nordic Summer In Overweight Middle-aged Participants

Petra Lundström, Maria J. Eriksson, Kenneth Caidahl, Anette Rickenlund. *Karolinska Institutet, Stockholm, Sweden.*

(No relevant relationships reported)

Background: Sun exposure is the main source to synthesize vitamin D. Obesity, type II diabetes mellitus, and living at high altitude are risk factors for low vitamin D status. Seasonal variations in affected populations are unknown. **Purpose:** We investigated the effect of sun exposure during a summer season on vitamin D status in Sweden, and its association with fat mass and deranged carbohydrate metabolism. **Methods:** One hundred sixty-one subjects (91 women and 70 men), with a mean age of 60 ± 5 years with body mass index ≥ 25 kg/m^2, with or without deranged carbohydrate metabolism were studied. The participants were divided into groups based on an oral glucose tolerance test. Glucose tolerance was classified as normal (NGT) ≤ 8.9 mmol·L, impaired glucose tolerance ≥ 8.9-12.1 mmol·L or T2DM ≥ 12.2 mmol·L. Blood samples, body composition, and food questionnaires were taken before and after a summer season with a second year follow-up.
Results: Eighty-five percent of participants showed low to deficient levels of vitamin D before summer (55.1 ± 21.5 nmol·L^{-1}). After summer the level increased significantly to 66.4 nmol·L^{-1}, ($P<0.01$) but remained below the recommended value (≥ 75 nmol·L^{-1}) in 65% of the subjects. Similar low vitamin D levels were found in a follow-up substudy. Before summer, we did not find any interactions between vitamin D, carbohydrate metabolism, or gender. There were no significant differences in the mean value of vitamin D before and after the second summer compared with the first. Before summer, Vitamin D in women with NGT correlated with fat mass (% and kg) ($r = -0.34$ -0.43, $P = 0.01$). There was no correlation between vitamin D levels and the intake of fatty fish.
Conclusion: In most of this overweight/obese population, sun exposure at high latitudes had a beneficial but often insufficient effect on circulating vitamin D levels compared with those currently recommended.

Continuous Glucose Monitoring in Older Adults: Impact of Aerobic Exercise and Metformin on Glucose Variability

Oscar D. Safairad[1], Hayden M. Schoenberg[2], Jaime L. Laurin[2], Benjamin F. Miller, FACSM[2], Karyn L. Hamilton, FACSM[2], Adam R. Konopka[1]. *[1]University of Illinois at Urbana-Champaign, Urbana, IL. [2]Colorado State University, Fort Collins, CO.* (Sponsor: Karyn L. Hamilton, FACSM)

(No relevant relationships reported)

A greater magnitude and frequency of glucose fluctuations within or between days is defined as impaired glucose variability (GV) and is a risk factor for Type 2 Diabetes. Glycated hemoglobin (HbA1c) is the standard approach to provide an index of long-term GV (~3 months). Continuous glucose monitoring (CGM) has emerged as a tool to measure glucose every 5 minutes to ascertain short-term GV. **PURPOSE:** Identify if GV is impaired in older, non-diabetic individuals and determine the influence of aerobic exercise with or without metformin on GV in older adults. **METHODS:** CGM was used to measure cumulative GV over 7-10 days in young ($n=5$, 28yr, 23kg/m^2) and older ($n=17$, 64yr, 32kg/m^2) adults. In a double blinded fashion, older adults were randomized to consume placebo ($n=9$) or Metformin ($n=8$) during 12-weeks of aerobic exercise training (AET). Participants were provided a standardized beverage (300 kcal) after each exercise. CGM was also implemented during and after the 12-week intervention. Cumulative mean glucose, indices of intra-day (continuous overall net glycemic action (CONGA$_{4h}$)) and inter-day (mean of daily differences (MODD), average daily risk range (ADRR)) GV were calculated by EasyGV software. Mean glucose was also determined every 24-hr after AET. **RESULTS:** Older adults have greater (P<0.05) mean glucose (6.3 ± 0.7 vs. 5.3 ± 0.3), CONGA$_{4h}$ (5.2 ± 0.4 vs. 4.4 ± 0.3), MODD (1.2 ± 0.4 vs. 0.9 ± 0.1), and ADRR (7.4 ± 4.8 vs. 2.6 ± 1.2) versus young. Compared to baseline, cumulative mean glucose and ADRR were lower (P<0.05) during AET in older adults on placebo (Mean, 6.2 ± 0.6 vs 5.5 ± 1.0; ADRR, 6.9 ± 3.3 vs 4.8 ± 1.7) or metformin (Mean, 6.3 ± 0.7 vs 5.5 ± 0.7; ADRR, 8.2 ± 6.3 vs 5.5 ± 2.0). When taking metformin, CONGA$_{4h}$ was also lower during AET (5.2 ± 0.4 vs 4.9 ± 0.3). Cumulative GV was not different after AET in either group. However, in

the metformin group, 24-hr mean glucose was decreased (P<0.05) 1 day after AET and gradually increased the next 7 days (P≤0.06 Days 5-7 vs. Day 1) back to baseline. **CONCLUSION:** In older adults, cumulative mean glucose and GV were decreased toward young values during AET. While improvements in cumulative GV dissipated after AET, the addition of metformin to exercise may delay the return of 24-hr glucose to baseline values. These data highlight the need for regular exercise to sustain improvements in GV in older adults.

Effect of Moderate Intensity Exercise Dose on Lipoprotein Concentrations and Particle Size in Older Women

Ryan R. Porter, J. Larry Durstine, FACSM, Charity B. Breneman, Xuewen Wang. *University of South Carolina, Columbia, SC.* (Sponsor: J. Larry Durstine, FACSM)

(No relevant relationships reported)

Lipoprotein concentrations are well established biological markers associated with cardiovascular disease (CVD) risk. Recent research has placed great importance on the function of different lipoprotein subfractions (medium and small VLDL; small and large LDL; small, medium and large HDL). Current literature supports exercise as being protective by affecting lipoprotein particle size and concentration, whereas little research has been conducted to determine the effects of exercise dose on these outcomes.
PURPOSE: To determine if exercise dose has an effect on VLDL, LDL, and HDL particle size and concentrations in older sedentary women after 16 weeks of moderate-intensity aerobic exercise.
METHODS: Sixty-five women (age = 64.7 ± 4.2 years) were randomized into higher-dose (n = 30) and lower-dose (n = 35) exercise groups. Supervised treadmill walking sessions lasted approximately 35 or 55 minutes, 3 times per week, for lower-dose and higher-dose groups, respectively. All exercise was completed at an intensity of 50-55% of heart rate reserve. Fasting plasma samples were collected before and after exercise intervention. Plasma lipoprotein particle concentrations and average sizes were determined by nuclear magnetic resonance spectroscopy.
RESULTS: Exercise, in the entire sample, lowered total HDL and small VLDL particle concentration (1.5 ± 3.6 µmol/L and 4.2 ± 16.4 nmol/L; p<0.01 and p<0.05, respectively), and increased mean HDL particle size (0.1 ± 0.3 nm; p<0.01). When analyzed by exercise groups, the lower-dose group displayed a decrease in total HDL particle concentration (1.9 ± 3.1 µmol/L; p=0.001), while the higher-dose group displayed an increase in mean LDL particle size (0.3 ± 0.5 nm; p<0.05). Both exercise higher-dose and lower-dose treatments were found to significantly increase mean HDL particle size (0.1 ± 0.2 nm and 0.1 ± 0.3 nm, respectively; p<0.05) with no significant difference between groups.
CONCLUSIONS: The results from this study support that exercise in sedentary older women decreased CVD risk. Though the HDL particle concentration decreased in the lower-dose group, maintenance of HDL particle concentration in the higher-dose group along with the increase in mean HDL and LDL size are characteristics associated with lower CVD risk. Supported by NIH Grant R00AG031297

Resistance Exercise and Low Dose Protein Ingestion Augments Anabolic Signaling Mechanisms In Older Women

Susannah E. Scaroni[1], Sarah K. Skinner, 61801[1], Joseph W. Beals[1], Stephan van Vliet[1], Elizabeth Poozhikunnel[1], Ralf Jager[2], Martin Purpura[2], Jonathan Oliver[3], Scott Paluska, FACSM[1], Nicholas A. Burd[1]. *[1]University of Illinois at Urbana-Champaign, Urbana, IL. [2]Increnovo LLC, Milwaukee, WI. [3]Texas Christian University, Fort Worth, TX.* (Sponsor: Scott Paluska, FACSM)

(No relevant relationships reported)

Resistance exercise enhances skeletal muscle anabolic signaling responses to the ingestion of sub-optimal amounts of protein in young men. However, the effectiveness of resistance exercise to potentiate the phosphorylation of the mechanistic target of rapamycin (mTORC1) to the ingestion of minimal amount of protein in aging women has not been well characterized. **PURPOSE:** We compared the phosphorylated-state of mTORC1 before and after ingestion of ~14 g whey protein or water at rest and after resistance exercise in middle-aged and older women. **METHODS:** 10 women (59 ± 2 y; BMI: 25 ± 1 kg/m^2; LBM: 46 ± 2 kg) performed a bout of unilateral leg extension exercise (3 sets × 12 repetitions at 60% estimated 1RM) prior to ingesting whey protein (0.3g/kg LBM; WHEY, $n=5$) or water (WATER $n=5$). Blood and skeletal muscle biopsies were used to measure plasma amino acids and insulin concentrations and phosphorylation of mTORC1 at Ser2448 at 2 and 4 h of the postprandial phase in both exercise (EX) and non-exercised (CON) legs. **RESULTS:** Plasma branched chain amino acid concentrations were increased from basal (2.5-fold) in WHEY ($P<0.05$), but not in WATER condition ($P>0.05$). Plasma insulin concentrations increased after WHEY (2.3 ± 0.8 fold change from basal, $P=0.02$), but not after WATER ingestion (1.0

± 0.1 fold-change, P=0.45). WHEY ingestion increased mTORC1 phosphorylation at 2 h (3.4±0.6 and 1.7±0.3 fold-change in EX and CON, respectively $P<0.05$). There were no changes in mTORC1 phosphorylation after WATER ingestion at any time point ($P>0.05$). **CONCLUSION:** Our data demonstrated that consuming a minimal amount of protein immediately after resistance exercise resulted in a greater, but transient, phosphorylation of anabolic signaling mechanisms involved in protein translation over that induced by feeding or resistance exercise alone.

Calorie Restriction Promotes Constant Physical Activity Levels Throughout Total Lifetime of Female Mice

Jorge Z. Granados[1], Ayland C. Letsinger[1], Heather L. Vellers[1], Victor A. Garcia[1], Jeremiah D. Velasco[1], Edward C. Nagle[1], Layla C. Perez[1], Madison Spier[2], Isabel Lambertz[2], Robin Fuchs-Young[2], J. Timothy Lightfoot, FACSM[1]. *[1]Texas A&M University, College Station, TX. [2]Texas A&M University Health Science Center, College Station, TX.* (Sponsor: J. Timothy Lightfoot, FACSM)

(No relevant relationships reported)

BACKGROUND: Physical inactivity contributes to incidence of diseases and decreased life expectancy. Previous data has shown that chronic overfeeding via high fat high sugar diet (HFHS) reduces voluntary wheel running (WR) activity in mice. **PURPOSE:** Determine the effects of a 12% calorie restriction diet (DR) vs. an *ad-lib* HFHS diet on physical activity (PA) levels (distance, duration, speed) throughout total lifetime in female SENCAR mice. **METHODS:** SENCAR mice were bred and offspring were weaned at 3 weeks of age onto a HFHS (20% protein, 45% fat, 24% sucrose + 10% fructose water), an *ad-lib* standard chow (CONT; 20% protein, 10% fat, 57% cornstarch), or a DR (12% kcal restriction, 20% protein, 10% fat, 57% cornstarch). At 4 weeks of age, female mice were housed in pairs and two plastic running wheels were mounted inside each cage. WR distance (km/day) and duration (min/day) were recorded and used to calculate average speed (m/min) via a mounted computer system. Repeated measures ANOVA determined the effect of diet on WR activity relative to varying percentages of total lifetime (15%, 25%, 50%, 75%, and 100%). **RESULTS:** 116 female mice [HFHS (n=42), DR (n=55), CNTL (n=19)] were analyzed. Both *ad lib* HFHS and *ad lib* CONT diets significantly decreased distance, duration, and speed after 25% of the total lifespan. All PA variables remained unchanged for the DR mice with the only significant reduction occurring in duration between 75% (221 ± 98min/day) to 100% (188 ± 79min/day) of total lifetime. Additionally, correlations of determination were observed for body weight vs HFHS (.44), DR (.04), and CONT (.34) diets. **CONCLUSIONS:** DR mice maintained activity levels across their lifespans as compared to *ad lib* CONT and *ad lib* HFHS mice whose activities decreased over their lifespan. These findings substantiate our previous data and propose that minimal calorie restriction may serve a novel intervention to prevent physical inactivity across the lifespan.

Leucine-Enriched Protein Supplementation Does Not Augment Muscle Mass and Strength Gains During Resistance-Type Exercise Training in Older Males

Andrew M. Holwerda, Maarten Overkamp, Kevin J.M. Paulussen, Joey S.J. Smeets, Annemie P. Gijsen, Joy P.B. Goessens, Lex B. Verdijk, Luc J.C. van Loon. *Maastricht University Medical Centre+, Maastricht, Netherlands.* (Sponsor: Professor Janice L. Thompson, PhD, FACSM)

(No relevant relationships reported)

Purpose: The proposed benefits of protein supplementation on the skeletal muscle adaptive response to resistance-type exercise training remain unclear. Protein ingestion after exercise and prior to sleep have been shown to augment muscle protein synthesis during recovery from exercise. However, it remains to be established whether dietary protein ingestion after exercise and before sleep augments muscle mass and strength gains during resistance-type exercise training in older individuals. **Methods:** Forty-one healthy older males (70±1 y) completed 12 weeks of whole-body resistance-type exercise training (3 sessions·week^{-1}) and were randomly assigned to ingest either protein (20 g whey plus 1 g leucine; n= 21) or an energy-matched placebo (n= 20) after exercise and each night prior to sleep. Maximal strength was assessed by one-repetition maximum (1RM) testing before and after training. Muscle hypertrophy was assessed at the whole-body (dual-energy X-ray absorptiometry), upper leg (computed tomography scan), and muscle fiber (biopsy) levels. Muscle protein synthesis during week 12 of training was assessed by providing deuterated water (^{2}H$_2$O) and collecting muscle biopsies. **Results:** Leg extension 1RM increased in both groups (placebo: 88±3 to 104±4 kg, protein: 85±3 to 102±4 kg; $P<0.001$), with no differences detected between groups ($P>0.05$). Appendicular lean mass (placebo: 26.7±0.7 to 27.7±0.7 kg, protein: 26.0±0.5 to 26.6±0.5 kg; $P<0.001$) and quadriceps cross sectional area

(placebo: 67.8±1.7 to 73.5±2.0 cm^2, protein: 68.3±1.4 to 72.3±1.4 cm^2; $P<0.001$) increased in both groups, with no differences detected between groups ($P>0.05$). Muscle fiber hypertrophy occurred in type II (placebo: 5486±418 to 6492±429 μm^2, protein: 5367±301 to 6259±391 μm^2; $P<0.001$), but not in type I fibers (placebo: 6059±364 to 6600±269 μm^2, protein: 5935±246 to 6171±305 μm^2; $P>0.05$), with no differences detected between groups ($P>0.05$). Muscle protein synthesis rates were 1.62±0.06 and 1.57±0.05 %·d^{-1} in the placebo and protein groups, respectively, with no differences detected between groups ($P>0.05$). **Conclusion:** Leucine-enriched protein supplementation after exercise and before sleep does not augment skeletal muscle mass or strength gains after resistance-type exercise training in older males.

(No relevant relationships reported)

Resistance exercise enhances the anabolic sensitivity of myofibrillar protein synthesis rates (MPS) to the ingestion of a moderate amount of protein in young and older men. However, the effectiveness of resistance exercise to potentiate postprandial MPS after the ingestion of minimal dose of protein in aging women has not been well characterized. **PURPOSE:** We compared changes in MPS to ingestion of ~14 g whey protein or water at rest and after resistance exercise in middle-aged and older women. **METHODS:** 10 women (59±2 y; BMI: 25±1 kg/m^2; LBM: 46±2 kg) performed a bout of unilateral leg extension exercise (3 sets × 12 repetitions at 60% estimated 1RM) prior to ingesting whey protein (0.3g/kg LBM; WHEY, n=5) or water (WATER n=5). Primed continuous infusions of L-[$ring$-^{13}C$_6$]phenylalanine, blood, and skeletal muscle biopsies were used to measure MPS over 4 h postprandial phase in both exercise (EX) and non-exercised (CON) legs. **RESULTS:** Plasma essential amino acid concentrations were increased from basal (2.5-fold) in WHEY group ($P<0.05$), but not in WATER group ($P>0.05$). EX significantly increased MPS above basal in both WHEY (5-fold) and WATER (2.3-fold) groups over the 4-hour postprandial period ($P<0.05$). MPS were not significantly increased above basal rates in the CON leg throughout the postprandial period in either condition (P=0.104). No group differences in MPS were observed between the WHEY or WATER groups in either the EX or CON legs ($P>0.05$). **CONCLUSION:** A moderate volume of resistance exercise significantly increased MPS in aging women. However, the ingestion of a low dose of whey protein immediately after resistance exercise did not potentiate the MPS response when compared to ingesting water. Therefore, more targeted anabolic strategies are warranted to maximize the MPS response to feeding and exercise in older women.

Impact Of Altitude On Sample Size Estimations For Exercise Performance:Implications For Research

Roy Salgado, Samuel Cheuvront, FACSM, Upendra Bhattarai, Robert Kenefick, FACSM. *US Army Research Institute of Environmental Medicine, Natick, MA.*

(No relevant relationships reported)

Adequate sample size is needed to detect a meaningful change in an outcome variable in response to an experimental intervention (e.g. dietary supplements). **Purpose:** To calculate and compare the sample size needed to detect a significant and meaningful improvement (5 - 20%) in exercise performance using different modes (i.e. cycling and running) of exercise at 3500 and 4300 m altitude for test selection. **Methods:** A total of 62 sea level (SL) residents (58 men and 4 women; mean ± SD; 24 ± 5 yrs, 176.0 ± 7.6 cm, 78.4 ± 11.4 kg; 49.3 ± 6.4 ml·kg^{-1}·min^{-1} VO2peak) completed either a: 1) 720kj cycle time trial (TT) at 3500 m (n = 6), or at 4300 m (n = 17); 2) a 5000/6000W cycle TT at 4300 m (n = 13); 3) a 11.2 km treadmill TT at 3500 m (n=11); or 4) a 3.2 km TT at 4300 m (n = 15) at SL and within two days upon arrival to altitude. Sample size

(n) was calculated as: n = 16*CV (%)/Δ perf (%), where CV (%) = typical error (sec)/ mean TT perf (sec) and Δ perf (%) = 5, 10, and 20% improvement in performance to be detected. **Results:** Table 1 provides sample size estimations needed to detect a change in cycling and running performance of 5, 10, and 20% at 3500 and 4300 m of altitude. **Conclusion:** The findings indicate that performance measured using running as a mode of exercise when compared to cycling requires a smaller sample size to detect a significant and meaningful change.

Ischemic Preconditioning and Cycling Time Trial Performance in Hypoxia

Chad C. Wiggins, Keren Constantini, Timothy D. Mickleborough, Robert F. Chapman, FACSM. *Indiana University, Bloomington, IN.* (Sponsor: Robert F. Chapman, FACSM)

(No relevant relationships reported)

Ischemic preconditioning (IPC) of the legs prior to exercise has been shown as a novel approach to improve performance in a number of different exercise modes in normoxia. Very little has been done potential mechanisms behind the performance improvements in well-trained subjects, and less has been done examining the influence of these mechanisms during exercise in hypoxia. **PURPOSE:** To determine if IPC is an effective intervention for improving 5km cycle time trial (TT) performance in both normoxia and hypoxia. **METHODS:** Thirteen men (age= 24 ± 4 years, $\dot{V}O_2$max= 63.1 ± 5.1 ml·kg⁻¹·min⁻¹) completed four randomized trials of each combination of hypoxia ($F_IO_2 = 0.16$) or normoxia with a resting pre-exercise IPC protocol (4 x 5min at 220mmHg) or SHAM (4 x 5min at 20mmHg) procedure. Following the IPC/SHAM protocol subjects completed two constant load bouts and a 5km time trial on a cycling ergometer. Breath-by-breath $\dot{V}O_2$, oxyhemoglonin saturation, and skeletal muscle oxygenation/extraction (measured via near-infrared spectroscopy) were continuously monitored throughout the trials. **RESULTS:** IPC significantly improved 5km TT time in normoxia by 0.9 ± 1.7% compared to SHAM (IPC: 491.2 ± 33.7s vs. SHAM: 495.9 ± 34.5s, P < 0.05). IPC did not alter 5km TT performance times in hypoxia. Muscle oxygenation, extraction, and tissue saturation did not differ between treatments or inspirates (P > 0.05). **CONCLUSION:** IPC improves 5km cycling TT performance in normoxia only. Muscle oxygenation was unchanged suggesting that highly trained subjects choose power output based on a set level of muscular oxygenation regardless of the fraction of inspired oxygen or treatment with IPC.

Muscle Oxygenation & Systemic Metabolic Responses during Maximal Sprint Exercise in Hypoxia among Athletes

Nobukazu Kasai, Yuka Motomura, Akiho Ikutomo, Kazushige Goto. *Ritsumeikan University, Kusatsu, Japan.* (Sponsor: Robert Kraemer, FACSM)

(No relevant relationships reported)

The influence of maximal sprint exercise in moderate hypoxia on muscle oxygenation and systemic metabolic responses has not been fully elucidated. **PURPOSE:** The purpose of the present study was to determine the effects of maximal sprint exercise in moderate hypoxia on muscle oxygenation, systemic oxygen uptake and power output among competitive athletes. **METHODS:** Seven sprinters (height; 176.1 ± 2.2 cm, body weight; 67.8 ± 3.4 kg, BMI; 22.6 ± 0.7 kg/m²) participated. They performed two trials under either hypoxic (HYP, F_IO_2: 14.5%, a simulated altitude of 3000m) or normoxic (NOR, F_IO_2: 20.9%) conditions in a randomized, with a single-blind and crossover design. The exercise in each trial consisted of three consecutive sets of 20-s maximal sprints with a 5 min rest period between sets. Time-course changes in percutaneous oxygen saturation (SpO_2,

power output during exercise, blood lactate, glucose concentrations, and muscle oxygenation [oxy-hemoglobin (Hb), deoxy-Hb, total-Hb], and respiratory variables were evaluated.

RESULTS: A significant main effect of number of set was observed for mean power output during exercise ($P<0.01$). However, no significant interaction (trial × number of set, $P=0.76$) or main effect of trial ($P=0.66$) for mean power output was observed. There were significant main effects of trial ($P<0.01$) and time ($P<0.01$) for blood lactate concentration, and post-exercise blood lactate concentrations were significantly higher in the HYP (22.8 ± 0.6 mmol/L) than in the NOR (20.0 ± 0.7 mmol/L, $P<0.05$). Both trials showed significant increases in deoxy-Hb and total-Hb during the exercise (main effect of time, $P<0.01$). However, deoxy-Hb and total-Hb tended to be higher in the HYP during the latter sets of sprint. Accumulated VO_2 during exercise was significantly lower in the HYP (1419 ± 76 ml) than in the NOR (1973 ± 120 ml, $P<0.01$), whereas accumulated VCO_2 was not significantly different between the trials (main effect of trial, $P=0.65$).

CONCLUSION: No apparent difference in muscle oxygenation kinetics during maximal sprint exercise was found between hypoxic and normoxic conditions. However, exercise-induced elevations of muscle deoxygenation (deoxy-Hb) tended to be augmented under hypoxic condition.

Cardiac Function and SMO_2 During HIIT at Altitude and Sea Level with Oxygen Contrast Training

Frank Wojan[1], Craig Broeder, FACSM[1], Peter Chomentowski[1], Anthony Deldin[2]. *[1]Northern Illinois University, DeKalb, IL. [2]Loyola University, Chicago, IL.* (Sponsor: Craig Broder, Ph.D., FNAASO, FACSM)

(No relevant relationships reported)

PURPOSE: This study investigated how high-intensity interval training (HIIT) at altitude (ALT) versus sea level (SL) with and without supplemental oxygen recovery (SRO2) affected cardiac function and skeletal muscle %O2 saturation (SMO2). **METHODS:** Eight cyclists aged 42.4 ± 7.7 (HT: 68.9 ± 4.6; WT: 177.9 ± 26.6; Body Fat: 19.3% ± 7.5%; VO2 max L/min 4.38 ± 1.01) performed a baseline cycling VO2max test and four treatment trials (TRA - ALTHIIT/SRO2; TRB - SLHIIT/ SLrecovery; TRC - ALTHIIT/SLrecovery; TRD - steady-state (SS) cycling). Each HIIT work period (n=3) was 75s with 120s recovery at 75% and 50% of VO2max, respectively. For TRD, subjects cycled at a workload equal to the mean O2 uptake equal of TRB (Control-Trial). O2 uptake was measured using a breath X breath metabolic cart for VO2 max and TRB. Cardiac function (HR, Cardiac Output (Q), Stroke Volume (SV)) was assessed using impedance cardiography. SMO2 was measured in the vastus-intermedius quadricep muscles using Moxy NIR devices. Data was analyzed using a w/in repeated measures design (Treatment (4) X 3 HIIT/ Recovery Periods). **RESULTS:** Despite identical workloads, HR was significantly lower during SS cycling compared to the HIIT trials by 7.6% (SS: 118.0 ± 3.4; Mean HIIT TR HRs: 127.0 ± 3.7, p=0.002). ALTHIIT/SRO2 (TRA: 141.8 ± 9.2) showed a lower SV by 8.4% compared to the ALTHIIT/SLrecovery trial (TRC: 154.3 ± 9.2). Q was significantly lower during the HIITw/SRO2 (TRA:17.7 ± 1.1) compared to SLHIIT/SLrecovery & ALTHIIT/SLrecovery (TRB: 19.8 ± 1.1; TRC:19.8 ± 1.1) by 12% (P=0.04). SMO2 data showed a trend for ALTHIIT/SRO2 & SS cycling to have higher SMO2 values compared to the both HIIT trials without SRO2 (p=0.09). During recovery, ALTHIIT/SRO2 showed improved HR recovery 5.2% (p=0.01), increased SMO2 re-saturation rate 12.6% (p=0.01), and lowered Q 11.9% (p=0.01) compared to the altitude-sea level recovery trial. **CONCLUSION:** These results suggested that supplemental O2 recovery lowered cardiac demand (Q) at the same HIIT workload by maintaining HIIT SMO2 better by enhancing the overall recovery process. Supported by a grant from LiveO2 and Exercising Nutritionally, LLC

Effects Of HIIT Training While Using A Breathing-restrictive Mask Compared To Increased Environmental Altitude

Bryanne N. Bellovary[1], Kelli E. King[1], Tony P. Nuñez[2], James J. McCormick[1], Andrew D. Wells[1], Kelsey C. Bourbeau[1], Zachary J. Fennel[1], Zidong Li[1], Kelly E. Johnson[3], Terence Moriarty[1], Christine Mermier[1]. *[1]University of New Mexico, Albuquerque, NM. [2]Metropolitan State University of Denver, Denver, CO. [3]University of Saint Mary, Leavenworth, KS.* (Sponsor: Dr. Ann L. Gibson, FACSM)

(No relevant relationships reported)

Purpose: To determine whether six weeks of high intensity interval training (HIIT) while wearing a breathing-restrictive mask (mask) (model 2.0, Training Mask LLC, Cadillac, MI) set to simulate 2550 m improves VO_2max and submaximal VO_2 compared with training in hypobaric hypoxia (2550 m) and control conditions (1550 m). **Methods:** Thirty participants volunteered and were consented and randomized into a mask (M) (n = 10; 5 men), altitude (A) (n = 10; 6 men), or control (C) (n =

10; 4 men) group. Participants maintained their normal routine. Pre- and post-testing included a VO_2max on a cycle ergometer with continuous metabolic gas analysis allowing submaximal power outputs (PO) measures of economy. All participants completed POs of 100, 125, and 150W as they exercised to VO_2max. Ventilatory threshold 2 (VT2) was determined graphically using metabolic equivalents. Participants cycled on an ergometer 2x/week for 30 min/session for six weeks. Sessions included a 5-min warm-up and cool-down with 20 min of HIIT (30s at 100% peak power output (PPO) of preVO_2max, 90s active recovery at 25W, 10 bouts). Repeated measures ANOVA and one-way ANOVA determined statistical significance for training changes and percent change, respectively ($p < 0.05$). **Results:** All groups significantly improved PPO by 8.3-13.0% (M: $F_{(1,9)} = 17.28$, A: $F_{(1,9)} = 7.45$, C: $F_{(1,9)} = 11.96$, $p < 0.05$). The M group improved PO at VT2 by 13.8% ($p = 0.009$). There was a nonsignificant improvement (8.3%) in PO at VT2 for the A group ($p = 0.054$). However, no significant differences occurred between groups for PPO and PO at VT2 ($p = 0.481$ and 0.250, respectively). The M group was significantly less economical (higher VO_2) at 125W before and after training compared with the C group ($p = 0.003$). However, percent change in submaximal VO_2 at 100, 125, and 150W were not different between groups ($p = 0.907$, 0.743, and 0.985, respectively). Percent improvements in VO_2max were not different between groups (C = 3.6%; M = 2.6%; A = 6.5%; $p = 0.623$). **Conclusion:** Since all groups demonstrated similar HIIT adaptations, using the mask or training in hypobaric hypoxia may not be needed for training adaptations. The protocol followed a live low, train high altitude model which typically lacks training improvements compared with a live high, train low altitude model.

Muscle Oxygenation During Repeated Double-poling Sprint Exercise Under Hypoxic Condition

Keiichi Yamaguchi, Nobukazu Kasai, Daichi Sumi, Haruka Yatsutani, Kazushige Goto. *Ritsumeikan University, Kusatsu, Japan.* (Sponsor: Robert R Kraemer, FACSM)

(No relevant relationships reported)

PURPOSE: To compare acute physiological responses to repeated double-poling sprint exercise between normoxic condition and hypoxic condition.
METHODS: Eight male athletes (19.8 ± 1.0 yrs, 174.9 ± 6.5 cm, 71.1 ± 5.8 kg) completed repeated exercise (double-poling exercise) under either hypoxic (HYP, FiO_2: 14.5 %) or normoxic condition (NOR, FiO_2: 20.9 %). The exercise consisted of 9×20 s maximal sprint exercise (40 s or 5 min rest periods between sprints). Power output, muscle oxygenation of triceps brachii muscles (evaluated by near infrared spectroscopy; NIRS), arterial oxygen saturation (SpO_2) and respiratory variables were continuously monitored throughout exercise. Changes in blood lactate and glucose concentrations were also determined.
RESULTS: SpO_2 during exercise remained significantly lower in HYP ($P < 0.05$). Mean power output during exercise did not differ significantly between HYP and NOR. No significant difference between the trials was observed for blood lactate and glucose concentrations. Both trials showed significant increases in deoxygenated hemoglobin (deoxy-Hb) (241.7 ± 46.9 % in HYP vs. 175.8 ± 27.2 % in NOR) and total hemoglobin (total-Hb) (138.0 ± 18.1 % in HYP vs. 112.1 ± 6.7 % in NOR) for triceps brachii muscle, but the exercise-induced elevations of these variables were significantly greater in HYP ($P < 0.05$). During exercise, systemic oxygen uptake was significantly lower in HYP (2126 $\pm$ 108 ml/kg/min) than in NOR (2531 $\pm$ 74 ml/kg/min) ($P < 0.05$).
CONCLUSIONS: Exercise-induced elevation of total-Hb was profound during repeated double-poling sprint exercise in hypoxia, suggesting augmented blood volume (blood perfusion) in working muscles. In addition, power output during exercise was not affected by hypoxia, although systemic oxygen uptake was significantly lower.

High-intensity Interval Training In Hypoxic Condition Accelerate The Anerobic Glycolytic System

Marie Oriishi[1], Hayato Ohnuma[2], Masahiro Hagiwara[3], Ryo Yamanaka[4], Toshiyuki Ohya[5], Kazunori Asaba[6], Takashi Kawahara[2], Yasuhiro Suzuki[2]. *[1]Tsukuba University, Ibaraki, Japan. [2]Japan Institute of Sports Sciences, Tokyo, Japan. [3]Japan Olympic Committee, Tokyo, Japan. [4]Teikyoheisei University, Chiba, Japan. [5]Chukyo University, Aichi, Japan. [6]Yamanashi Gakuin University, Yamanashi, Japan.*

(No relevant relationships reported)

We previously demonstrated that 7 days of intermittent hypoxic training improved performance in the maximal anaerobic running test (MART) (ACSM 2015). It is expected that the high-intensity interval training (HIT) in hypoxic condition is one of the key of performance enhancement method. However, the differences of physiological response during HIT between in hypoxia and in normoxia is not clear. **PURPOSE**: The purpose of the present study was to compare the physiological response during HIT in hypoxic condition with normoxic condition in well-trained 400m or 800m runners.**METHODS**: Thirty-five well-trained university female 400m or 800m runners were assigned to either hypoxic group (n=18) or normoxic group (n=17). The hypoxic group completed 5 sets of 30 seconds maximal effort pedaling in a normobaric hypoxic room (FIO2=14.4%; 3000m). The rest periods between each sets were 4 minutes. The normoxic group completed the same exercise in ambient normobaric normoxia (60m). Mean power and peak power of each sets were recorded. Blood lactate concentration (La) was measured 1 minute after each sets of pedaling. **RESULTS**: No significant differences with hypoxic and normoxic group were found in mean power of each sets (hypoxic group: 464.7 $\pm$ 56.2, 396.4 $\pm$ 39.0, 324.7 $\pm$ 31.6, 286.2 $\pm$ 28.2, 245.7 $\pm$ 24.5, normoxic group: 455.5 $\pm$ 61.5, 396.9 $\pm$ 43.0, 339.0 $\pm$ 31.6, 293.2 $\pm$ 29.8, 249.1 $\pm$ 25.6 W). No significant differences between hypoxic and normoxic group were found in peak power of each sets (hypoxic group: 577.0 $\pm$ 77.2, 509.7 $\pm$ 55.1, 407.0 $\pm$ 46.6, 345.8 $\pm$ 41.9, 287.6 $\pm$ 30.6, normoxic group: 553.3 $\pm$ 85.4, 493.2 $\pm$ 61.6, 412.1 $\pm$ 45.3, 344.9 $\pm$ 41.0, 287.5 $\pm$ 34.0 W). La values from hypoxic group were significantly higher than normoxic group after every sets of pedaling ($p < 0.01$, 1st set: 16.5 $\pm$ 2.5 vs. 13.3 $\pm$ 2.1, 2nd set: 19.9 $\pm$ 2.5 vs. 16.7 $\pm$ 2.0, 3rd set: 21.7 $\pm$ 2.5 vs. 17.5 $\pm$ 1.9, 4th set: 21.1 $\pm$ 2.4 vs. 17.6 $\pm$ 1.9, 5th set: 21.2 $\pm$ 2.2 vs. 17.9 $\pm$ 1.7 mmol/l).**CONCLUSIONS**: The power produced during high-intensity interval training is not affected by hypoxic condition. However, energy production through anaerobic glycolytic system seems to accelerate in hypoxic condition.

Changes in Bone Mineral Density of Middle and Long Distance Runners Across an Indoor Season

Ronald Otterstetter, FACSM[1], Jordan T. Olson[1], Marissa N. Baranauskas[2], Brian Miller[1], Michelle M. Boltz[1], Laura Richardson[1], Matthew Juravich[1]. *[1]The University of Akron, Akron, OH. [2]Indiana University, Bloomington, IN.*

(No relevant relationships reported)

INTRODUCTION: Bone mineral density (BMD) is an important aspect of bone health in endurance runners. Musculoskeletal overuse injuries to the bone, such as stress reactions and stress fractures, are of major concern to endurance runners and coaches because of the debilitating nature they have on training and performance. A greater understanding of BMD in these athletes can lead to a reduction in stress injuries to bone. PURPOSE: To determine changes in total and segmental BMD over the course of an indoor track season between sexes and between middle and long distance event groups. METHODS: Volunteers from a collegiate track team (N=21; men=13/women=8; Age= 20.3 +/- 1.1 yrs.) were recruited. Dual x-ray absorptiometry (DEXA) was used to measure BMD before and after the 8-week indoor track and field season. Runners were classified as long or middle distance based on their current and past training history. Total and segmental BMD data were collected from DEXA output. A 2x2 factorial design using an ANCOVA procedure, adjusting for the pre-season BMD, was used to identify differences by sex and distance. RESULTS: Significant differences ($p<0.001$) were observed in leg BMD by sex (Men= 1.54 ± 0.12 g/cm²; Women= 1.34 ± 0.04 g/cm²) with an adjusted mean difference of 0.176 g/cm². The men had an increase in their leg BMD, while women did not change over the length of the season. No other significant differences were found in total body BMD or any segmental BMD measures when comparing event classification or sex. CONCLUSION: The findings provide support for BMD awareness with runners to facilitate mechanisms for reduced injuries. For the current study, the stress placed on the bones of the runners over the span of an indoor track and field season was enough to maintain and even elicit favorable changes in leg segmental BMD. Training volume and intensity were not factors in BMD changes across a track season. Additional investigation on differences among sex is warranted for healthy endurance athletes.

Bone Mineral Density in Master Olympic Weightlifters

Kayleigh Erickson[1], Mara Mercado[1], Kailey Goins[1], Monica R. Lininger[2], Bryan Riemann[1]. *[1]Armstrong State University, Savannah, GA. [2]Northern Arizona University, Flagstaff, AZ.*

(No relevant relationships reported)

Research has demonstrated the effects of resistance training on bone mineral density (BMD). Olympic style weightlifting, unlike traditional resistance training, uses

the entire body to conduct higher load lifts at higher velocities and lower training volumes. Little research has been done in looking at the Olympic style weightlifting and the impact it can impose on the body. Whether this mode of training results in similar BMD adaptations is unknown, particularly in middle and older age adults. **PURPOSE**: To determine the influence of age and sex on BMD in Masters Olympic Weightlifters when body mass index, weightlifting experience and strength were controlled. **METHODS**: Men (n = 27) and women (n= 24) competitors from the 2017 National Masters Championship (age: 35 to 76 years) volunteered for BMD (g/cm^2) measurement using a dual energy X-ray absorptiometry (DXA) for the following sites: spine (L1-L4), femoral neck, radius and total body. For each site, separate regression models were developed using age, sex, body mass index (BMI), experience level (years of competitive lifting), and strength (meet clean and jerk performance to body mass ratio). **RESULTS**: The set of independent variables were statistically significant predictors of BMD for the radius (P<.001, R$^2_{adj}$=.50), femoral neck (P=.009, R$^2_{adj}$=.25) and total body (P=.001, R$^2_{adj}$=.36). The model for the spine was not statistically significant (P=.056, R$^2_{adj}$=.15). BMI and strength, individually, were significant predictors of radial BMD while BMI was a significant predictor for total body BMD. Neither sex nor age were significant predictors of BMD for any of the four sites. **CONCLUSIONS**: Previous studies have noted that with aging, BMD declines, especially in women post-menopause. Our study revealed that there were no sex differences, nor was age or weight lifting experience significant predictors for BMD at the four sites considered. One interpretation of these results is that the Olympic style weight training may reduce age and sex related declines in BMD. Future research will compare BMD between age and sex matched runners and sedentary individuals to determine the accuracy of this interpretation.

Effect Of Symmetric Weight Training On Imbalanced Humerus Bone Mineral Density Of Arms In Baseball Pitchers

Maryam Rahmani[1], Chen-Wei Chung[2], Chia-Hua Kuo, FACSM[3]. [1]Islamic Azad University Science and Branch, Tehran, Iran, Islamic Republic of. [2]Shih Hsin University, Taipei, Taiwan. [3]University of Taipei, Taipei, Taiwan. (Sponsor: Chia-Hua Kuo, FACSM)
(No relevant relationships reported)

Background: Mechanical stress is known as a strong stimulus for bone growth. **Purpose**: To examine effect of bilateral balanced weight training on the disparity in bone mineral density (BMD) between dominant and non-dominant arm of baseball players. **Methods**: Baseball players (N = 25, aged 18-22 y) participated in this study after baseline measurement under overnight fasted condition. Participants received either high protein (36% protein, 6.8 kcal per kg) or low protein (12% protein, 6.8 kcal per kg) supplementations immediately after each resistance workout, 3 days a week, for 12 weeks. Three days after the last exercise-training bout, BMD were assessed by dual-energy x-ray absorptiometry (DEXA). **Results**: The baseline data show an unequivocal greater humerus bone mineral density in the dominant arm compared to contralateral non-dominant arm (~20% greater) for all baseball players without exception. However, none other locations had significant asymmetry in BMD between limbs. Weight training significantly increased humerus bone BMD (main effect), but mildly decreased total body BMD. Resistance training increased BMD in humerus bone of dominant arm and decreased whole-body BMD. No interactive effect of training and diet on BMD was found. **Conclusion**: Weight training leads to bone mineral redistribution between arm and leg, but the difference of humerus bone between both arms cannot be altered.

A 9-month Jumping Intervention to Improve Bone Acquisition in Adolescent Male Athletes: The PRO-BONE Study

Dimitris Vlachopoulos, Alan R. Barker, Esther Ubago-Guisado, Craig A. Williams, FACSM, Luis Gracia-Marco. *University of Exeter, Exeter, United Kingdom.*
(No relevant relationships reported)

Participation in different loading sports during growth can have different effects on bone status and development. However, there is no evidence how to improve bone acquisition in adolescent athletes involved in weight-bearing and non-weight bearing sports. **PURPOSE**: To investigate for first time the effect of a 9-month jumping intervention programme on bone mass, geometry and microarchitecture in adolescent males participating in weight-bearing (soccer, SOC) and non-weight bearing (swimming, SWI & cycling, CYC) sports. **METHODS**: 93 adolescent males (13-15 years) were included. Sport groups were randomised to intervention and sport (INT-SWI=19, INT-SOC=15, INT-CYC=14) or sport only (CON-SWI=18, CON-SOC =15, CON-CYC=12). The intervention comprised a progressive jumping programme of 3 levels (3 months each) using weighted vests (Level 1= 20 jumps, 0 kg, 3 sets/day, 3

times/week; Level 2= 20 jumps, 2 kg, 4 sets/day, 3 times/week; Level 3= 20 jumps, 5 kg, 4 sets/day, 4 times/week). Dual-energy x-ray absorptiometry (DXA) assessed bone mineral content (BMC), hip structural analysis (HSA) assessed cross-sectional area (CSA), cross-sectional moment of inertia (CSMI) and section modulus, trabecular bone score (TBS) assessed bone microarchitecture and quantitative ultrasound assessed bone stiffness before and after the intervention. One-way analysis of covariance compared the bone gains after controlling for pre-intervention bone, change in lean mass and post maturity status. Significance was set at p<0.05. **RESULTS**: INT-CYC gained significantly (p<0.05) higher total body less head BMC (5.0 %), lumbar spine BMC (4.6 %), femoral neck BMC (9.8 %) and bone stiffness (12.3 %) than CON-CYC. INT-CYC gained significantly higher CSA (11.0 %), CSMI (10.1 %) and TBS (4.4 %) outcomes than CON-CYC. INT-SWI gained significantly (p<0.05) higher femoral neck BMC (6.0 %), legs BMC (4.2 %) and bone stiffness (12.7 %) than CON-SWI. INT-SWI gained significantly (p<0.05) higher CSMI outcomes (10.9 %) than CON-SWI. There were no significant (p>0.05) differences between INT-SOC and CON-SOC for any bone outcomes (0.9-3.9 %). **CONCLUSIONS**: The present 9-month jumping intervention improved bone outcomes in non-weight bearing sports, such as swimming and cycling, but not in a weight-bearing sport, such as soccer.

Calcium, PTH, And CTX Responses to Treadmill Walking During Different Thermal Environments in Older Adults

Sarah J. Wherry, Christine M. Swanson, Pamela Wolfe, Rebecca S. Boxer, Rpbert S. Schwartz, Wendy M. Kohrt, FACSM. *University of Colorado Anschutz Medical Campus, Aurora, CO.* (Sponsor: Wendy Kohrt, FACSM)
(No relevant relationships reported)

Serum ionized calcium (iCa) decreases and parathyroid hormone (PTH) and c-terminal telopeptides of type I collagen (CTX; marker of bone resorption) increase during endurance exercise in younger and older adults. Evidence from equine models suggests this may be due to dermal calcium loss. **PURPOSE:** To determine if exercise in a warm environment exaggerates the decrease in iCa and increases in PTH and CTX compared to a cool environment. **METHODS:** Women (n=5) and men (n=7) aged 61-78 years performed two identical 1-hour treadmill walking bouts under warm (~28°C) and cool (~21°C) conditions at ~75% of maximal heart rate iCa, PTH, and CTX were measured every 15 minutes starting 15 minutes before and continuing for 60 minutes after exercise. Sweat calcium loss was estimated from sweat volume and sweat calcium concentration. Changes in iCa, PTH, and CTX were adjusted for plasma volume shifts. Between and within group differences were evaluated using maximum likelihood estimation in a repeated measures model. **RESULTS:** There was no difference in sweat calcium loss between thermal conditions. iCa decreased similarly during exercise in both conditions (W: -0.16, 95% CI: -0.28, -0.08 mg/dL; C: -0.16, 95% CI: -0.24, -0.04 mg/dL). After adjusting for plasma volume shifts, change in iCa$_{ADJ}$ was significant only for the warm condition (-0.24, 95% CI: -0.44, -0.04 mg/dL), but there was no difference between conditions. PTH increased similarly during exercise in both conditions (W: 16.4, 95% CI: 6.2, 26.5 pg/mL; C: 17.3, 95% CI: 8.1, 26.4 pg/mL). Adjusting for plasma volume shifts did not change the results. CTX increased similarly in both conditions (W: 0.08, 95% CI: 0.05, 0.11 ng/mL; C: 0.08, 95% CI: 0.01, 0.16 ng/mL), and adjusting for plasma volume shifts did not change the results. There were no differences between conditions for any outcome, even after adjusting for plasma volume shifts. **CONCLUSION:** Differing thermal conditions do not appear to be a major factor in the decrease in iCa and the increases in PTH and CTX observed during exercise in older adults. This may be due to the low sweat calcium loss during both conditions or small temperature difference. Future studies should determine if there are sex- or age-related differences that modify the relationship between sweat calcium loss and the activation of bone resorption during exercise.

Bone Density Measurements in an Elite Population of Older Weightlifters

Kevin R.m. Coyle[1], Bryan L. Riemann[2], Robert LeFavi[2], Kailey Goins[2], Kayleigh Erickson[2], Mara Mercado[2], Jody Stone[2], Jeremy Ford[2], David R. Hooper[1]. [1]*Jacksonville University, Jacksonville, FL.* [2]*Armstrong State University, Savannah, GA.*
(No relevant relationships reported)

In the aging population, low bone mineral density (BMD) is a prevalent health concern, ranging from the milder condition of osteopenia, to the more severe osteoporosis. Resistance training, particularly with heavy resistance that loads the axial skeleton is often prescribed as an intervention to increase BMD. Training for the sport of Olympic Weightlifting requires consistently exposing the axial skeleton to high loads and thus could lead to elevated BMD. **PURPOSE:** The purpose of this study was to measure total body and lumbar spine BMD in Olympic Weightlifters competing in the Masters National Championships. **METHODS:** 26 men (age: 49.8 ± 11.6 years; height: 172.9 ± 7.3 cm; weight: 85.0 ± 13.1 kg) and 21 women (age: 47.1 ± 9.3 years;

height: 158.9 ± 29.6 cm; weight: 67.8 ± 13.7 kg) competing in the 2016 Masters National Championships for Olympic Weightlifting were invited to the laboratory to undertake dual-energy x-ray absorptiometry (DXA) scans, including total body (TB) and posterior-anterior (PA) spine. A median split for age was performed, separating younger men (YM) (age: 41.2 ± 5.2 years) from older men (OM) (age: 60.4 ± 6.8 years) and younger women (YW) (age: 39.4 years) from older women (OW) (age: 53.7 ± 6.6 years). Independent T-tests were performed to compare age group within sex differences and also to compare sex within age group. **RESULTS:** Overall mean Z-score was not different between men and women for TB (men: 1.5 ± 1.5 vs. women: 2.1 ± 1.1) or PA spine (men: 1.2 ± 1.9 vs. women: 2.0 ± 1.5). Furthermore there were no significant differences between YM and OM for TB (YM: 1.6 ± 1.4 vs. OM: 1.4 ± 1.7) or PA spine (YM: 1.4 ± 2.0 vs. OM: 1.0 ± 1.8), or YW and OW for TB (YW: 2.3 ± 1.1 vs. OW: 1.7 ± 1.2) or PA spine (YW: 2.4 ± 1.1 vs. OW: 1.4 ± 1.8). Comparably, there were no significant differences between YM and YW, nor OM and OW in either TB or PA spine Z-scores. **CONCLUSIONS:** These data demonstrate that both men and women, including younger and older populations, all equally benefit from long-term, heavy resistance exercise that loads the axial spine when performed at the elite level. Based on these high Z-scores, it appears that this benefit is substantial and could be an effective intervention at developing bone density in populations with osteopenia or osteoporosis.

3082 Board #7   June 2 9:00 AM - 11:00 AM

Relationships between Circulating MicroRNAs, Bone Mineral Density and Muscle Function in Postmenopausal Women

Zhaojing Chen[1], Breanne Baker[2], Michael Bemben, FACSM[2], Debra Bemben, FACSM[2]. [1]*California State University, San Bernardino, San Bernardino, CA.* [2]*University of Oklahoma, Norman, OK.* (Sponsor: Debra Bemben, FACSM)
(No relevant relationships reported)

MicroRNAs (miRNAs, miRs) are short, non-coding RNA molecules that regulate gene expression at posttranscriptional level. Recent research has indicated that some miRNAs, such as miR-21 and miR-23a, target on genes of osteogenesis (Lian et al. 2012) and/or muscle atrophy (Wada et al. 2011). In the process of aging, there are progressive declines in bone mineral density (BMD) and muscle function, which potentially may be regulated by these miRNAs. **PURPOSE:** To examine the relationships between specific circulating miRNAs and bone density and muscle function in older postmenopausal women. **METHODS:** Seventy-five postmenopausal women aged 60 to 85 years old participated in this study. Body composition and areal BMD (aBMD) were measured by DXA. Volumetric BMD (vBMD) and bone strength were measured by pQCT. Grip strength was assessed by the digital grip strength dynamometer, whereas gait speed was assessed using the 4-meter path. Muscle power was assessed through countermovement jumps on the jump mat. Serum levels of miRNAs (miR-21, -23a, -24, -100, -125b) were analyzed using real-time PCR. **RESULTS:** MiR-21 was significantly negatively correlated with left trochanter BMC (r = -0.252, p = 0.048), right trochanter BMC (r = -0.294, p = 0.020), and cortical vBMD at tibia 38% site (r = -0.253, p = 0.047). There also was a trend for a significant correlation between miR-21 and lumbar spine aBMD (r = -0.249, p = 0.051). MiR-125b was significantly positively correlated with jump velocity (r = 0.263, p = 0.05) and relative jump power (r = 0.294, p = 0.028). **CONCLUSION**: Our results suggest that a higher expression level of circulating miR-21 is associated with decreased BMD in relatively healthy postmenopausal women, whereas a higher expression level of circulating miR-125b is associated with a greater jump power. Future investigations are needed to further explore circulating miRNAs in osteoporotic or fragile older adults.

Bone Mineral Density In Older Adults With T2DM After Exercise Training: Results From Hart-D

Matthew C. Scott[1], Neil M. Johannsen[1], Damon L. Swift[2], Conrad P. Earnest, FACSM[3], Timothy S. Church[4]. [1]*Louisiana State University, Baton Rouge, LA.* [2]*Eastern Carolina University, Greenville, NC.* [3]*Texas A&M, College Station, TX.* [4]*Pennington Biomedical Research Center, Baton Rouge, LA.* (Sponsor: Conrad P. Earnest, FACSM)
(No relevant relationships reported)

PURPOSE: To examine the effects of 9-months of exercise training on whole body and regional bone mineral density (BMD) in individuals with type II diabetes mellitus (T2DM). **METHODS:** Participants (N=191, men=71; age =57±8.y; BMI=34.4±5.8kg/m²; whole body BMD=1.19±0.13g/cm²; VO_{2peak}=19.5±4.4ml/kg/min;mean±SD) from the HART-D study (NCT00458133) were randomized to aerobic (AER), resistance (RES), combined training (COMB) or a non-exercise control (CON). Compliant participants (>70% of sessions) with complete baseline and follow-up data for BMD (lumbar, thoracic, pelvis, and leg derived from whole body scans by DXA), peak oxygen uptake (VO_{2peak}), isokinetic leg strength (peak torque at 60 deg/s), and anthropometry were included in this ancillary analysis. Associations between baseline BMD values (lumbar, thoracic, pelvis, leg and whole body BMD) were compared with age, sex, and baseline measures for VO_{2peak}, isometric strength, and T2DM duration. Changes over 9-months were analyzed for group effects after adjusting for baseline. Changes in BMD were compared with age, sex, and changes in VO_{2peak} and muscle strength. **RESULTS:** Baseline associations showed that age was inversely related to pelvis BMD (p=0.006, r=-0.20) and females had significantly lower thoracic, lumbar, and whole body BMD (p<0.001). VO_{2peak} was correlated to leg (p<0.001, r=0.31) and whole body (p=0.02, r=0.17) BMD, and isokinetic leg strength was correlated to thoracic (p<0.001, r=0.26), pelvic (p<0.001, r=0.28), leg (p<0.001, r=0.46), and whole body (p<0.01, r=0.34) BMD. All groups increased whole body BMD with exercise training (P<0.05); however, no group effects were found for BMD changes after 9-months (p>0.10). Changes in pelvic BMD were found to be higher in females (p=0.04) than males and changes in VO_{2peak} were inversely correlated with changes in thoracic BMD (p=.04, r=-.15). No significant effects were observed. **CONCLUSION:** Sex, aerobic fitness, and muscle strength had similar relationships with BMD in individuals with T2DM as typically found in the normal adult population. However, group changes after 9-months of exercise training, while increased, were not different from the changes in CON. *Funding provided by the National Institutes of Health, R01-DK068298.*

The Effect of Treadmill Walking, Smartphone Use and School Work on Positive and Negative Affective States in College Students

Jacob E. Barkley, Andrew Lepp, Ashlyn Grose. *Kent State University, Kent, OH.* (Sponsor: Ellen Glickman, FACSM)
(No relevant relationships reported)

Excessive internet-connected, cellular telephone (smartphone) use is associated with greater anxiety and lower quality of life in college students. However, the acute effect of a bout of smartphone use on positive and negative affect and how this may differ from other, common activities (i.e., low-intensity exercise, school work) in college students, has not been studied.
PURPOSE: To compare the effects of separate bouts of smartphone use, treadmill walking, and school work on positive and negative affect in college students.
METHODS: Forty one college students (n = 25 female, 21.7 ± 2.0 years old) completed four, 30-minute conditions (control, treadmill walking, smartphone, school work), on separate days, in a controlled, laboratory environment: 1) Control, participants were seated on a chair in a quiet room. 2) Walking, participants walked at 3.1 mph on a treadmill. 3) Smartphone, participants utilized their smartphones to interact with their personal social-media accounts (e.g., Facebook, Twitter). 4) School work, participants completed self-selected school work (e.g., studying). Participants completed the positive and negative affect scale pre- and post-condition.
RESULTS: Analyses of variance revealed a significant (F = 22.3, p < 0.001) condition by time interaction for positive affect which significantly increased (t = 4.2, p < 0.001) from pre- to post-condition during walking (21.8 ± 8.4 pre, 27.4 ± 9.9 post), did not change (t = 1.2, p = 0.24) during school work (21.8 ± 7.7 pre, 23.0 ± 8.2 post) and significantly (t ≥ 3.7, p ≤ 0.001) decreased during both the smartphone (21.5 ± 8.1 pre, 17.2 ± 6.7 post) and control (19.8 ± 7.8 pre, 14.9 ± 5.8 post) conditions. There was also a significant (F = 15.6, p = 0.05) condition by time interaction for negative affect which significantly decreased (t = 2.3, p = 0.03) from pre- to post-condition during school work (13.4 ± 4.4 pre, 12.4 ± 4.1 post) and did not significantly change (t ≤ 1.6, p ≥ 0.11) for the remaining conditions (control: 12.5 ± 3.5 pre, 13.7 ± 4.1 post; walking: 12.3 ± 3.7 pre, 11.8 ± 2.7 post; smartphone: 12.5 ± 3.3 pre, 12.4 ± 2.6 post).
CONCLUSION: Walking on a treadmill increased positive affect and school work decreased negative affect in college students. Conversely, a bout of smartphone use significantly decreased positive affect and did not reduce negative affect.

3086　Board #2　June 2 9:00 AM - 11:00 AM

Physical Activity And Tablet-based Stem Learning: Effects On Children'S Executive Function In Low-income Childcare

April Bowling, Chris Marcella, Sarah Boucher, Katherine Donnelly, Samantha Durand, Jacqueline Ochoa, Kevin Finn, FACSM. *Merrimack College, North Andover, MA.* (Sponsor: Kevin Finn, FACSM)

(No relevant relationships reported)

Low-income children are at disproportionate risk of low physical activity (PA) and school achievement. Exercise has been shown to positively affect executive function (EF) in children, and may act to prime the brain for learning. Likewise, tablet-based learning applications are an engaging educational modality that can be employed in diverse settings. However, little research exists in real world settings, particularly regarding the robustness of EF improvements after engagement with electronic learning technologies. **PURPOSE:** To investigate changes in children's EF pre-/post-PA, versus pre-/post-PA incorporating a tablet-based STEM learning platform in a real-world low-income childcare setting. **METHODS:** Children (n=19, ages 7-10) attending a YMCA summer childcare program serving low-income families participated in a control condition (40 minutes of quiet reading), and two, 40 minute PA sessions, one immediately followed by 5-10 minutes of a tablet-based science, technology, engineering, and math (STEM) lesson (PA+tablet). PA sessions utilized aerobically-oriented games led by trained staff. Pedometers were used to measure children's total steps during PA. EF was measured and pre- and post- all three conditions. Children were randomly assigned to condition order. Relationships between condition and Stroop score changes were assessed using multi-level mixed effects linear regression, controlling for condition order, test administrator, child age and gender. **RESULTS:** Children averaged 954.5 steps per PA session (SD±751.8). Relative to the control condition, participation in PA was associated with a 0.73 point improvement in Stroop score; that improvement was not significant (p=0.71). However, participation in PA+tablet resulted in a 3.5 point deterioration in Stroop score relative to the control condition (p=0.08). **CONCLUSION:** In a real world setting serving children at risk of low-physical activity and scholastic achievement, PA may prime children for learning by improving EF, but improvements do not appear to be sustained after engagement in tablet-based STEM learning.

3087　Board #3　June 2 9:00 AM - 11:00 AM

Chronic Systemic Inflammation Moderates the Relationship Between Adiposity and Behavioral and Neuroelectric Indices of Attention

Grace M. Niemiro[1], Anne M. Walk[1], Caitlyn G. Edwards[1], Melisa A. Bailey[1], Sarah K. Skinner[1], Michael De Lisio[2], Nicholas A. Burd[1], Hannah D. Holscher[1], Naiman Khan[1]. [1]*University Of Illinois at Urbana - Champaign, Urbana, IL.* [2]*University Of Ottawa, Ottawa, ON, Canada.*

(No relevant relationships reported)

PURPOSE: Two-thirds of the US population today is living with overweight or obesity, signifying a serious public health concern. One co-morbidity of obesity is chronic inflammation, which contributes to cardiovascular and metabolic disease, and is often indicated by elevated plasma C-reactive protein (CRP) concentrations. Further, adiposity has been linked to decrements in selective aspects of cognitive function. However, the potential interactive effects of adiposity and inflammation on cognitive function are limited. This study aimed to examine the relationships among plasma CRP concentrations, cognitive function, and adiposity. **METHODS**: 36 adults (25-45 years) underwent a fasted venous blood draw for measurement of CRP and a dual x-ray absorptiometry (DXA) scan for quantification of whole body adiposity. Cognitive function was assessed using a two-stimulus visual oddball paradigm while underlying event-related brain potentials were recorded. Specifically, the latency of the P3 waveform in a central-parietal region of interest (ROI) was used to index attentional resource allocation and information processing speed, respectively. **RESULTS**: According to bivariate correlations, plasma CRP was positively associated with whole body percent fat (r=0.55, p<0.001). Whole body percent fat and CRP were negatively correlated with target accuracy (r=-0.28, p=0.048; r=-0.44, p=0.003; respectively). Whole body percent fat was correlated with lower peak latency difference (target peak latency - non-target peak latency) in the ROI (r=-0.38, p=0.01), signifying poorer modulation in cognitive processing speed. Yet, adjustment of plasma CRP using partial correlations revealed that the relationship between adiposity and target accuracy (r=-0.13, p=0.23), and P3 peak latency difference (r=-0.24, p=0.09) was mitigated (All, P >0.05). **CONCLUSIONS**: The cross-sectional relationship between adiposity and cognitive function was moderated by the extent of systemic inflammation in overweight and obese adults. Future studies are needed to determine whether reducing chronic systemic inflammation via exercise and nutritional manipulations prevents the negative implications of adiposity for cognitive function.

3088　Board #4　June 2 9:00 AM - 11:00 AM

Adults' Smartphone Use Predicts Being an Active Couch Potato

Andrew Lepp[1], Jacob E. Barkley[1], Curtis Fennell[2]. [1]*Kent State University, Kent, OH.* [2]*University of Montevallo, Montebalo, AL.* (Sponsor: Ellen Glickman, FACSM)

(No relevant relationships reported)

Physical activity is typically negatively associated with sedentary behavior. However, individuals who exercise regularly but allocate large amounts of time to sedentary behavior are an exception to this relationship and known as "active couch potatoes" (ACP). The ACP is of concern as the negative health effects of sedentary behavior appear to be independent of the benefits of physical activity. Previously published research found a positive relationship between smartphone use and sedentary behavior but no relationship between smartphone use and physical activity. Therefore, being a high smartphone user may predict being an ACP (i.e., being highly sedentary yet sufficiently physically active). This idea was previously explored with a correlational study using a sample of college students. In that study, smartphone use was associated with being an ACP. However, this relationship has not been tested in adults beyond college age. Furthermore, previous research did not include the most commonly studied predictor of sedentary behavior - TV viewing. **PURPOSE:** To test whether adults' smartphone use, TV viewing, sex and age predicts being an ACP. **METHODS:** A sample of 423 adults ($n = 277$ female, 40 ± 16 years old) completed surveys assessing physical activity and sedentary behavior. Daily smartphone use and TV viewing were also assessed. Participants were coded as an ACP (or not) based off scores from the physical activity and sedentary behavior surveys. A binary logistic regression was used to test whether smartphone use, TV viewing, sex and age were predictors of being an ACP. **RESULTS**: The binary logistic regression model was statistically significant, $\chi 2 = 50.96$, $p < 0.001$ ($df = 4$). Sex and TV watching were not significant predictors of being an ACP (Wald ≤ 1.148, $p \geq 0.284$). Age and smartphone use were significant predictors of being an ACP (Wald ≥ 6.545, $p \leq 0.011$). Results revealed an inverse relationship between age and the likelihood of being an ACP, and a positive relationship between smartphone use and the likelihood of being an ACP. **CONCLUSIONS**: Similar to college students, increased smartphone use predicted being an ACP in adults beyond college age. Because TV viewing was not a predictor, greater attention should be given to understanding the relationship between smartphone use and the health compromising ACP lifestyle.

3089　Board #5　June 2 9:00 AM - 11:00 AM

Factors Related to Accelerometer-determined Patterns of Physical Activity in Adults: The Houston Train Study

Erin E. Dooley[1], Deborah Salvo[1], Kelley Pettee Gabriel, FACSM[1], Ashleigh M. Johnson[1], Casey P. Durand[2], Gregory Knell[2], Samantha J. Kreis[1], Ipek N. Sener[3], Harold W. Kohl, III, FACSM[1]. [1]*The University of Texas Health Science Center at Houston (UTHealth) School of Public Health in Austin, Austin, TX.* [2]*The University of Texas Health Science Center at Houston (UTHealth) School of Public Health in Houston, Houston, TX.* [3]*Texas A&M Transportation Institute, Texas A&M University System, Austin, TX.*

(No relevant relationships reported)

Meeting U.S. Physical Activity (PA) Guidelines has health benefits. Yet, little is known about factors related to changes in PA over time, particularly among minority populations. **PURPOSE:** To examine sociodemographic, PA preferences (for walk and bike), and health factors related to accelerometer-derived patterns of 1-year PA change in the Houston Travel Related Activity in Neighborhoods (TRAIN) Study, a majority-minority cohort. **METHODS:** Participants wore an ActiGraph wGT3X-BT monitor and completed self-report surveys at baseline and follow-up. Valid wear time was defined as ≥ 4 days, ≥ 10 hrs/day. PA was stratified by meeting Guidelines using total MVPA defined by Freedson. Four PA patterns were defined: (i) maintain high activity above Guidelines, (ii) increased to meet Guidelines, (iii) decreased from meet to not meet Guidelines, and (iv) maintained low activity. Multinomial logistic regression was used to examine associations between studied factors and each PA pattern, with the 'maintain high' group as referent. **RESULTS:** Complete data were available for 153 adults (19% maintained high activity, 8.5% increased, 13% decreased, 59.5% maintained low activity). Controlling for all variables, males (OR = 0.3, 95% CI = 0.1, 0.9) had lower odds of being in the 'maintain low' group. Blacks (vs. whites, OR = 18.8, 95% CI = 2.6, 275.0), those liking biking (vs. strongly liking, OR = 4.6, 95% CI = 1.3, 15.6), and older participants (vs. younger, on continuous scale, OR = 1.1, 95% CI = 1.0, 1.1) had higher odds of being in the 'maintain low' group. Factors directly associated with being in the 'increased' group were being black (vs. white, OR = 17.9, 95% CI = 1.3, 120.9), strong dislike for biking (vs. strongly liking OR = 25.2, 95% CI = 1.6, 401.3), and having

more chronic diseases (vs. less, on continuous scale, 95% CI = 1.5, 11.7). Having low educational attainment (vs. high, OR = 0.04, 95% CI = 0.0, 0.9) was inversely associated with being in the 'increased' group. No studied factors were significantly associated with being in the 'decreased' group.

CONCLUSION: PA patterns are dynamic and suggest that sociodemographic, PA preferences, and health factors relate to change patterns over time. Future studies should examine the role of these factors over longer follow-up periods, and consider these factors when designing interventions.

3090　Board #6　　　　　　　June 2 9:00 AM - 11:00 AM

Computerized Forecast Modeling to Predict Energy Intake: Perceptions of Adopting New Technology

Marissa Baranauskas, Judith A. Juvancic-Heltzel, Laura Richardson, Shiva Sastry. *The University of Akron, Akron, OH.* (Sponsor: Ronald Otterstetter, FACSM)

(No relevant relationships reported)

Alarming trends in obesity precipitate the examination of current weight-management strategies used by exercise professionals (EPs). Unaddressed energy balances negatively affect the efficacy of weight-management interventions. However, the scope of practice of EPs limits their ability to address energy imbalances through observation of trends in dietary intake. Common methods, such as the 24-hr dietary recall, tend to underestimate energy intake (EI) especially in overweight and obese populations, and are associated with poor adherence. Furthermore, traditional dietary recall methods assess past EI without considering how future EI patterns change over time. Therefore, the development of new technologies to accurately facilitate EPs in addressing EI imbalances, and improve the effectiveness of weight-management interventions is warranted.

PURPOSE: To investigate perceptions of a new technology designed to track EI via computerized forecast modeling. METHODS: Evaluating perspectives towards technology can be difficult using traditional Likert scale surveys. Q Methodology provides an avenue to systematically study subjectivity by using factor analysis and correlation to assess agreement and variances of views. Participants (N = 11, 2 males, 9 females; 47 ± 17 yrs.; BMI 26± 5 kg·m-1) sorted 44 statements from "most like my view" to "most unlike my view." The Q sort consisted of statements associated with the Transtheoretical Model of behavior change, barriers, and the adoption of a new technology to track EI. RESULTS: Factor analysis revealed two factors of participants' views: compliant dieters and dedicated exercisers. CONCLUSION: Two converging views emerged surrounding the adoption of a new technology designed to track nutritional intake. Consensus between factors provides tangible evidence of technology apprehension. Overall, the analysis identifies how facets of a diverse population will perceive a novel technology designed to track EI, and provides insight into how distinct barriers can be overcome to enhance adoption. Conducting preliminary research regarding perceptions of technology adoption can enhance the development and marketability of an EI forecasting system.

Effects of Physical Activity Trackers and Motivational Interviewing on Mood in Chronic Low Back Pain

Maria Perez, Laura D. Ellingson, Jeni E. Lansing, Kathryn J. Southard, Jacob D. Meyer, Gregory J. Welk, FACSM. *Iowa State University, Ames, IA.* (Sponsor: Gregory J. Welk, FACSM)

(No relevant relationships reported)

Annually, ~23% of individuals suffer from chronic low back pain (CLBP). Physical activity (PA) is a recommended treatment and increasing PA also improves mood-related symptoms, which are prevalent in those with CLBP. However, effective strategies to increase PA and their effects on mood in CLBP are unknown. **PURPOSE:** We examined the effects of using an activity tracker (AT) alone or in combination with motivational interviewing (MI) on PA and mood in CLBP. **METHODS:** Fifty-one adults with CLBP (51% women; mean age 44 ± 10.6) were randomized to receive either: an AT (AT, n = 18), an AT with three sessions of MI (MI, n = 17) or were placed in a wait-list control group (WL, n = 16) for 12 weeks. Changes steps/day (activPAL) and mood (Profile of Mood States [POMS]) over the intervention were evaluated with Group X Time repeated measures ANOVA and effect sizes (Cohen's d). Correlation coefficients (Pearson's r) assessed relationships between changes in PA and changes in mood. **RESULTS:** There were non-significant (p > 0.05) increases in steps/day for intervention groups (MI: $1,019 \pm 2,665$; AT: $897 \pm 2,468$) and a small decrease for WL (-182 ± 2,434). POMS Total Mood Disturbance (TMD) improved across all groups (p = 0.001). Groups were not significantly different for either outcome (p > 0.05); however, larger effect sizes were observed for intervention groups for PA (MI d = 0.30; AT: d = 0.28; WL: d = 0.06) and TMD (MI: d = 0.42; AT: d = 0.48; WL: d = 0.28). When examining POMS subscales, significant improvements were observed across groups for Depression (p = 0.023) and Fatigue (p < 0.020). For Vigor, there was a significant Group X Time interaction (p = 0.011). Vigor improved for AT (d = 1.02) and MI (d = 0.52) and decreased for WL (d = 0.46). Across groups, change in PA

was significantly and positively associated with change in Vigor (r = 0.32; p = 0.022). When examining groups individually, the association remained significant for the MI group only (r = 0.62; p = 0.006).

CONCLUSION: Results suggest that AT alone and with MI may be effective for improving PA and vigor in CLBP. Future research is needed to determine the intervention components that are most effective for increasing PA and to elucidate possible mechanisms underlying the beneficial effects of changes in PA for patients with CLBP.

Behavior Change Theory Taxonomy Analysis of Smartphone Apps for Fitness, Nutrition, and Weight Loss

Joy Furlipa, Kimberly Reich. *High Point University, High Point, NC.*

(No relevant relationships reported)

A majority of Americans do not meet physical activity or nutrition guidelines for health. Convenient interventions to support healthy behaviors may be beneficial. Smartphone use has become ubiquitous, with apps that are an integral part of life for many. The health and fitness category of apps is robust and growing, but the potential for these apps to affect health behavior change is poorly understood. **PURPOSE**: To evaluate top-ranked fitness, nutrition, and weight-loss smartphone apps for incorporation of evidence-based behavior change strategies. **METHODS**: Two investigators coded descriptions of the 150 top-ranked "free" apps in the health and fitness category of the US iOS app store for evidence of health behavior change strategies using the Behavior Change Technique (BCT) Taxonomy (v1). Prevalence of taxonomy items were calculated and Pearson correlations were estimated for the relationship between BCTs per app and customer ranking, as well as for the relationship between BCTs per app and app store ranking. Significance was set at p < 0.05. **RESULTS**: 71 app descriptions were identified as fitness, nutrition, and/or weight-loss focused. Of those, 45.1% incorporated goals and planning; 57.7% incorporated feedback and monitoring; 56.8% incorporated social support; 29.6% incorporated comparison of behavior; 29.6% incorporated shaping knowledge; 22.5% incorporated associations; 11.6% incorporated reward and threat; 9.9% incorporated antecedents; and 5.6% incorporated natural consequence. Only 17 of the 93 techniques in the BCT taxonomy were utilized across all coded apps. There was a trend towards a weak negative correlation between number of BCTs per app and app store ranking (r = -0.22, p = 0.06) and no significant correlation between number of BCTs and customer rating (r = -0.02, p = 0.87). 45.1% of the "free" apps offered a premium version, in addition, and 11.3% required a paid subscription after download. **CONCLUSIONS**: Goal planning, monitoring, feedback, and social support were the most common strategies found in the popular fitness, weight-loss, and nutrition apps, though more must be learned about their effectiveness. Furthermore, there is potential to incorporate a greater variety of health behavior change techniques.

G-23　Thematic Poster - **Jumping and Landing**

Saturday, June 2, 2018, 9:00 AM - 11:00 AM

Association Of Flexibility And Jump Landing Kinematics On The Recovery Of Lower Body Power And Strength Following Exhaustive Exercise

Thomas Kopec[1], Mark Richardson[2], Phillip Bishop[3], Lizzie Hibberd[2], James Leeper[2], Bailey Welborn[2], Mike Esco, FACSM[2]. *[1]Samford University, Birmingham, AL. [2]University of Alabama, Tuscaloosa, AL. [3]Liberty University, Lynchburg, VA.* (Sponsor: Mike Esco, FACSM)

(No relevant relationships reported)

PURPOSE: The purpose of this study was to determine the relationship between knee flexion range of motion (ROM) and jump landing kinematics evaluated via the landing error scoring system (LESS) and the change in performance variables following an exhaustive bout of exercise. **METHODS:** Participants were measured for ROM and LESS, and then completed performance tests consisting of vertical jump (VJ), and isometric quadriceps strength assessment (ISO). Next, participants completed an exhaustive bout of exercise, and upon termination, performance variables were reassessed. Participants returned for follow-up testing at 24-, 48-, and 72-hours.

Abstracts were prepared by the authors and printed as submitted.

RESULTS: ROM was significantly correlated with the changes in VJ (ΔVJ_{24}, r = .65) and the changes in ISO (ΔISO_{24}, r = .75) at 24-hours after baseline, and ROM was also significantly correlated with the change in VJ (ΔVJ_{48}, r = .66) and the change in ISO (ΔISO_{48}, r = .79) at 48-hours follow-up, but not at 72. LESS scores were significantly correlated with ΔISO_{24} (r = .67), as well as ΔISO_{48} (r = .62), respectively, but not at 72. **CONCLUSIONS:** These findings indicate that higher levels of flexibility resulted in better mitigation of the decreases to VJ and ISO following the exhaustive bout of exercise at both 24- and 48-hours post-exhaustive exercise, but not at 72. A possible explanation for the association between higher LESS scores (poorer mechanics) and faster return of ISO towards baseline may be that those with poorer LESS scores exerted less effort during the exhaustive exercise bout and therefore did not manifest a high level of muscle damage. However, this was not supported by the non-significant relationships between LESS and the number of repetitions participants completed (r = .27); or LESS and RPE following exercise (r = -.27). The reason for these finding remains unclear. Clinicians can use ROM before training to predict the recovery of lower extremity power and strength following intense physical activity.

Pearson partial correlation coefficients		
	ROM (control LESS)	LESS (control ROM)
VJ	.27	.57
ISO	-.38	-.03
ΔVJ_{IP}	.31	.37
ΔISO_{IP}	.50	.41
ΔVJ_{24}	.65*	.44
ΔISO_{24}	.75*	.62*
ΔVJ_{48}	.66*	.37
ΔISO_{48}	.79*	.62*
ΔVJ_{72}	.43	.18
ΔISO_{72}	.45	.44

Countermovement Jump Kinetics and Performance Changes from 1st to 4th year in Division I Collegiate Athletes

Demitra R. Philosophos, Jennifer L. Sanfilippo, Mikel R. Stiffler-Joachim, Bryan C. Heiderscheit, Daniel G. Cobian. *University of Wisconsin-Madison, Madison, WI.*
(No relevant relationships reported)

The countermovement jump (CMJ) is a common test of athletic ability. Kinetic analysis indicates phase-specific CMJ ground reaction rate of force development (RFD) and rate of force unloading (RFU) are associated with jump performance. Collegiate athletes complete strength and conditioning regimens to maximize athletic ability and sports performance, but it is unclear what elements of the CMJ moderate these performance improvements.
PURPOSE: To evaluate the changes in CMJ ground reaction force-time curve eccentric (ECC) and concentric (CONC) phase variables between the 1st and 4th year of participation in Division I collegiate athletics, and determine if and how these adaptations relate to changes in jump performance.
METHODS: 79 healthy NCAA Division I athletes (60 males) participating in football, soccer, basketball, hockey, and wrestling performed maximal CMJs on force plates (800 Hz) as part of standard yearly preseason evaluations. ECC and CONC phase force-time curve variables were computed, and Wilcoxon Signed-Ranks tests were used to evaluate changes in variables of interest between 1st and 4th year CMJ performance. Spearman's correlation was used to evaluate associations between CMJ height and force-time curve variable differences.
RESULTS: Jump height increased significantly (p < .001) from 1st to 4th year (38.3 ± 9.5 cm to 40.1 ± 9.1 cm), along with early phase (0-50%) ECC RFD (44.1 ± 37.6 N/s/kg to 55.1 ± 35.1 N/s/kg). Improved jump height was significantly associated with increased peak ECC RFD (rs = .274, p = .015), late phase (50-100%) ECC RFD (rs = .308, p = .006), and peak CONC RFU (rs = -.383, p < .001). Across the cohort, the force-time curve variable most strongly associated with CMJ height was peak CONC RFU (rs = -.560, p < .001).
CONCLUSIONS: Improved CMJ performance is associated with increased ground reaction force ECC RFD and CONC RFU from 1st to 4th year of participation in Division I collegiate athletics. Our results suggest that CMJ height may be maximized by training to enhance the rate of unloading through rapid generation of hip, knee, and ankle extensor torque in combination with utilization of stored elastic energy.

Reliability And Between-limb Symmetry Of Joint Kinetics And Kinematics During A Countermovement Jump

Bryan C. Heiderscheit, Mikel R. Stiffler-Joachim, Jennifer L. Sanfilippo, Daniel G. Cobian. *University of Wisconsin-Madison, Madison, WI.*
(No relevant relationships reported)

Investigations of lower extremity movement biomechanics in injured populations are often designed with the assumption that limb symmetry and reliability across measurement intervals are inherent. However, the between-limb variation and long term reliability of lower extremity kinetics and kinematics in healthy comparison groups is unknown.
PURPOSE: To evaluate the test-retest reliability and between-limb symmetry of hip, knee, and ankle joint kinetics and kinematics of the countermovement jump (CMJ) in healthy Division I collegiate athletes.
METHODS: 22 Division I collegiate cross country athletes (13 females, age 19.7 ± 1.1, BMI 20.8 ± 2.2) performed maximal CMJs as part of preseason evaluations in 2 consecutive years. Whole body kinematics and ground reaction forces were recorded bilaterally. Eccentric (ECC), concentric (CONC), and landing (LAND) phase sagittal plane hip, knee, and ankle joint angles, moments, and powers were computed. Between session reliability was assessed with intraclass correlation coefficients (ICC). To evaluate limb symmetry, median between-limb differences were expressed as a percentage of the median absolute values of each variable.
RESULTS: Most variables demonstrated fair to good reliability (.4 < ICC <.75). CONC phase hip, knee, and ankle joint moment impulses (ICCs 0.69 - 0.73), peak powers (ICCs 0.75 - 0.82), and LAND phase peak angles (ICCs 0.70 - 0.71), excursions (ICCs 0.70 - 0.82), and peak powers (ICCs 0.66 - 0.72) demonstrated the greatest consistency. Rate of hip, knee, and ankle joint moments during the ECC (ICCs 0.37 - 0.56) and CONC phases (ICCs 0.37 - 0.58) were less reliable. Between-limb variation in hip and knee joint peak angles throughout all CMJ phases was < 5% of absolute values. LAND moments, impulses, powers, and work demonstrated substantially greater between-limb asymmetry (14 - 46% of absolute values) than CONC phase variables (6 - 12%).
CONCLUSIONS: CMJ CONC phase hip, knee, and ankle joint impulses and powers have the greatest limb symmetry and reliability across intervals in healthy collegiate athletes. Sports medicine clinicians and scientists should be aware of the expected between-limb asymmetry and variation across testing intervals when assessing CMJ biomechanics in injured populations or attempting to evaluate the effects of intervention.

Biomechanical Risk Factors For Recurrent Ankle Sprains During Landing/Cutting In Ankle Instability Patients: 6-month Follow-up

S. Jun Son, Dustin Bruening, Brent Feland, Matthew Seeley, Ty Hopkins, FACSM. *Brigham Young University, Provo, UT.* (Sponsor: J. Ty Hopkins, FACSM)
(No relevant relationships reported)

Altered movement patterns have consistently been observed in chronic ankle instability (CAI) patients during landing and cutting tasks. Altered foot placement along with changes in joint moments have been identified as risk factors for ankle sprains. However, to examine a causal effect between biomechanical factors and risk of ankle injury, research should be conducted in a prospective design.
PURPOSE: To identify biomechanical risk factors related to recurrent ankle sprains during jump landing/cutting in CAI patients at a 6-month follow-up.
METHODS: 91 of 100 CAI patients completed a 6-month follow-up survey, and 13 CAI patients (7M, 6F, 22 ± 2 yrs, 174 ± 11 cm, 75 ± 15 kg, 84 ± 5% FAAM-ADL, 65 ± 12% FAAM-Sports, 5.8 ± 3 sprains) reported recurrent sprains within 6 months, and 78 CAI patients (39M, 39F, 22 ± 2 yrs, 174 ± 11 cm, 74 ± 14 kg, 85 ± 6% FAAM-ADL, 69 ± 10% FAAM-Sports, 3.3 ± 2 sprains) did not have recurrent injury after the initial data collection where subjects performed 10 jumps consisting of a maximal vertical jump-landing and cutting at 90°. Functional linear models were used to detect between-group differences. If 95% confidence intervals did not cross zero, differences were significant.
RESULTS: Figure 1 shows that CAI patients who suffered ankle sprains within 6 months showed several biomechanical differences including (i) more plantarflexion, less knee flexion and more knee abduction angles, and (ii) increases in plantarflexion, inversion, knee extension, knee abduction and hip abduction moments over various portions of stance relative to those who did not have recurrent injury.
CONCLUSIONS: CAI patients who suffered recurrent sprains within 6 months demonstrated altered foot placement (4° more plantarflexion) along with more inversion moment and altered frontal knee and hip biomechanics. Moreover, these patients reported a greater number of previous ankle sprains (5.8 sprains) relative to those who did not have reinjury at a 6-month follow-up (3.3 sprains).

Figure 1. Grand ensembles for lower extremity joint angles and internal moments in the sagittal and frontal planes during a jump landing/cutting task between CAI patients who experienced recurrent ankl sprains within 6 months and CAI patients who did not have recurrent sprain injury at a 6-month follow-up. 0% of stance indicates inital foot contact, 50% of stance indicates peak ankle dorsiflexion and knee flexion, and 100% of stance indicates toe-off during the task. When 95% confidence intervals (shaded area) did not cross the zero (horizontal red line), between-group differences were significant. Abbreviations: DF, dorsiflexion; PF, plantarflexion; Add, adduction; Abd, abduction.

The Biomechanical Pattern Of Multidirectional Single-leg Landing In Professional Dancers And Non-dancers

Ana M. Azevedo[1], Raul Oliveira[1], Joao R. Vaz[2], Nelson Cortes[3]. [1]University of Lisbon, Lisbon, Portugal. [2]University of Nebraska at Omaha, Omaha, NE. [3]George Mason University, Manassas, VA.
(No relevant relationships reported)

Professional dancers (PD) have a high injury rate (42% to 97%) with more than 50% occurring in the lower extremity (LE). PD are required to perform repetitive multidirectional single-leg landings. Therefore, it is important to investigate the landing biomechanical strategies in various jump directions between PD and non-dancers (ND).
PURPOSE: To compare LE biomechanics during multidirectional single-leg landings between PD and ND.
METHODS: 15 PD (27±7years, 1.69±0.1m, 57.8±9.3kg), and 15 ND (25±5 years, 1.69±0.1m, 66±10.2kg) conducted single-leg jumps in three directions (diagonal-DJ, frontal-FJ, and lateral-LJ) followed by a vertical jump. The second landing was used for analysis. Dominant LE biomechanical data was collected using a motion capture system (200Hz) and a force plate (1000Hz). Visual3D was used for data processing. LE joint angles (°) of the hip (HF), knee (KF), ankle, and foot; internal joint moments (Nm/Kgm); and ground reaction force (BW) were calculated at: initial contact (IC), peak knee flexion (PKF), and peak vertical ground reaction force (vGRF). Repeated measures ANOVAs were conducted (p<0.05).
RESULTS: A main effect was found for direction (p<0.05). LJ (2.9±0.5) had the lowest vGRF compared to FJ (3.1±0.6) and DJ (3.3±0.7). HF at PKF was lower in the FJ direction (32±12), compared to LJ (39±11) and to DJ (39±10). A main effect for group was attained (p<0.05). Particularly, PD (2.9±0.5) had lower vGRF than ND (3.3±0.7). At IC, PD had lower HF (19.3±4.7), KF (-3.1±3.5), and 1st metatarsophalangeal extension (MTPE: -9.9±7.0), and higher hindfoot-tibia (-32.7±4.5), and forefoot-tibia (-49.1±6.1) plantarflexion (PF) than ND (HF: 25.2±6.6, KF: -13.6±4.1, MTPE: -4.8±7.5, hindfoot-tibia: -23.8±6.8, forefoot-tibia: -30±12.5). Lastly, at IC, PD had a lower knee abductor moment (.12±.16) than ND (-.01±.14). Yet, at vGRF, PD had a higher knee adductor moment (-.51±.3) than ND (-.41±.2). No other difference was found (p>0.05).
CONCLUSION: This study demonstrated that PD had an extended landing pattern compared with ND. Despite the extended landing posture at IC, PD showed a lower vGRF, suggesting that a higher PF angle of the ankle may improve energy absorption and dissipate landing forces. Further research should investigate the role of PDs' ankle range of motion and shock absorption in landings.

3099　　　**Board #6**　　　　　　June 2 9:00 AM - 11:00 AM

The Relationship Between Vertical Ground Reaction Force And Audio Characteristics During A Single-Leg Landing

Caroline Lisee, Thomas Birchmeier, Arthur Yan, Brent Geers, Kaitlin O'Hagan, Caitlin Davis, Christopher Kuenze. Michigan State University, East Lansing, MI.
(No relevant relationships reported)

Landing kinetic are associated with injury risk and altered after injury, but are difficult to assess clinically. Relationships between soundwave characteristics and kinetics have only been reported during bilateral tasks. Preliminary evidence may support the use of sound as a clinically feasible technique of landing kinetic evaluation. **Purpose:** To assess the relationship between kinetics(peak vertical ground reaction force (vGRF), linear loading rate (LR), instantaneous LR) and soundwave characteristics(peak audio amplitude, audio frequency) during a single leg landing task. **Methods:** Physically active participants (15 males/11 females, age=24.81±3.6 years, height=176±9.05 cm, mass=74.86±14.4 kg) with no injuries in the past 3 months completed 5 single leg landings per limb onto a force plate while soundwave characteristics were recorded with a microphone. Means and standard deviations were calculated for all landings of each limb and considered independent outcomes for a total of 52 landings. Loading time was defined from initial contact to peak vGRF. Linear and instantaneous LR were defined as the slope during loading time and peak slope during the middle 60% of loading time respectively. Audio frequency was calculated from the onset of sound to peak audio amplitude defined as the largest peak to peak amplitude of sound. Outliers were detected through the Grubb's Outlier Test and 1 data point was removed from each of the peak amplitude and audio frequency datasets for a final sample of 51 limbs. Spearman's *rho* correlations were used to assess relationships between soundwave and kinetics due to non-normally distributed data. **Results:** Peak audio amplitude was moderately correlated with non-normalized vGRF(rho=0.356, p=0.010), normalized vGRF(rho=0.486, p=0.001), linear LR(rho=0.500, p=0.001), and instantaneous LR(rho=0.368, p=0.009). Audio frequency was moderately correlated with instantaneous LR(rho=-0.394, p=0.005). **Conclusion:** Peak audio amplitude may be more useful for assessing normalized vGRF and linear LR, but audio frequency may be more useful for instantaneous LR assessment. Evidence of soundwave and kinetic relationships support continued refinement of soundwave measurement techniques especially in feedback based interventions and for use in previously injured populations.

3100　　　**Board #7**　　　　　　June 2 9:00 AM - 11:00 AM

Limited Dorsiflexion Range of Motion Alters Joint Kinematics during Landing/Cutting in Chronic Ankle Instability Patients

Kaitland Garner, S. Jun Son, Dustin Bruening, Brent Feland, Matthew Seeley, Ty Hopkins, FACSM. Brigham Young Univerrsity, Provo, UT. (Sponsor: J. Ty Hopkins, FACSM)
(No relevant relationships reported)

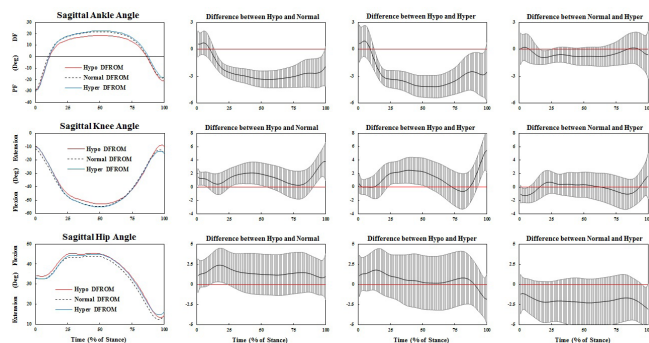
Limited dorsiflexion range of motion (DFROM) has consistently been demonstrated in chronic ankle instability (CAI) patients. Further, reduced DFROM appears to increase the risk factor for ankle sprains. However, DFROM seems to vary between CAI patients, which could result in altered movement patterns and risk of injury.
PURPOSE: To examine lower extremity joint angles during a jump landing/cutting task within a CAI population categorized by DFROM.
METHODS: 100 CAI subjects were classified into 3 subgroups based on DFROM, measured by the weight-bearing lunge test: a Hypo (14M, 10F; ≤ 39°; 35±2.5°, 23±2 yrs, 176±13 cm, 80±13 kg), Normal (25M, 32F; 40-50°; 46±2.6°, 21±2 yrs, 174±7 cm, 72±14 kg), or Hyper DFROM group (11M, 8F; ≥ 51°; 54±3°, 22±2 yrs, 175±11 cm, 74±14 kg). Subjects performed 5 jumps consisting of a maximal vertical forward jump-landing plus a side-cut at 90°. Functional linear models were used to detect between-group differences. If 95% confidence intervals did not cross zero, differences were significant.
RESULTS: Figure 1 shows that CAI subjects with Hypo DFROM had up to 4° less DFROM and 2.5° less knee flexion, relative to Normal and Hyper DFROM groups, during the jump landing/cutting task, and increased hip flexion (2.5°) during initial landing compared to the Normal DFROM group.
CONCLUSIONS: Static DFROM on the weight-bearing lunge test influences sagittal-plane joint kinematics in the lower extremity during jump landing/cutting. CAI subjects with Hypo DFROM show decreases in DFROM and knee flexion, but these limitations did not increase hip flexion during most of stance (a small increase during initial landing relative to the Normal DFROM group). This stiffer landing/cutting movement pattern could increase impact loading of the lower extremity and may increase the risk of ankle reinjury.


Figure 1. Grand ensembles for sagittal-plane joint angles in the lower extremity during a jump landing/cutting task between the Hypo, Normal, and Hyper DFROM groups. 0% of stance indicates initial foot contact, 50% of stance indicates peak ankle dorsiflexion and knee flexion, and 100% of stance indicates toe-off during the task. When 95% confidence intervals (shaded area) did not cross the zero (horizontal red line), between-group differences were significant.

G-24   Free Communication/Slide - **New Strategies to Increase Physical Activity in Youth**

Effects of a School-Based Physical Activity Intervention on Cardiometabolic Health Five Years After Cessation

Geir K. Resaland[1], John Bartholomew, FACSM[2], Lars Bo Andersen[1], Sigmund A. Anderssen[3], Eivind Aadland[1]. *[1]Western Norway University of Applied Sciences, Sogndal, Norway. [2]The University of Texas at Austin, Austin, TX. [3]Norwegian School of Sport Sciences, Oslo, Norway.* (Sponsor: John Bartholomew, FACSM)

(No relevant relationships reported)

While there have been several school-based physical activity (PA) interventions targeting improvement in cardiovascular disease (CVD) risk factors, including cardiorespiratory fitness (CRF), few have assessed the long-term effect on a cardiometabolic health composite score. PURPOSE: To determine the effect of a two-year school-based PA intervention on CVD risk five years after cessation. Methods: We recruited two elementary schools, assigned to intervention (n=125 children) or control (n=134 children). The intervention school offered 210 min/week more PA than the control school over two consecutive years (4th and 5th grades) during 2004-2007. A follow-up assessment was conducted 5-y post intervention (10th grade) during 2011-2012 where 180-210 (73-85%) children provided valid data. Primary outcomes were several CVD risk factors: triglyceride (TG), total to high-density lipoprotein cholesterol ratio (TC:HDL ratio), insulin resistance (HOMA), systolic blood pressure (SBP), waist circumference (WC), and (CRF measured as) peak oxygen uptake (VO2peak). These variables were analyzed individually and as a composite score through linear mixed models, including random intercepts for children. Results: Analyses revealed significant effects of the intervention five years after cessation for HDL (ES=.22), diastolic BP (ES=.48), VO2peak (ml/kg/min) (ES=.29), and the composite risk score (ES=.38). These effects were similar to the immediate results following the intervention. In contrast, while TC:HDL ratio initially decreased post intervention (ES=.27), this decrease was not maintained at 5-y follow-up (ES=.09), whereas WC was initially unchanged post intervention (ES=.02), but decreased at 5-y follow-up (ES=.44). Conclusion: These data reveal that the significant effects of a two-year school-based PA intervention remained in effect for CVD risk factors five years after cessation of the intervention. As cardiometabolic health can be maintained long-term after school-based PA, this paper demonstrates the sustainability and potential of schools in the primary prevention of future CVD risk in children.

3103   June 2 9:15 AM - 9:30 AM

Effects of Integrating Physical Activity into Early Education Learning Standards on Preschoolers' Physical Activity Levels

Sofiya Alhassan, FACSM, Christine St. Laurent, Sarah Burkart, Cory J. Greever, Matthew Ahmadi. *University of Massachusetts, Amherst, Amherst, MA.*

(No relevant relationships reported)

Preschool centers are ideally situated to intervene on preschoolers' health behaviors such as physical activity (PA), diet, and sleep (PADS). In order for health behavior interventions to be sustainable within the preschool center, the intervention needs to be implemented by classroom teachers. Unfortunately, teachers are constrained by demands such as meeting early childhood education learning standards (state mandated policies). It is possible that integrating health behavior lessons and activities into learning standard could improve teachers' compliance with health behavior interventions. **PURPOSE:** To examine the impact of integrating health behavior interventions into learning standards on preschoolers' PA, diet and sleep behavior. **METHODS:** This was a parallel group pilot randomized control study. Data were collected in Spring 2016 and analyzed in Fall 2016. Two preschool centers were randomized to either the PADS (children, n = 60) or the control (CON; children, n = 54) group. The PADS intervention consisted of a PA, diet, and sleep curriculum and activities embedded into Massachusetts early education learning standards and was implemented for four days/week for 12 weeks. PADS also had a parent component, which was delivered online. CON preschool participated in their usual activity. PA was assessed using accelerometers for seven days per week. Diet and sleep variables were assessed using a parent report surveys. Outcome variables were assessed at baseline, 6-weeks, and 12-weeks. **RESULTS:** After adjusting for baseline differences, significant group by visit interaction were observed for during preschool-day percent of time spent in moderate-to-vigorous PA (PADS; baseline = 7.7% ± 3.6, 12-week = 11.7 ± 3.8; CON, baseline = 10.7% ± 3.7, 12-week = 10.9% ± 3.5; p = 0.03) and sedentary time (PADS; baseline = 83.6% ± 5.8, 12-week = 77.2% ± 6.4; CON; baseline = 79.1% ± 5.4, 12-week = 78.4% ± 5.5; p = 0.05). At 6-week, significant improvement (p = 0.02) was observed in percent of time spent in total daily vigorous activity for the PADS compared to the CON group. **CONCLUSION:** This pilot study provides preliminary evidence that integrating health behaviors into learning standards are feasible and potentially an effective way for increasing preschoolers PA level but not effective in changing either diet or sleep behaviors.

3104   June 2 9:30 AM - 9:45 AM

Fueling Learning Through Exercise (FLEX) - Long-term Impact Of School-based Programs On Children's Moderate-to-Vigorous Physical Activity

Jennifer M. Sacheck, FACSM[1], Sarah Amin[1], Stephanie Anzman-Frasca[2], Virginia Chomitz[2], Kenneth Chui[1], Paula Duquesnay[1], Miriam Nelson, FACSM[3], Catherine Wright[1], Christina Economos[1]. *[1]Tufts University, Boston, MA. [2]University of Buffalo, Buffalo, NY. [3]University of New Hampshire, Durham, NH.*

(No relevant relationships reported)

Purpose: Schoolchildren do not meet current recommendations for school-time and daily moderate-to-vigorous physical activity (MVPA), which is further exacerbated by a steady decline in MVPA over the elementary school years. Our objective was to evaluate the impact of two innovative school-based PA programs, *100 Mile Club®* and *Just Move/NYP™,* on school-time (sMVPA) and total daily MVPA among lower-income schoolchildren.
Methods: Elementary schools (n=18) were randomized to *100 Mile Club* (walk/run program), *Just Move* (active classroom breaks), or control. Teachers/champions were trained to implement programming for 3rd and 4th grade students. Consented children were measured at baseline (pre-intervention), mid-point (6 months), and end-point (18 months). MVPA was measured via 7-day accelerometry (Actigraph GTX3+). Height/weight were measured to assess weight status. Demographics were collected by parent report. Mixed effects linear regression models were used to examine the impact of program on sMVPA and total daily MVPA adjusting for school-level clustering, sex, grade, BMI status, free/reduced-price lunch eligibility (FRPL), wear-time, and average daily temperature.
Results: 982 children (8.7 ± 0.7 years; 44% male; 64% non-white; 40% overweight/obese; 55% FRPL; 38% *100 Mile Club*, 32% *Just Move,* 31% control) had valid accelerometer wear-time (≥3 days, ≥10 hr/day) over the three time points. At baseline, 8.4% (18.3 ± 8.6 min/day) and 19.8% (44.9 ± 20.1 min/day) fulfilled the 30-min sMVPA and 60-min total daily MVPA recommendations, respectively. There was a significant program effect on sMVPA (p = 0.002), but not for daily MVPA (p = 0.47). Pair-wise comparisons suggest that this difference was driven by a decrease in sMVPA in control schools from mid- to end-point (Bonferroni p = 0.004; -2.3 min, 95%CI -4.3,

-0.4); while sMVPA in both intervention groups remained stable over the 18-month intervention period (*100 Mile Club*: 18.1, 18.9, 18.4 min/day; *Just Move*: 17.6, 16.8, 17.5 min/day).

Conclusion: Two very different school-based PA programs appeared to be effective in preventing the decline in sMVPA that is typically seen with increasing grade level. Multiple opportunities for PA during school hours are needed to move the needle on children meeting sMVPA recommendations.

Funding provided by NIH-NICHD.

Effect of the Kiddie Cats on the Move Intervention On Preschoolers' Physical Activity

Connie Tompkins, Lori E. Meyer, Erin K. Shoulberg, Caroline Martin, Marissa Dennis, Allison Krasner, Betsy Hoza. *University of Vermont, Burlington, VT.*

(No relevant relationships reported)

Young children spend a significant amount of time in structured preschool settings; however, the majority of this time is spent in sedentary behaviors. Given that obesity, physical activity (PA), and sedentary behaviors track throughout development, interventions aimed at increasing PA opportunities for young children in the preschool setting may be critical in establishing healthy trajectories for young children. **PURPOSE:** To examine PA in preschool-aged children during school days when a PA curriculum was administered as compared to non-intervention days. **METHODS:** A pilot PA curriculum, *Kiddie CATs on the Move*, was implemented in local preschools over 23-weeks, 2-3 times per week by classroom teachers and college students enrolled in a service-learning course. Physical activity was objectively measured by accelerometry during the preschool day at 3 intervention timepoints. A total of 32 children (M_{age} = 3.91±0.6, 12 males, 20 females) who had at least 2 days of valid data on both intervention days and non-intervention days were included in the analyses. Minutes per hour (min/hr) of moderate-to-vigorous (MVPA), total PA (light + MVPA), and sedentary as well as percentage of time spent in each were calculated. Paired-samples t-test was used to compare intervention vs. non-intervention days. **RESULTS:** Children engaged in significantly more total PA (min/hr) on days when the PA curriculum was administered vs. non-intervention days (17.2±3.5 vs. 16.0±3.5, p<0.001) and significantly more min/hr in MVPA (9.5±2.7 vs. 8.5±2.9, p<0.001). On intervention days, children spent significantly less time in sedentary behavior compared to days without the intervention (71.3% vs. 73.4%, p<0.001). **CONCLUSIONS:** The current findings suggest the *Kiddie CATs on the Move* curriculum significantly increased the amount of time preschoolers engaged in PA (total and MVPA) throughout their school day. This teacher- and student-led intervention in the preschool setting may represent a viable approach to increase PA and aid in the establishment of healthy behaviors in young children.

Physical Fitness Changes are Independent of Adiposity in an Afterschool Translational Health Program

Carolina Velasquez, Emily W. Flanagan, Kara Bolon, Arlette C. Perry, FACSM. *University of Miami, Coral Gables, FL.*

(No relevant relationships reported)

Background: As obesity rates continue to rise in children and adolescents, physical fitness (PF) levels are reported to decrease. Given the fact that low PF levels are associated with adverse medical conditions and fewer schools require physical education, improving PF levels has been the target of many afterschool programs. However, not all afterschool programs have been successful in improving PF levels in minority children. In adults, improvements in aerobic fitness (AF) are observed concomitantly with decreases in adiposity. However, less is known about this relationship in children, particularly minority children. **Purpose**: The present study was done to determine whether a translational health in nutrition and kinesiology (THINK) program focusing on education, clinical activities, and free play can improve PF independent of adiposity. **Methods**: A total of 73 participants (35 Latino, 31 Black, and 7 White) 8-12-years enrolled in a YMCA afterschool program. All participants were randomly assigned to THINK or control (CON) programs. Muscular strength (MS) was assessed using grip dynamometer and AF was assessed using the NIH *two-minute walk test* as part of their PF evaluation. Adiposity was measured using skinfold thickness of the triceps (TRI) and subscapular (SS). Means and standard errors were evaluated for all dependent variables in both THINK and CON groups. An analysis of covariance was performed to determine differences between groups over time after adjustment for pretest scores. **Results:** Significant differences were found in MS between THINK and CON even after for controlling for SS (THINK x̄=14.641 ±1.724; CON x̄=6.554 ± 2.391; p=.010) and TRI (THINK x̄=14.771±1.767; CON x̄= 6.425±2.496; p=.013). Significant differences were also observed between THINK and CON in AF after controlling for SS (THINK x̄=39.952±10.738, CON x̄=-7.125±14.681; p=.016) and TRI (THINK x̄=41.352±11.130, CON x̄=-9.630±15.60; p=.016). **Conclusion**: A translational health program such as the THINK which

targets exercise physiology knowledge, clinical experiences, and structured free play can improve PF measures independent of adiposity levels in predominantly minority children participating in an afterschool setting.

3107　June 2 10:15 AM - 10:30 AM

Impact of Social Support on Changes in Physical Activity among Children Participating in School-based Programs

Sarah A. Amin, Kenneth Chui, Paula J. Duquesnay, Catherine M. Wright, Virginia R. Chomitz, Christina D. Economos, Jennifer M. Sacheck, FACSM. *Tufts University, Boston, MA.*

(No relevant relationships reported)

PURPOSE: Teacher and peer social support (SS) enhances children's physical activity (PA) engagement and represents an important consideration for implementing school-based PA interventions. We aimed to assess changes in school PA social support (S-SS) among children participating in school-based PA programming and examine if changes in moderate-to-vigorous PA (MVPA) differed by S-SS level.
METHODS: Eighteen MA schools from lower-income districts were enrolled in the *FLEX* study and randomized to control, *100 Mile Club®* (walking/running club), or *Just Move/NYP™* (active classroom breaks). Demographic data were collected by parent report. Third and fourth grade children were recruited and measured for height/weight and 7-day accelerometry (Actigraph GT3X+). SS for PA was self-reported and a S-SS score (6 items) was median split into low and high categories. For each program group, the association between low vs. high S-SS and changes in MVPA from baseline (pre-intervention) to 6 months were examined using mixed effects models adjusting for sex, grade, race, BMI category, free/reduced price lunch eligibility (FRPL), mean temperature, and school-level clustering.
RESULTS: 747 children (8.7±0.7 years, 43% male, 64% non-white, 56% FRPL, 40% overweight/obese) had valid accelerometer wear-time (≥3 days, ≥10 hrs/day) and 20% (45.6±19.3 min/day) met the 60-min total daily MVPA recommendations at baseline. There were modest changes in high S-SS from baseline to 6 months for children participating in Just Move (4% increase), 100 Mile Club (7% increase), and control (7% decrease) (p>0.05). The interaction between S-SS and time point was not significant for the control or 100 Mile Club group (p>0.05). In Just Move, there was an interaction between time point and S-SS (p=0.02). Pairwise comparisons indicated no difference in MVPA for children reporting low vs. high S-SS at baseline (p>0.05). However, at 6 months, Just Move children with high S-SS had 3.8 min (95% CI: 0.69-6.91) more MVPA than those with low S-SS (p=0.016; Bonferroni adjusted p=0.09).
CONCLUSIONS: Children participating in active classroom breaks who reported high S-SS had increased MVPA compared to those reporting lower support. Future work should consider how to effectively support and sustain S-SS to encourage school-wide improvements in PA behaviors.

3108　June 2 10:30 AM - 10:45 AM

Changes In Ability, Confidence, And Motivation Among Children In A Novel School-based Physical Literacy Intervention

Erin Hennessy[1], Daniel P. Hatfield[1], Kenneth Chui[2], Stephanie Herrick[3], Christine Odalen[3], Teri West[3], Rachel Pratt[3], Catherine Wright[1], Jennifer Sacheck, FACSM[1]. *[1]Tufts University Friedman School of Nutrition Science and Policy, Boston, MA. [2]Tufts University School of Medicine, Boston, MA. [3]New York Road Runners, New York, NY.* (Sponsor: Jennifer Sacheck, FACSM)

(No relevant relationships reported)

Programs that increase children's physical literacy (PL), defined as the *ability*, *confidence*, and *motivation* to be physically active for life, hold promise for helping children achieve physical activity recommendations, yet few studies have tested PL interventions. **PURPOSE:** To fill this gap, we conducted a pilot evaluation of a PL-based intervention in the school setting. **METHODS:** Three New York City elementary schools were recruited. The intervention included twice-weekly lessons during regularly scheduled 3rd/4th grade PE classes over 10 weeks between Feb-Jun 2017. Twenty lessons were selected from a bank of 400 activities designed to build running, locomotion, and balance skills through age-appropriate play and games. Lessons were linked to SHAPE America PE standards and involved a warm up activity, skill-based activity, games focused on the skill, and a cool down activity. *Ability* was measured by direct observation (eight tasks from the PL Assessment for Youth (PLAY*fun*) tools). Each task was graded on a four-point rubric (0-100), categorized as: Initial (0-25), Emerging (26-50), Competent (51-75) and Proficient (76-100). *Confidence* and *motivation* were measured by child-reported surveys; demographics were collected via parent-reported surveys. Height/weight were measured; body-mass index z-scores computed. Paired sample t-tests tested change in PLAY*fun* scores, reported as mean (SD). **RESULTS:** Baseline (T1) and post-intervention (T2) data were collected on n=45 children. Most children were 9.4 (0.5) years old (n=28), female (n=24), either Non-Hispanic Black or Hispanic (n=40), and of a healthy weight (n=30). Children improved in two running tasks: run there/back (T2:

50.4, T1: 45.2, Δ5.1 (11.7, p lt 0.01) and run/jump/land (T2: 42.8, T1:37.5, Δ5.3 (16.3), p=0.03); one locomotor task: crossovers (T2:27.0 T1:22.3 Δ4.8 (13.4), p=0.02); and the balance task: backward balance walk (T2:32.9 T1:29.2, Δ3.7 (10.8), p=0.02). Self-reported confidence and motivation were high (>4 on 5-point scales) at baseline with no change observed at post. **CONCLUSION:** Children participating in a PL-based program focused on running, locomotion, and balance may demonstrate improvements in PL domains, particularly motor skills. This study was funded by NYRR.

3109 June 2 10:45 AM - 11:00 AM

Physical Activity and Screen Time Recommendation Compliance in Preschoolers

Sarah Burkart, Christine W. St. Laurent, Sofiya Alhassan, FACSM. *University of Massachusetts Amherst, Amherst, MA.* (Sponsor: Sofiya Alhassan, FACSM)
(No relevant relationships reported)

Low physical activity (PA) and increased screen time (ST) is problematic for preschool-age children (2.9-5 years), and is attributed to childhood overweight/obesity. Due to this, several organizations have provided recommendations surrounding these behaviors. However, few studies have examined the compliance rates of preschoolers based on the recently released PA and ST recommendations (≥15 minutes of PA/hour and ≤60 min/day). **PURPOSE:** To assess preschool-age children's compliance with PA and screen time recommendations and identify variables contributing to compliance. **METHODS:** Baseline data from preschoolers (n=52, 50% male, age = 3.7±0.8 years, BMI % = 50.2±26.5) in two preschool centers participating in the Preschool Activity, Diet, and Sleep pilot study was utilized for this analysis. PA was measured with an Actigraph GT3X accelerometer worn on the lower back of children for seven consecutive days. PA data were reduced using Pate et al. cut points, and compliance was assessed for school-day (≥15 min/hour) and total day (≥180 min) recommendations. ST and parent variables were assessed with self-report validated questionnaires. Appropriate descriptive statistics were calculated for all variables. Logistic regression was used to determine differences in compliance based on gender, ST, school-day PA, parent PA, and parent PA knowledge. **RESULTS:** Children engaged in 11.3±3.6 min/hour of PA and 102.6±79.6 min/day of ST. The percentage of preschoolers meeting school-day recommendations and total day recommendations were 17.1% and 26.5%, respectively. Approximately 35.9% of preschoolers met ST recommendations. There were no gender differences in PA (*p*=0.052) or ST (*p*=0.91) compliance. Additionally, only school-day PA significantly contributed to the likelihood of meeting total day recommendations (OR=1.05, 95% CI=1.002, 1.104). **CONCLUSION:** Preschoolers' compliance with PA and ST recommendations was low in this sample. Additionally, only school-day PA was a significant predictor of meeting daily PA recommendations. No significant predictors were identified for ST compliance. Practical intervention strategies are needed to increase PA and reduce ST in preschoolers, specifically in the preschool environment.

G-25 Clinical Case Slide - **Arm**

Saturday, June 2, 2018, 9:00 AM - 10:40 AM

Left Anterior Arm Pain in a 79 year old Female Pilates Method Strength Trainer

Brittany J. Moore[1], Elena J. Jelsing[2], Jonathon T. Finnoff, FACSM[3]. *[1]Mayo Clinic, Rochester, MN. [2]Mayo Clinic, Minneapolis, MN. [3]Mayo Clinic College of Medicine and Science, Rochester, MN.* (Sponsor: Jonathan T. Finnoff, FACSM)
(No relevant relationships reported)

HISTORY: A 79 year old female presented to sports clinic with 2 weeks left anterior elbow pain that developed following a Pilates class. She described a pulling type of discomfort in the left antecubital region worse with elbow extension and improved with rest. She noted associated swelling in the region over the same period. She denied history of bruising, trauma, or obvious injury to the arm during the class. She exercised regularly with Pilates method and denied engaging in any novel activities prior to pain onset. She denied changes in strength or sensation. She had cochlear implants which were not MRI compatible.
PHYSICAL EXAMINATION: There was fullness about the left anterior distal arm to antecubital fossa which was tender and hard on palpation. The left biceps tendon was palpable in the antecubital fossa but less prominent than the contralateral side. She had a left elbow extension lag of 15 degrees; elbow flexion and forearm prono-supination range and strength were symmetric. She was neurovascularly intact.
DIFFERENTIAL DIAGNOSIS: 1. Distal biceps tendon tear 2. Distal biceps muscle tear 3. Brachialis muscle tear 4. Deep venous thrombosis 5. Sarcoma
TEST AND RESULTS: Elbow anterior-posterior & lateral radiographs: Normal. Elbow anterior musculoskeletal ultrasound: Lateral portion of brachialis muscle had heterogeneous echogenicity, large areas of hypoechogenicity in between fibers and discontinuity of proximal fibers with the distal insertion. Medial half of brachialis muscle had intact fibers. Remainder of exam was normal including brachialis tendon insertion, biceps muscle and tendon, vasculature, and nerves.
FINAL WORKING DIAGNOSIS: High grade partial thickness tear of the distal lateral brachialis muscle
TREATMENT AND OUTCOMES: She was managed with compression sleeve and initiation of physical therapy for range of motion with later progression to elbow flexor strengthening. Three months post injury she was at normal baseline for motion and activity.

3114   June 2 9:20 AM - 9:40 AM
Left Arm Pain and Numbness-Recreational Athlete

Paul A. Krebs, Clinton Hartz. *The Ohio State University, Columbus, OH.* (Sponsor: James Borchers, MD, MPH, FACSM)
(No relevant relationships reported)

History: A 41 year old right hand dominant female presented with left arm pain and numbness of 6 months duration with progressive worsening. Symptoms started in the distal posterior medial aspect of her arm and radiated to the 4th and 5th fingers of the hand. The pain was worse with lifting, swimming, biking, and tennis, forcing her to stop her normal athletic activities. She also noticed swelling in the distal aspect of the arm where the pain originated and a palpable bump. She denied history of trauma, clicking, locking, or instability.

Physical Exam: Neck exam showed full painless range of motion, no tenderness, and a negative Spurling test. Shoulder exam showed full strength and range of motion. Her left elbow had full range of motion with pain, no instability or crepitus. She had soft tissue tenderness and swelling in the distal arm medially with palpable nodules just proximal to the medial epicondyle. Cozen's, Speed's, and Yergason's tests were negative. She had 5/5 strength and full range of motion of her left hand. Neurologic exam showed decreased sensation in the ulnar nerve distribution. Capillary refill and radial pulses were intact.

Differential Diagnosis:
1. Cubital Tunnel Syndrome
2. Ulnar Neuropathy Secondary to Mass Effect
3. Fracture/Stress Fracture
4. Cervical Radiculopathy
5. Thoracic Outlet Syndrome

Tests and Results:
XR Humerus: No soft tissue swelling or acute osseous abnormality
Limited Diagnostic Ultrasound: 4 hypervascular nodules adjacent to ulnar nerve, likely lymph nodes

Final Working Diagnosis:
Ulnar neuropathy secondary to mass effect, lymphadenopathy, need to rule out malignancy.

Treatment and Outcomes:
1. MRI Left Humerus: abnormal enlarged lymph nodes. Mass effect evident along the ulnar nerve.
2. Referred to Hematology Oncology.
3. Biopsy: grade 1 follicular lymphoma.
4. PET scan: hypermetabolic lymphadenopathy above and below the diaphragm, uptake in the spleen and liver, consistent with a Stage III lymphoma.
5. Bendamustine/Rituximab (BR) was started because of its response rate and lower side effect profile compared to other chemotherapies.
6. Patient has undergone 2 cycles of BR with good response, including near resolution of her humeral disease.
7. She is restarting activities as tolerated. The expectation is that her ulnar neuropathy will improve with remission of her lymphoma.

3115   June 2 9:40 AM - 10:00 AM
Bilateral Wings

Nina Yaftali. *Rush, Chicago, IL.*
(No relevant relationships reported)

HPI:
19 year-old right hand dominant male high school recreational basketball player who presents with chief complaint of bilateral shoulder pain for one year. About one and half years ago patient was training in the gym when he did a heavy overhead press and heard an audible pop in his shoulders. He complained of a dull, achy posterior shoulder pain and mild winging of both his scapula. He stopped exercising, and went to see an orthopedist who recommended physical therapy. He was diagnosed with weak shoulders and rotator cuff tendonitis with a prescription of rotator cuff and scapular strengthening exercises. After one year of physical therapy, he notes no improvement.

PHYSICAL EXAM:
Alert, oriented Caucasian male. Bilateral scapular winging more prominent on right compared to left. Atrophy of periscapular region more prominent on left.
Full active range of motion bilaterally.
4+/5 strength in abduction, forward flexion, and external rotation bilaterally. Negative belly press or lift off sign bilaterally
Neck flexion and bilateral deltoids 4+/5 strength bilaterally
Rhomboids 2/5 strength bilaterally
5/5 biceps and triceps strength bilaterally
Positive O'Brien's and Hawkins on right.
Normal reflexes and sensation bilaterally.
Increased lumbar lordosis with ambulation

DIFFERENTIAL DIAGNOSIS:
1. Long thoracic nerve neuropathy
2. Axillary nerve neuropathy
3. Myotonic Dystrophy

4. Limb Girdle Muscle Dystrophy

TEST AND RESULTS:
MRI right shoulder: Minimal tendinosis of the supraspinatus and subscapularis tendon.
MRI left shoulder: Mild tendinosis of subscapularis tendon.
EMG: Myopathic process with chronic features affecting the right upper extremity and periscapular region.
Genetic test: FSHD1 confirmed

FINAL WORKING DIAGNOSIS:
Facioscapulohumeral muscle dystrophy

TREATMENT AND OUTCOMES:
Patient was prescribed physical and occupational therapy for stretching, and range-of-motion exercise. It is recommended he no longer do heavy weightlifting, just low intensity aerobic exercise. His pain is controlled with NSAIDS currently, as no other drug shows any clear benefit. He received a baseline pulmonary function test, and dilated retinal exam. Patient is doing well overall. The shoulder surgeon is evaluating him for possible scapular fixation if his range of motion worsens.

3116   June 2 10:00 AM - 10:20 AM
Shoulder Weakness- Football

Daniel Sisk, Mindy Loveless. *University of Washington, Seattle, WA.*
(No relevant relationships reported)

HISTORY: A 17-year-old high school football player sustained a left shoulder injury while tackling an opposing player to the ground. He had pain in the left shoulder that increased the following day with radiation into the neck. He was evaluated by orthopedics 5 days post-injury. Initial X-rays of the cervical spine and left shoulder were unremarkable and subsequent left shoulder MRI 12 days post-injury was also unremarkable. Over the next few weeks the pain resolved but weakness in the shoulder persisted. He was then referred to our clinic for further evaluation approximately 3 months post-injury with ongoing shoulder weakness. He denied paresthesias.

PHYSICAL EXAMINATION:
Weakness was isolated to left shoulder external rotation and abduction. Shoulder flexion, extension and internal rotation were intact. Inspection showed atrophy of left supraspinatus and infraspinatus. Full pain free ROM of neck. Sensation and reflexes were intact in upper extremities.

DIFFERENTIAL DIAGNOSIS:
1. Suprascapular nerve injury
2. Rotator cuff tear
3. Cervical radiculopathy
4. Brachial plexus injury

TEST AND RESULTS: Diagnostic US of left shoulder: Increased echogenicity of left supraspinatus and infraspinatus
EMG/NCS: Increased insertional activity, 1+ fibs, 2+ sharps, increased phasicity and decreased recruitment in supraspinatus and infraspinatus. Membrane instability in deltoid and teres minor. No other abnormalities.
Repeat MRI of left shoulder: Atrophy of supraspinatus and infraspinatus. No mass or anatomic abnormality

FINAL WORKING DIAGNOSIS:
Left suprascapular nerve injury

TREATMENT AND OUTCOMES:
1. Referral to surgery resulted in nerve transfer surgery from spinal accessory nerve to suprascapular nerve
2. One month post-op little to no return of external rotation with mild weakness in left shoulder shrug as expected course post-operatively
3. Returned to football one month after surgery with recommendation to avoid positions requiring tackling

3117   June 2 10:20 AM - 10:40 AM

Forearm Pain- Diving

Dorcas Copa, Jaime Aparicio. *Memorial Hermann Ironman, Houston, TX.*

(No relevant relationships reported)

Forearm Pain-Diving

D. Copa, Jaime Aparicio, Memorial Hermann Ironman, Houston, TX

E-mail: Dorcas.copa@memorialhermann.org

HISTORY: A 22 year old International and NCAA Division I female diver developed medial forearm pain during the Spring of 2017 experienced only during the pike position of her dive. The pain initially was during the activity only but progressed to pain after the activity had ended.

PHYSICAL EXAM:

The examination of the athlete was done in the athletic training room by a physical therapist. Subjectively, questions about female athlete triad indicated inconsistent menstrual cycle. However, she did consume adequate calories including foods with calcium and protein. Further questioning about hormone levels and nutrition indicated she had been found to have low levels of vitamin D in previous blood tests as well as very low estrogen. The athlete reported having to take estrogen supplements in the past.

The physical exam revealed normal active range of motion bilaterally, normal sensation, reflexes, and strength. Vascular system was noted to be intact. Upper limb nerve tension was tested, resulting in negative findings. Pin point pain with palpation along the ulna in two places, one approximately middle of the ulna and the other approximately 2 inches from the proximal radioulnar joint, reproduced her pain. Applied manual force at each end of the ulna over a fulcrum also reproduced her pain suggesting an osseous pathology so imaging was suggested by the physical therapist and ordered by the orthopedic surgical fellow.

DIFFERENTIAL DIAGNOSIS:

1. Ulnar Stress Reaction
2. Periostitis
3. Bone Contusion

TESTS AND RESULTS: Plain Radiographs demonstrate bowing of the ulna

WORKING DIAGNOSIS:

The final diagnosis was bowing of the ulna with a stress reaction.

TREATMENT AND OUTCOMES:

1. Increase core strength in pike position in create a "tighter" pike throughout the pike position during dive.
2. Scapulothoracic strengthening to offload the forearm during the dive.
3. Diving Technique
4. Vitamin D supplements and nutrition counseling.

G-34   Free Communication/Poster - **High Intensity Interval Training**

Saturday, June 2, 2018, 7:30 AM - 11:00 AM
Room: CC-Hall B

3132   Board #1   June 2 8:00 AM - 9:30 AM

Sports Related Fitness Evaluation and High Intensity Interval Training in Table Tennis Players

Pei-Fan Wang, Mei-Hua Tu, Li-Lan Fu. *National Taiwan Sport University, Taoyuan, Taiwan.*

(No relevant relationships reported)

PURPOSE: To investigate the effect of 8 weeks high intensity interval training (HIIT) in elite table tennis players.

METHODS: Twenty four elite table tennis player (age: 19.52 ± 1.21 yrs; playing experience: 11.17 ± 1.56 yrs) participated in this study and were allocated into HIIT exercise group (n = 12, TG) and control group (n = 12, CG). All subjects were assessed by graded exercise test (GXT), sub-maximal exercise test (SBT), and table tennis specific fitness test (TTSFT) before and after the intervention. The TG group received HIIT protocol 3 times/week for 8 weeks period. Control group maintained the regular training programs. Participants were asked to perform a running test to fatigue before and after the experiment intervention to measure VO_2max, exercise duration, VT, HRmax and RPE. All subjects completed two 6-min bouts of moderate-intensity (MIE) and severe-intensity (SIE) running incremental exercise test. TTSFT was executed using a mechanical table tennis ball thrower to control the exercise intensity. Each participant forehand topspin three position rally table tennis trials at frequency of 60 balls/min till exhaustion. The Polar heart rate monitor was used to record HR and exercise duration.

RESULTS: After HIIT, TG significantly improve VO_2max (53.19 ± 6.11 vs. 56.73 ± 4.39 ml/kg/min, $p < .05$), time to voluntary exhaust (14.14 ± 1.17 vs. 14.93 ± 0.73 min, $p < .05$), and LACpost (pre 9.99 ± 2.35 vs. post 11.07 ± 2.02 mmol/L, $p < .05$) of GXT

test, and better than CG (post 50.04 ± 6.40 ml/kg/min; 13.70 ± 1.64 min; LACpost 8.96 ± 1.23 mmol/L) ($p < .05$). The variables of CG showed no significant difference. TG significantly increase SIE velocity, VO2max (55.01 ± 4.76 vs. 58.05 ± 4.88 ml/kg/min, $p < .05$) and LACpost (pre 11.72 ± 1.89 vs. post 12.50 ± 1.51 mmol/L, $p < .05$) of SBT, and better than CG ($p < .05$). However, there were no significant difference in MIE test between TG and CG ($p > .05$). TG (pre 371.36 ± 112.97 vs. post 475.71 ± 165.62 sec, $p < .05$) showed significantly improvement in TTSFT compare to CG (pre 361.20 ± 79.18 vs. post 334.80 ± 128.00 sec, $p > .05$).

CONCLUSIONS: Eight weeks HIIT could effectively improve aerobic capacity, specific fitness and exercise performance of table tennis players. Incorporation of a suitable training program into the training routine might be important to improve the exercise perforamcne.

3133   Board #2   June 2 8:00 AM - 9:30 AM

Biomarkers of Inflammation and Angiogenesis Following Short Vs. Long Bouts of High-Intensity Training

Chad D. Markert[1], Khala N. Clemons[1], Emily E. Bechke[2], Cassie M. Williamson[2], Michael J. McKenzie, FACSM[1], Brian M. Kliszczewicz[2]. [1]*Winston Salem State University, Winston Salem, NC.* [2]*Kennesaw State University, Kennesaw, GA.*

(No relevant relationships reported)

Effects of varying types of high-intensity training (HIT) on the appearance and time course of circulating biomarkers have not been adequately characterized. **Purpose**: The purpose of this study was to examine the effects of HIT on biomarkers of inflammation and angiogenesis, over time, in HIT bouts of varying duration (short bout, 5 min, and long bout, 15 min). **Methods**: Ten males, 18-45 years old, who had participated in CrossFit for at least 6 months, were recruited from local affiliates. The participants completed a total of 3 lab visits [Visit 1: collection of descriptive data; the next 2 visits were randomized between the short bout and long bout]. All subjects completed the same exercises. Blood was drawn pre and post-exercise, and 1 hour, 3 hours, and 6 hours post-exercise, centrifuged, and plasma frozen for analysis. A multiplex assay (Millipore MagPix) was used to determine concentrations of the biomarkers of interest [interleukin 6 (IL-6), interleukin 10 (IL-10), tumor necrosis factor alpha (TNF-alpha), and vascular endothelial growth factor (VEGF)]. **Results**: The short bout produced results similar to those of the long bout. Repeated measures ANOVA revealed no trial-dependent differences ($p \leq 0.05$) in any of the biomarkers. Both temporal responses and concentrations were similar in the short and long bout. **Conclusions**: The biomarkers IL-6, IL-10, TNF-alpha, and VEGF all follow a similar pattern of peaking post-exercise, and returning to baseline within 6 hours, regardless of the duration of the HIT. A practical implication is that a 5 min bout of HIT may be just as effective as a 15 min bout in terms of eliciting certain specific physiologic responses. Supported by WSSU Office of Student Research, Honors Student Research Grant (K.N.C.).

Effect of Reducing Sprint Duration in A REHIT Protocol on Changes in VO$_2$max and Mood

Preeyaphorn Songsorn[1], Gulbin Nalçakan[2], Richard Metcalfe[3], Niels Vollaard[1]. [1]*University of Stirling, Stirling, United Kingdom.* [2]*University of Ege, İzmir, Turkey.* [3]*Ulster University, Belfast, United Kingdom.*

(No relevant relationships reported)

Sprint interval training (SIT) is associated with health benefits, but 'classic' SIT (6x30-s 'all-out' cycle sprints) requires high motivation and is associated with negative affective responses and high levels of perceived exertion. In order to make SIT more suitable for sedentary individuals, the number of sprints and sprint duration have previously been reduced to develop a reduced-exertion high-intensity interval training (REHIT) protocol consisting of 2x20-s 'all-out' cycle sprints within a 10-min session. This genuinely time-efficient protocol remains effective at improving aerobic capacity (VO_2max). It is unknown if further reducing the sprint duration in the REHIT protocol affects improvements in $\dot{V}O_2max$ or changes in mood. **PURPOSE**: To examine the effect of reducing sprint duration from 20-s to 10-s in a REHIT protocol on changes in $\dot{V}O_2max$ and psychological perceptions. **METHODS**: Thirty-five healthy untrained subjects (mean±SD age: 22±3 y; BMI: 25±5 kg·m^{-2}; $\dot{V}O_2max$: 37±8 mL·kg^{-1}·min^{-1}) were randomised into groups performing two 10-s sprints (REHIT10; n=18) or 2x20-s sprints (REHIT20; n=17), within a 10-min session performed 3 times a week for 6 weeks. $\dot{V}O_2max$ was examined before and after training. Rating of perceived exertion (RPE), psychological perceptions (BRUMS, PANAS and acceptability of HIT) were evaluated during training sessions. **RESULTS**: The increase in $\dot{V}O_2max$ was significantly greater in REHIT20 (2.77±0.75 vs. 3.04±0.75 L·min^{-1}, +10%) compared to REHIT10 (2.58±0.57 vs. 2.67±0.61 L·min^{-1}, +4%; time x group interaction effect: $p<0.05$). There were no significant differences between REHIT10 and REHIT20 in mean RPE (REHIT10: 13.6±0.4, REHIT20:14.5±0.4), changes in mood status, or affective responses. **CONCLUSIONS**: Reducing REHIT sprint duration from 20-s to

10-s attenuates improvements in V̇O$_2$max, and does not result in more desired affective responses. Our findings support the use of the original REHIT protocol consisting of 2x20-s sprints.

Chlorella Intake Further Enhances Anaerobic And Aerobic Capacities Increased By High Intensity Intermittent Training

Shumpei Fujie[1], Natsuki Hasegawa[1], Naoki Horii[1], Moe Oshiden[1], Katsunori Tsuji[1], YuZhong Xu[1], Toru Mizoguchi[2], Eri Okumura[2], Izumi Tabata, FACSM[1], Motoyuki Iemitsu[1]. [1]Ritsumeikan University, Kusatsu, Japan. [2]Sun Chlorella Corp., Kyoto, Japan. (Sponsor: Izumi Tabata, FACSM)
(No relevant relationships reported)

High intensity intermittent training (HIIT) enhances anaerobic and aerobic capacities. Our recent study have demonstrated in animal study that the 6-week combination of chlorella intake and HIIT further elevated glycolytic and oxidative phosphorylation as ATP supply in skeletal muscle as compared with chlorella alone and HIIT alone, resulting in enhancement of anaerobic and aerobic exercise capacities. However, the combined effects of chlorella intake and HIIT on anaerobic and aerobic capacities in human remain unclear. PURPOSE: The aim of this study was to investigate whether the combination of chlorella intake and HIIT further enhanced anaerobic and aerobic capacities as compared with HIIT alone in human. METHODS: Twelve healthy young male subjects (21 ± 1 years) were participated in this study. Subjects completed 3-week of exhaustive HIIT, consisting of 6-7 bouts of 20-second cycling on a leg ergometer at an intensity of 170% maximal oxygen uptake (VO2max) with a 10-second rest between each bout, 3 days/week. They orally took chlorella or placebo (10 tablets) after the breakfast and dinner between the 3-week in a double-blind, randomized, crossover design with 4 weeks between each intervention. We measured VO2max as an indicator of aerobic capacity and maximal oxygen deficit (MOD) as an indicator of anaerobic capacity. RESULTS: After each HIIT intervention, VO2max was significantly increased in both chlorella and placebo groups (P<0.05). However, the amount of change in VO2max after the intervention was significantly higher in chlorella intake than placebo intake (P<0.05). After each HIIT intervention, MOD was significantly increased in both chlorella and placebo groups (P<0.05). However, the amount of change in MOD after the intervention was significantly higher in chlorella intake than placebo intake (P<0.05). CONCLUSIONS: These results suggest that the combination of chlorella intake and HIIT may further enhance anaerobic and aerobic capacities in human.

Effect of a Short-Term HIIT Program on Systemic Brain-Derived Neurotrophic Factor in Healthy Males

Iván Rentería[1], Patricia C. García-Suárez[1], David O. Martínez-Corona[2], Luis M. Gómez-Miranda[1], Alberto Jiménez-Maldonado[1]
[1]Facultad de Deportes. Universidad Autónoma de Baja California, México.
[2]Escuela de Ciencias de la Salud. Universidad Autónoma de Baja California Campus Ensenada, México.

The brain-derived neurotrophic factor (BDNF) is a member of the neurotrophin family of growth factors. Several stimuli, such as physical exercise have the potential to increase BDNF production. Ambiguous findings regarding the exercise intensity that elicits changes in systemic BDNF levels have been reported in the literature. PURPOSE: To determine the effects of short-term high intensity-interval training (HIIT) on systemic BDNF levels in healthy males. METHODS: Eleven healthy young males (Age = 22.8 ± 2.3 yr.; body weight (BW) = 77.8 ± 11.9 kg; height = 173.4 ± 5.2 cm; BMI = 25.8 ± 3.3 kg/m²) participated in the study. A graded maximal exercise test (GXT) was used to determine the maximal aerobic power (MAP) required to design the exercise intensities. The short-term HIIT protocol consisted of cycle ergometer exercise 3 times/week for 4-weeks. Paired t-test was used to compare anthropometrics and cardiovascular variables, MAP and systemic BDNF levels before and after short-term HIIT. RESULTS: Short-term HIIT did not change significantly the systemic BDNF levels (Pre-HIIT = 18.8 ± 1.6 ng/mL vs. Post-HIIT = 19.2 ± 2.2 ng/mL, p = 0.6495). Similarly, the BW and BMI were not modify by HIIT. Contrary, the hearth rate recovery was improved after the HIIT program (Pre-HIIT=159.5 ± 11.9 vs Post-

HIIT = 148.1 ± 13.6, p= 0.04). **CONCLUSION**: The short-term HIIT protocol used in this study was unable to elicit significant changes on systemic BDNF levels in healthy males. The physiological mechanisms explaining this finding are currently under scrutiny. On the other hand, the same protocol improved the heart rate recovery in healthy men. These data suggest different response of the Central Nerve System and Peripheral Nerve System to the same exercise modality.

Effects of High Intensity Interval Training on Anaerobic Performance & Aerobic Power on Male Basketball Players

Seyed reza Seyedi. *Wuhan sport university, Wuhan, China.*
(No relevant relationships reported)

PURPOSE: High Intensity interval training (HIIT) has become an increasingly popular form of exercise due to its greater effects on exercise capacity and short time requirement. The purpose of this study was to compare two models of HIIT 15s and 30s training on anaerobic peak power, anaerobic average power, anaerobic power drop, time to peak power and aerobic power.
METHODS: Fourteen male basketball players (age: 22.4 ± 2.1 years, weight: 74.5 ± 6.7kg and height: 182 ± 7.3cm) participated in the study. Participants were healthy and active players of a collegiate varsity team, who were randomly assigned to 15s HIIT group and 30s HIIT group. After baseline metabolic, anthropometric, and fitness measurements, both groups performed HIIT three times a week for a period of six weeks. The training of the 30s HIIT group consisted of a total of 18 sessions of 4 to 8 repeats of 30-second sprint cycling at 95%of heart rate with 1-minute active rest between each repetition on an electromagnetically controlled cycle ergometer. The 15s HIIT group trained using the same frequency of workouts per week with 4 to 8 repetition, and applied 15s sprint cycling at 95%of heart rate with 1-minute interval between each repetition on the electromagnetically controlled cycle ergometer. For both groups, before and after the six-week long training anaerobic performance was measured by means of 30 second Wingate cycling ergometer test and aerobic power was measured by means of cycling. Peak power, average power, time to peak, drop of power and aerobic power data were collected and analyzed. Independent t test and paired t test were employed to examine the differences (p < .05) between groups, respectively.
RESULTS: The 15s HIIT group had significantly greater improvements on peak power (0.704±0.601), and average power (0.748±0.347) than the 30s HIIT group did on peak power (-0.260±1.06), and average power (-0.395±0.831). Meanwhile, the 30s HIIT group had significantly greater values on drop power (3.394±2.318), time to peak (1.66±1.10), and aerobic power (3.142±2.544) than the 15s HIIT group did on drop power (-0.484±1.621), time to peak (1.110±0.981), and aerobic power (4.142±3.132).
CONCLUSIONS: It is concluded that the 15s HIIT model may result in greater effects on anaerobic power (peak and average powers) and the 30s HIIT model may yield great aerobic power.

The Effects Of A Three-week Hiit Program On Physiological And Physical Performance Parameters

Linghao Kong[1], Qingwei Jin[2], Susan Sotir[1], Vincent Paolone, FACSM[1], Jeff Gagnon[1], Samuel Headley, FACSM[1]. [1]Springfield College, Springfield, MA. [2]Tianjin University of Sports, Tianjin, China. (Sponsor: Samuel Headley, FACSM)
(No relevant relationships reported)

High Intensity Interval Training (HIIT) has been demonstrated to have a positive effect on a number of physiological variables in several clinical populations. However, little work has been done on this topic in China. **PURPOSE:** To investigate the effects of a 3-week HIIT program on physiological and physical performance parameters (blood pressure, time to exhaustion, peak heart rate, lactate threshold, and O$_{2peak}$) among three different Chinese groups. **METHODS:** Thirty males were categorized by current health status (blood pressure, O$_{2peak}$, and frequency of exercise per week): to healthy active group (n = 10; age = 21.9±2.8, height = 176.5 ± 4.8, weight = 71.8 ± 9.3, percentage of body fat = 13.0 ± 6.12), healthy inactive group (n = 10; age = 20.9 ± 1.85, height = 172.8 ± 4.4, weight = 69.1 ± 10.5, percentage of body fat = 18.35 ± 7.0), or prehypertensive group (n = 10; age = 22.1 ± 2.0, height = 176.3 ± 7.4, weight = 71.8 ± 12.8, percentage of body fat = 20.47). Baseline testing included body fat estimation, blood pressure measurement, and a O$_{2peak}$ test conducted on a treadmill. Subjects completed a 3-week, 3 sessions per week intervention. Each session included a warm-up (5 min), 10 HIIT cycles (60 sec high intensity at 90% O$_{2peak}$ and 60 sec active recovery at 45% O$_{2peak}$, 20 min), and a cool-down (5 min). Post intervention assessments repeated the baseline measures. Six 2 (Time) x 3 (Group) mixed factorial ANOVAs were performed to determine if differences existed in the dependent variables. **RESULTS:** No significant interaction was found for any dependent variables. Significant main effects were identified for systolic blood pressure (120.1±8.3 to 116.8±7.2 mmHg, $p < 0.001$) diastolic blood pressure (72.3±6.7 to 69.5±5.5 mmHg, $p < 0.001$), time to exhaustion (16.0 ± 3.2 to 18.0 ± 2.5

SATURDAY, JUNE 2, 2018

min, $p<0.001$), O_{2peak} (42.2 ± 6.8 to 45.5 ± 6.2 ml·kg^{-1}·min^{-1}, $p < 0.001$), and lactate threshold (67.1 ± 12.8 to 79.6 ± 11.0 %, $p < 0.001$) over time. Systolic blood pressure and diastolic blood pressure decreased, time to exhaustion, O_{2peak}, and lactate threshold increased, regardless of groups. No significant main effect was found for peak heart rate (183.7 ± 8.8 vs. 184.3 ± 8.8, $p > 0.05$). **CONCLUSION:** A 3-week HIIT program lowered resting systolic and diastolic blood pressure, while increasing time to exhaustion, lactate threshold, and O_{2peak} for all three groups included.

Acute Physiological Responses During Steady State and High Intensity Interval Training in Inactive Men

Toni LaSala, Jordan L. Cola, Racine R. Emmons, Michael A. Figueroa, Francis Frabasile. *William Paterson University, Wayne, NJ.* (Sponsor: Gordon Schmidt, FACSM)

(No relevant relationships reported)

Abstract

High Intensity Interval Training (HIIT) has become an increasingly popular mode of exercise, especially with those with the perception of a lack of time. These intervals have been shown to decrease the time spent being active while simultaneously providing similar results to steady-state training to elicit the cardiovascular adaptations. **Purpose:** To investigate the changes between steady-state training and HIIT training on respiratory exchange ratio (RER), peak oxygen consumption (VO$_{2peak}$), heart rate (HR) and rate of perceived exertion (RPE) in recreationally trained, college-aged participants. **Methods:** Thirteen men 21 to 27 years old (M= 23.31, SD ± .07) were recruited for the study. Subjects participated two sessions and were randomly assigned to two groups: Steady-State (SS) or High Intensity Interval Training (HIIT) training on a treadmill. SS training consisted of a 3-minute warm-up at 2.0 mph with a 0% grade followed by the Balke Protocol. HIIT protocol consisting a 5-minute warm-up at 3 mph at 0% grade, followed by maximum effort sprints for 30 seconds followed by a 30 second active recovery with sprint intervals beginning at 4.5mph increasing by .5mph after recovery interval. **Results:** There was a significant difference in RER between groups (t (12) = 2.30, $p <$.05, $d = $.55). However, no significant differences in VO$_2$ (t (12) = -1.06, $p =$.31, $d=$.36) and HR (t (12) = -.812, $p = $.43, $d =$.26) were identified using a paired samples t-test, between treadmill conditions (SS, HIIT). Furthermore, there were no significant differences (z = -1.51, $p = $.13, $r = $.54) in RPE after conducting a Wilcoxon matched pairs signed-rank test. The results suggest that training at higher intensities for a shorter period of time yielded similar results to training at lower intensities for a longer duration. **Conclusion:** HIIT training allows for increased cardiovascular health in a time efficient manner, which can accommodate various schedules.

Testosterone and Cortisol Responses after Short-term High-intensity Interval Exercise Training in Healthy Humans

Giorgos Paradisis, Anastassios Philippou, Popi Stavrinou, Gregory Bogdanis, Maria Maridaki. *National and Kapodistrian University of Athens, Athens, Greece.*

(No relevant relationships reported)

High intensity interval training (HIIT) has recently gained popularity as an effective stimulus for eliciting adaptations in various aspects of physical fitness. Those adaptations may also involve complex hormonal changes, however less is known about the hormonal responses to this type of exercise training. **PURPOSE**: This study investigated the changes in serum levels of the competitive (anabolic vs catabolic) hormones testosterone (TESTO) and cortisol (CORT) caused by a 3-week HIIT regimen in healthy humans. **METHODS:** Eight physically active males (age: 24.3 ± 1.4 y, body mass: 77.9 ± 2.9 kg, height: 179 ± 1 cm, body fat: 9.7 ± 1.3%) performed three HIIT sessions/week over 3 weeks. Each session included four to six 30-s bouts of high-intensity cycling separated by 4 min of recovery. Blood samples were withdrawn before and at 0.5, 24 and 48 hrs post-exercise. Serum levels of TESTO and CORT were measured by ELISA using commercially available kits. Two-way ANOVA was used for statistics. **RESULTS:** Before training, acute exercise significantly elevated CORT levels by 120.5% (p<0.05) at 0.5 hrs post exercise (357.3±54.7 ng/ml, 137.4±16.8 ng/ml and 179.9±28.5 ng/ml, at 0.5, 24 and 48 hrs after exercise, respectively, compared to 194.9±29.0 ng/ml at baseline; mean±SE). Training reduced the CORT levels both at baseline (122.1 ng/ml) and post exercise (231.9±35.0 ng/ml, 78.7±6.3 ng/ml and 78.7±8.2 ng/ml, at 0.5, 24 and 48 hrs after exercise, respectively) compared to the pre-training levels (p<0.05-0.01); however post-training CORT levels remained significantly elevated at 0.5 hrs post exercise (p<0.01). Circulating levels of TESTO did not change significantly over time, neither before nor after the 3-week HIIT regimen (p>0.05). Interestingly, however, after training the TESTO/CORT ratio increased at 48 hrs post exercise (p<0.05) and was significantly higher at 24 and 48 hrs post exercise compared to the corresponding pre-training time points (65.0% vs 35.9% and 85.3% vs 67.1%, at 24 and 48 hrs, respectively; p<0.05). **CONCLUSION:** Our findings suggest that HIIT triggers beneficial responses of CORT and TESTO/

CORT ratio, which may reflect a specific drive towards anti-catabolic and/or regulatory adaptations to exercise-induced stress. More studies are needed to further characterize the hormonal responses to HIIT in humans.

Physiological Effects of Increasing Battling Rope Weight During 6 weeks of High Intensity Interval Training

Derek PD Bornath, Kevin J. Milne, Kenji A. Kenno. *University of WIndsor, Windsor, ON, Canada.*

(No relevant relationships reported)

Acute battling rope (BR) high intensity interval training (HIIT) increases oxygen consumption, and 4 weeks of BR HIIT has reported significant increases in female upper body maximal oxygen consumption (MVO$_2$), and skeletal muscle endurance. **PURPOSE:** To determine if increasing BR weight during 6 wks of HIIT increases upper body MVO$_2$ and upper body skeletal muscle strength, endurance and power. **METHODS:** 18 recreationally active men and 15 women (23±2y) performed 10 BR HIIT sets, 30s work: 60s rest, 3x/week, for 6 wks. For the first 3 weeks, women used 40 ft, 1.5", 20lb BR and men used 50 ft, 1.5", 25lb BR, after which BR weight was increased by 10lb using a heavier rope for another 3 wks in both groups. Upper body MVO$_2$ (arm ergometer) and skeletal muscle performance (isometric shoulder [shld] flexion/extension, dynamic shoulder power, maximum sit-ups and push-ups) was assessed at baseline, and after 3 and 6 wks. **RESULTS:** During BR HIIT male and female heart rates were >85% of predicted maximums, and peak HIIT blood lactates (BLa) reached 10.79 and 8.33 mmol/L, respectively. See table below for MVO$_2$ and skeletal muscle performance adaptations after 3 and 6 wks of BR HIIT.

		baseline	3 wks	6 wks
upper body MVO2 (ml/kg/min)	male	36.5±5	39.9±7[a]	43.9±7[bc]
	female	31.5±5	34.3±5[a]	38.8±5[bc]
isometric shld flexion (lb)	male	93±18	96±16[a]	99±18[bc]
	female	45±9	50±9[a]	53±10[bc]
isometric shld extension (lb)	male	47.1±7	48.8±7	49.6±6[c]
	female	23.2±5	25.4±4[a]	25.3±4.7[c]
dynamic shld power (N)	male	3904±528	4274±523[a]	4597±536
	female	2883±372	3264±465[a]	3425±451[bc]
situps (#)	male	44.9±15	50.4±15[a]	55±15[bc]
	female	43.7±17	50.3±20[a]	55.7±24[bc]
pushups (#)	male	41.6±17	45.9±16[a]	48.8±18[bc]
	female	27.4±9	32.3±10[a]	37.1±11[bc]

a=baseline vs. 3 wks p<.05, b=3 vs 6 wk p<.05, c=baseline vs 6 wks p<.05
CONCLUSION: 3 wks of BR HIIT can significantly increase upper body MVO$_2$ and skeletal muscle strength, endurance and power in male and female university students. Increasing BR weight plus 3 more wks of BR HIIT produced additional significant improvements in MVO$_2$ and skeletal muscle performance, suggesting progressive overload training principles can be applied to BR training.

Hormonal Responses after Short-term High-intensity Interval Exercise Training in Healthy Humans

Maria Maridaki[1], Roxane Tenta[2], Popi Stavrinou[1], Gregory Bogdanis[1], Anastassios Philippou[1]. *[1]National and Kapodistrian University of Athens, Athens, Greece. [2], School of Health Science and Education, Harokopio University, Greece, Athens, Greece.*

(No relevant relationships reported)

High intensity interval training (HIIT) elicits multiple physiological adaptations which may involve complex hormonal changes, as HIIT is characterized by high physiological demands and stress, and might disturb the levels of hormones associated with energy expenditure and exercise-induced stress. PURPOSE: This study investigated the changes in serum levels of thyrotropin (TSH), free thyroxine (fT4) and prolactin (PRL) caused by a 3-week HIIT regimen in healthy humans. METHODS: Eight physically active males (age: 24.3 ± 1.4 yrs, body mass: 77.9 ± 2.9 kg, height: 179 ± 1 cm, body fat: 9.7 ± 1.3%) performed three HIIT sessions/week over 3 weeks. Each session included four to six 30-s bouts of high-intensity cycling separated by 4 min of recovery. Blood samples were withdrawn before and at 0.5,

24 and 48 hrs post-exercise. Serum levels of TSH, fT4 and PRL were measured by ELISA using commercially available kits. Two-way ANOVA was used for statistics and data are presented as mean±SE. RESULTS: TSH levels peaked at 0.5 hr post exercise, both before (3.41 ± 0.44, 4.85 ± 1.54, 3.14 ± 0.283, and 2.91 ± 0.31 μIU/ml, at baseline, 0.5, 24 and 48 hrs post-exercise, respectively) and after the 3-week HIIT regimen (2.55 ± 0.34, 4.14 ± 0.70, 2.44 ± 0.22, and 2.37 ± 0.49 μIU/ml, at baseline, 0.5, 24 and 48 hrs post-exercise, respectively). FT4 levels peaked 24 hrs post exercise, both before (2.66 ± 0.17, 2.71 ± 0.09, 2.99 ± 0.22, and 2.61 ± 0.04 ng/dl, at baseline, 0.5, 24 and 48 hrs post-exercise, respectively) and after the 3-week HIIT regimen (2.70 ± 0.17, 2.90 ± 0.17, 3.16 ± 0.12, and 2.77 ± 0.07 ng/dl, at baseline, 0.5, 24 and 48 hrs post-exercise, respectively). PRL levels peaked at 0.5 hrs post exercise, both before (38.80 ± 9.90, 66.0 ± 16.32, 27.86 ± 4.40, and 20.14 ± 7.90 ng/ml, at baseline, 0.5, 24 and 48 hrs post-exercise, respectively) and after the 3-week HIIT regimen (25.32 ± 4.81, 55.0 ± 9.39, 24.03 ± 2.50, and 20.76 ± 4.76 ng/ml, at baseline, 0.5, 24 and 48 hrs post-exercise, respectively), reaching statistical significance compared to baseline only after the 3-week regimen (p<0.01). CONCLUSION: Our findings suggest that HIIT triggers mild acute hormonal changes, particularly of PRL, which may reflect regulatory responses to exercise-induced stress; however more studies are needed to further characterize the hormonal responses to HIIT in humans.

The Physical and Psychological Effects of Tactical High-Intensity and Jiu-Jitsu Training on Law Enforcement Officers

Charlie Shervheim, Nick Powell, Maxwell Rasmussen, Jennifer Dysterheft. *Hamline University, St. Paul, MN.* (Sponsor: Robert Pettitt, FACSM)

(No relevant relationships reported)

Law enforcement officers (LEO) require speed, strength, agility, and endurance for their job; however, the training requirements for many LEO departments are minimal. Tactical-specific high-intensity interval training (TS-HIIT) and jiu-jitsu martial arts practices are theoretically effective in improving performance in tactical fields, however no research exists this. **Purpose:** To examine whether TS-HIIT and jiu-jitsu training is more effective than current training practices to improve physical and psychological variables of experienced LEO. **Methods:** 10 experienced LEO were recruited from local departments. Baseline testing included the Perceived Stress Scale (PSS), WHO Quality of Life (WQ), General Self-Efficacy Scale (GSES), and skills-test. The skills-test examined upper-body maneuverability, heavy-object manipulation, lower-body power output, shooting accuracy, ground grappling/gun retention, memory recall, and decision-making. LEO then completed a six-week TS-HIIT and jiu-jitsu program for three hours per week. LEO repeated baseline measures after completion and will again at three months post-completion. **Results:** Despite previous experience, 65% of LEO failed baseline tests. Preliminary t-test analysis revealed significant improvements in grappling technique, timing, and score ($p = 0.02$) as well as time to complete the skills-test ($M = -6.65$ s; $p = 0.01$) post-intervention. Improvements on the grappling test were noted by less time gain control of the situation, prolonged time to failure, or improving from failed baseline tests to passing post-intervention. Two of the 10 LEO did not improve on the grappling test. LEO recalled 30% more phrases during the memory retention test post-intervention ($p = 0.01$). Post-intervention, there was no significant change in shooting accuracy ($p = 0.37$), perceived stress levels, (PSS; $p = 0.58$), or perceived quality of life (WQ; $p = 0.30$). The decision-making task was removed due to a number of participants having already viewed the specific scenarios used during data collection. **Conclusion**: Preliminarily, results indicate that a TS-HIIT and jiu-jitsu program may be critical for improving LEO fitness levels, memory retention, and gun retention skills. Three-month follow-up testing will be completed January 2018 to examine skill retention.

Longitudinal Comparison Of Polarized Vs. High Intensity Multimodal Training In Recreational Runners

Andrew Carnes. *Bellarmine University, Louisville, KY.* (Sponsor: Sara E. Mahoney, FACSM)

(No relevant relationships reported)

Empirical endurance training studies support a polarized distribution, i.e., a high volume of low intensity training combined with less at high intensity. Few studies include recreational runners, who typically train with low volume. CrossFit Endurance© (CFE) targets these runners, emphasizing low volume, high intensity intervals and multimodal circuit training. Anecdotally, CFE enhances performance to a similar extent as higher volume run training, but empirical data have not been available.
PURPOSE
Longitudinally compare changes in performance and fitness after 12 weeks of CrossFit Endurance© or polarized training in recreational runners.
METHODS
Twenty-one (N=21) participants completed 12 weeks of CrossFit Endurance (CFE), n=12, or polarized endurance training (PET), n=9. Both groups trained 5 d · wk⁻¹. PET ran 5 d · wk⁻¹ while CFE ran 3 d · wk⁻¹ and performed CrossFit 3 d · wk⁻¹ (run + CF 1 d · wk⁻¹). Duration, intensity, and distance were recorded via GPS and HR monitoring. Intensity was classified as low, moderate, or high (Zone 1, 2, or 3) according to ventilatory thresholds. PET was prescribed greater volume (295 ± 67 min · wk⁻¹), predominantly in Z1 ($86/14\%$ in $Z1/\geq Z2$). CFE emphasized lower volume (110 ± 18 min · wk⁻¹) Z3 running ($48/52\%$ Z1/$\geq$Z2). Performance (5-km TT) was assessed at baseline (BL) and at 6 (MID) and 12 weeks (POST). VO₂ max and body composition (BC) were assessed at BL and POST.
RESULTS
Two-way ANOVA showed a significant main effect of time on TT ($F = 40.1$, $p < .001$, $\eta_p^2 = 0.74$), VO₂ max ($F = 24.0$, $p < .001$, $\eta_p^2 = 0.56$), and BC ($F = 20.2$, $p < .001$, $\eta_p^2 = 0.51$), and a significant group*time interaction on VO₂ max ($F = 4.13$, $p = .05$, $\eta_p^2 = .18$). Both groups ($p \leq .001$) improved TT from BL–POST (-88 $\pm$ 55 s), BL-MID (-57 $\pm$ 40 s), and MID-POST (-31 $\pm$ 37 s). VO₂ max (46.2 ± 6.8 to 49.1 ± 7.4 ml·kg·min⁻¹) and BC (15.5 ± 6.7 to 13.0 ± 6.9 %BF) improved BL - POST ($p < .001$ for both). However, the VO₂ max increase was larger in PET (4.3 ± 3.6 vs. 1.78 ± 1.9 ml·kg·min⁻¹). No interaction occurred for TT ($F = 0.23$, $p = .79$) or BC ($F = 0.02$, $p = .88$).
CONCLUSION
Recreational runners achieved similar improvement in 5-km performance and body composition through polarized training or CFE, but PET yielded a greater increase in VO₂ max. Both programs appear efficacious for recreational athletes. Extrapolation to longer distances requires additional research.

Optimal Inspiratory Muscle Training Dose(s) to Enhance Respiratory Function Characteristics and Running Performance

Kyle R. Barnes, Sara M. Dansforth, Katie G. Smyth. *Grand Valley State University, Allendale, MI.* (Sponsor: Stephen Glass, FACSM)

(No relevant relationships reported)

PURPOSE Inspiratory muscle training (IMT) is a form of resistance training for the muscles primarily involved in the processes of breathing using a resisted breathing trainer. However, the optimal IMT loading parameters to elicit specific physiological adaptations are unknown. The authors adopted a dose-response design to determine the IMT load most effective for enhancing various inspiratory muscle function characteristics and performance. **METHODS:** 29 trained runners performed a 1-mile (1609-m) time trial and a series of breathing tests using an inspiratory breathing trainer and software. Runners were then randomly assigned to 1 of 5, six week IMT programs ranging in resistance from 30-70% of peak strength index (S_{IND}) in 10% increments. Maximal and submaximal inspiratory breathing tests were repeated each week and 1-mile performance was repeated after six weeks. To identify the optimal IMT group (resistance) for each measure, each runner's percentage change was modeled as a quadratic function of the rank order of the intensity of IMT. Uncertainty in the optimal IMT and in the corresponding effect on the given measure was estimated as 90% confidence limits (CL) using bootstrapping. **RESULTS:** There was a clear optimum for performance at Group 3.2 (52% of S_{IND}) with a possibly beneficial effect of 3.2% (CL = 2.8-3.5%). There was a strong trend toward Groups 2 to 3 (40-50% of S_{IND}) having the optimal IMT resistance to improve S_{IND} (mean improvement of 36.5%, CL = 29.2-45.7%), peak inspiratory flow (19.5%, 13.3-24.4%), training load (37.8%, 27.4-46.3%), flow (40.3%, 28.6-54.1%), power (52.3%, 43.5-65.1%), and energy (45.6%, 29.4-60.9%) with very-likely beneficial effects on all measures. Improvements in inspiratory volume (15.3%, 10.7-17.4%) were optimal at Group 4.0 (60% S_{IND}). Correlations between changes in performance and changes in inspiratory muscle function characteristics were trivial-small. IMT training at 2-wk was unlikely or possibly beneficial with the magnitude of effects trivial-small. At 4- and 6-wk, effects were greater and more beneficial than the previous 2-wk with no visual plateau in improvements. **CONCLUSION:** IMT between 40-50% of S_{IND} appears to be optimal for most inspiratory muscle characteristics, while IMT at slightly higher resistances (~52% S_{IND}) is optimal for 1-mile performance.

Feasibility of Predicting Bone Mineral Density in Distance Runners with an Artificial Neural Network

Alec C. Miller, Kevin S. Ryan, Toni D. Uhrich, Kristof Kipp. *Marquette University, Milwaukee, WI.* (Sponsor: Paula E. Papanek, FACSM)

(No relevant relationships reported)

Bone mineral density (BMD) is used to assess the risk of stress fractures in distance runners. Given that the standard assessment of BMD with Dual X-ray Absorptiometry (DXA) is very expensive, a possible solution would be to establish models that can predict BMD from data that is easier and cheaper to acquire. Artificial Neural Networks (ANN) are able to model non-linear and complex associations between biomechanical and physiological variables, and could pose a solution to the aforementioned problem. **PURPOSE**: Determine the feasibility of predicting BMD in distance runners with an ANN. **METHODS**: BMD of the femoral neck was assessed in twenty-three collegiate distance runners (16 male) using DXA. They also ran on an instrumented treadmill at their long-slow distance pace. Ground reaction forces (GRF) were collected and Rate of Loading (RoL) was derived. Average peak values were calculated for the right and left leg, and were pooled for all analyses. Simple and multiple linear regression models were used to assess associations between input (body mass, GRF, RoL) and output variables (BMD). In addition, a three-layer feedforward ANN with 20 hidden neurons was trained fifteen separate times to also model the same associations. The prediction ability of all models was compared based on their associated correlation coefficients. Further, the root mean squared error (RMSE) of the multilinear regression model and ANN were also compared. **RESULTS**: Significant simple linear correlations were found between BMD and body mass (r = 0.645, p = 0.008), BMD and GRF (r = 0.534, p = 0.038), and BMD and RoL (r = 0.567, p = 0.025). In addition, the multiple linear regression model (adjusted r = 0.630, p = 0.001, RMSE = 0.161) and ANN (training r = 0.865, p = 0.001; test r = 0.697, p = 0.003; RMSE = 0.161) were also able to fit predict the association between input and output variables. **CONCLUSIONS**: An ANN can feasibly predict BMD in distance runners, and is able to do so better than standard regression models. While the developed ANN performed well with the inputs of body mass, GRF, and RoL, there are other variables (e.g., stride parameters or caloric balance) that should be included in future studies, as they are easier to assess and would provide a more holistic model of known risk factors for stress fractures in distance runners.

3147 Board #16 June 2 8:00 AM - 9:30 AM

The Effect of Physiological Performance Variables on 3000m Times in Collegiate Mid-Distance and Distance Runners

Matthew Miltenberger, Alexander Zubko, Shala Davis, FACSM, Chad Witmer. *East Stroudsburg University, East Stroudsburg, PA.* (Sponsor: Dr. Shala Davis, FACSM)

(No relevant relationships reported)

Collegiate mid-distance (MD) runners and distance (D) runners compete in the 3000m. Previous research has identified VO_2max, velocity at lactate threshold (vLT), %VO_2max at lactate threshold, and running economy (RE) to correlate with 3000m performance. Research is lacking on if differences in these variables, and pacing strategy, affects 3000m performance between groups. **PURPOSE:** To identify how physiological performance variables relate to 3000m time, and if differences in these variables, and pacing strategies, occurs between groups. **METHODS:** 11 male NCAA Division II runners (5 MD, 6 D) were used. Subjects completed a 3000m time trial on a synthetic 200m indoor track, where 3000m time and split times were recorded using a single-beam timing gate. A discontinuous 3-minute stage lactate threshold protocol was used to measure vLT, lactate threshold (LT), and running economy at 14.5km/h, 16km/h, and 17.5 km/h ($RE_{14.5}$, RE_{16}, $RE_{17.5}$). A modified Astrand VO_2max test was used to assess VO_2max, with the speed set at 16.1km/h and grade increasing 2% every two minutes. **RESULTS:** VO_2max (r=-.629), $RE_{14.5}$ (r=.632), RE_{16} (r=.756), %VO_2max at LT (r=0.675), 600-1200m time (r=.784), 1200-1800m time (r=.962), and 1800-2400m time (r=.719) significantly correlated to 3000m time (p<0.05), when merging subjects. In the D group, %VO_2max at LT (r=.875), RE_{16} (r=.853), 600-1200m time (r=.882), and 1200-1800m time (r=.965) significantly correlated to 3000m time (p<0.05). In the MD group, 1200-1800m time (r=.932) significantly correlated to 3000m time (p<0.05), and VO_2max had a trend towards significance with 3000m time (r=-.829, p=.083). Statistically different mean differences in VO_2max (D=67.00±2.64 vs MD=63.56±1.52ml/kg/min), and vLT (D=15.10±0.19 vs MD=14.33±0.35km/h) was observed between groups (p<0.05). A graphical difference in pacing strategy was observed between groups. **CONCLUSION:** 1200-1800m time is the most important split time for 3000m performance. VO_2max was the best physiological performance indicator in MD runners, and RE_{16} was the best physiological performance indicator in D runners. Runners should be trained differently according to their training status, to improve 3000m performance.

Long Ground Contact Time Enhances Running Economy at High-Intensity Running

Fumiya TANJI, Hayato OHNUMA, Ryosuke ANDO, Tatsuaki IKEDA, Yasuhiro SUZUKI. *Japan Institute of Sport Sciences, Tokyo, Japan.*

(No relevant relationships reported)

Running economy (RE) determines the difference in distance running performance in highly-trained runners. Studies have highlighted RE importance during high-intensity running. Although RE is related to ground contact time (Tc), the relationship between RE at high-intensity running and Tc is not elucidated. It is also unclear whether the hamstrings muscle, which contribute to high-intensity running, affect RE and Tc. **PURPOSE:** We aimed to clarify the relationships among RE, Tc at intensity below and above the lactate threshold (LT) run, and hamstring muscle's cross-sectional area in highly-trained long-distance runners. **METHODS:** We enrolled 11 highly trained male distance runners (IAAF score: 1038 ± 48). They underwent treadmill running test to assess the LT, and RE. RE was evaluated at 270 (RE270) and 360 m/min (RE360) as the intensity below and above the LT, respectively. Tc was also valuated at the same velocity (Tc270; Tc360). Both medial and lateral hamstring muscles' cross-sectional areas (MHA and LHA, respectively) were calculated using MRI at 50% position of the right thigh. **RESULTS:** The subjects' LT, RE270 and RE360 were 337 ± 17 m/min, 0.90 ± 0.08 kcal/kg/km, and 1.00 ± 0.07 kcal/kg/km, respectively. The Tc270, Tc360, MHA and LHA values were 195 ± 17 ms, 164 ± 9 ms, 1.24 ± 0.18 cm^2/kg$^{0.67}$, and 0.99 ± 0.11 cm^2/kg$^{0.67}$, respectively. RE270 showed a significant relationship with Tc270, MHA, and LHA (r = -0.81, 0.75, and 0.60, respectively; $P < 0.05$), but no relationship was noted with IAAF score (r = -0.55; $P = 0.08$). Tc270 was related to MHA and LHA (r = -0.63 and -0.67; $P < 0.05$). Although RE360 showed a significant relationship with IAAF score, Tc360, and MHA (r = -0.73, -0.65, and 0.69, respectively; $P < 0.05$), no relationship was noted with LHA (r = 0.35; $P = 0.30$). Tc360 did not exhibit any significant relationship with MHA (r = -0.55; $P = 0.08$) and LHA (r = -0.52; $P = 0.10$). **CONCLUSION:** The findings of this study are as follows: (a) RE at high rather than low intensity is related to running performance; (b) longer Tc enhances RE; (c) superior RE and long Tc at low intensity are related to small hamstring muscles, but these associations disappear, except between RE and MHA, at high intensity. These results suggest that long Tc at high-intensity contributes to superior RE, but not to hamstring muscles, and leads to higher running performance.

3149 Board #18 June 2 8:00 AM - 9:30 AM

Relationship Between Running Economy and Achilles Tendon Length.

Jacquelyn Crow, Eric Sobolewski, Randolph Hutchison, Scott Murr. *Furman University, Greenville, SC.* (Sponsor: Tony Caterisano, FACSM)

(No relevant relationships reported)

Longer tendon length has been shown to be related to better running economy because longer tendons can store more energy to produce more force during concentric contraction. Running economy is traditionally defined as having a lower VO_2 at the same submaximal speed. However, studies have not tested if this relationship also occurs in male and female elite distance runners at faster speeds. **PURPOSE:** To determine if Achilles tendon length influences running economy. **METHODS:** The researchers used ultra sound technology to measure the right Achilles Tendon length of twenty-two varsity collegiate runners (20.09 ± 1.63 yrs), 12 males (178.44 ± 6.74 cm, 65.21 ± 6.62 kg) and 10 females (167.22 ± 7.73 cm, 54.45 ± 4.80 kg). After the researchers measured Achilles Tendon length, participant completed a VO_2 max test and running economy was determined by assessing VO_2 at submaximal speeds. The men ran at speeds of 10.0, 10.4 and 10.8 mph, and the females ran at speeds of 8.4, 8.8, and 9.2 mph. The relationship between tendon length and running economy was assessed using Pearson correlation coefficients. **RESULTS:** For collegiate male runners, there was a significant negative relationship between Achilles Tendon length and running economy (r = -0.76 — -0.71, $p \leq .01$). When tendon length was normalized to height (tendon length/height) the relationship between tendon length and running economy was no longer significant (r = -0.32— -0.24, p = 0.32-0.45). For collegiate female runners, there was no significant relationship between Achilles Tendon length and running economy alone (r = 0.24-0.39, p = 0.06-0.51) or when normalizing to height (r =0.35—0.44, p =0.23-0.40). **CONCLUSION:** These findings indicate that longer Achilles Tendons in collegiate male runners are related to improved running economy. In collegiate female runners, tendon length is not significantly associated with running economy. However, there was a negative correlation between Achilles Tendon length and running economy for the males and a positive correlation for the females indicating that longer tendon length might be more beneficial for male runners and shorter tendon might be slightly more economical for females. Other factors besides tendon length attribute to running economy, but this study indicates that for male's tendon length plays a role in running economy.

3150   Board #19   June 2 8:00 AM - 9:30 AM

Impact of Wearing Compression Pants on HR, RPE, Lactic Acid During a Submaximal Run

Jacob Whitmore, Mike Ryan, Shinichi Asano, Paul Reneau. *Fairmont State University, Fairmont, WV.*
(No relevant relationships reported)

Compression pants, waist to ankle, have grown in popularity among recreational and athletic populations for improving performance, however, minimal is known about the effects of compression pants on submaximal exercise. **PURPOSE:** The purpose of this study was to investigate the impact of wearing compression pants on physiological responses to a 12 min run. **METHODS:** College aged males (n=8) participated in three separate running sessions. Subjects initially performed a graded exercise test to anchor the RPE scale. Thereafter subjects were assigned to run on a treadmill at a set speed of 8 mph for 12 minutes either while wearing or not wearing compression pants, order of tests was randomized. Lactic acid, HR, and RPE were recorded every 3 minutes during the test, and every 3 minutes after the test for 6 minutes. Subjects were instructed to wear the pants for no longer than 30 minutes prior to the running tests. Dependent T-tests were performed on LA, HR, and RPE at each 3 min measurement of the test and recovery, with an alpha set at p<.05. **RESULTS:** Lactic acid levels were significantly lower (p<.05) with compression pants on at the 12 and 18 minute marks. RPE was significantly higher (p<.05) with the compression pants on at the 3 and 6 minute marks. No other significant differences (p>.05) were found in RPE and no significant differences (p>.05) were found in HR.

Test	With/Without Compression	3 min	6 min	9 min	12 min	15 min	18 min
LA (mmol/l)	With Compression	9.78 (5.95)	8.04 (2.10)	9.15 (4.55)	8.85* (4.24)	9.28 (5.85)	5.3* (2.05)
	Without Compression	11.18 (6.56)	9.45 (4.94)	10.65 (6.0)	12.25* (4.12)	11.74 (6.25)	9.25* (3.06)
HR (bpm)	With Compression	135 (18.85)	150 (22.93)	160 (19.83)	162.5 (21.37)	112 (9.8)	106 (15.3)
	Without Compression	138.5 (17.1)	146 (21.17)	162 (16.42)	168 (18.27)	121.6 (20.65)	110.5 (11.7)
RPE	With Compression	10.63* (1.4)	11.88* (1.73)	12.5 (2.14)	13.88 (1.73)	9.38 (1.69)	8.25 (0.89)
	Without Compression	9.5* (1.93)	10.88* (1.96)	12.25 (1.83)	13.38 (2.26)	9.86 (1.64)	8.75 (1.16)

(*p<.05)

CONCLUSION: Wearing compression pants was shown to lower your lactic acid levels at the 12 min point and 6 min after completion of submaximal exercise. RPE was shown to be higher initially but then the differences became non-significant. Compression pants were shown to not make any significant changes in HR.

3151   Board #20   June 2 8:00 AM - 9:30 AM

Modeling Critical Speed and D′ in Elite Track & Field Athletes

Timothy J. Fulton, Robert F. Chapman, FACSM. *Indiana University, Bloomington, IN.*
(No relevant relationships reported)

PURPOSE: 1) To determine if there are sex differences in critical speed (CS) and $D′$, 2) to develop a model to predict CS, and 3) to determine the percent of CS various races are run at in elite track and field athletes.
METHODS: Inclusion criteria were athletes with personal best times in each of the 1500m, 3000m, and 5000m events faster than 4:10, 8:55, and 15:20 (women) or 3:38, 7:45, and 13:30 (men) since January 1, 1997. CS and for each athlete were calculated using the linear method [D = CS * t + $D′$, where D is the distance ran and t is the time it took (in seconds) to cover that distance]. A second data set was compiled which included all those who met the above criteria *and* had a 10,000m time faster than 32:15 (women) or 28:00 (men).
RESULTS: 115 women and 127 men met the initial inclusion criteria. A subset of athletes, 51 women and 48 men, also met the 10000m inclusion criteria. The average Pearson correlation coefficient for the regression line used to calculate CS and $D′$ was > 0.9999. As expected, men had a significantly faster CS (m/s) than women (6.10 ± 0.13 vs. 5.39 ± 0.13; $p < 0.001$), however $D′$ (m) was not significantly different (204.0 ± 35.8 vs. 197.5 ± 39.6; $p = 0.18$). For both men and women, 5000m time was the best predictor of CS. The men's prediction model was CS = -0.0105 * 5000m time (s) + 14.347 ($R2 = 0.9522$; $p < 0.001$) and the women's was CS = -0.00761 * 5000m time (s) + 142.180 ($R2 = 0.9313$; $p < 0.001$). 1500m race pace was 112.8 ± 2.8% (women) and 113.2 ± 2.8% (men) of CS. 3000m race pace was 106.7 ± 1.5% (women) and 107.1 ± 1.7% (men) of CS. 5000m race pace was 103.6 ± 0.7% (women) and 103.7 ± 0.7% (men) of CS. 10000m race pace was 98.7 ± 1.5% (women) and 98.6 ± 1.5% (men) of CS. There were no significant differences between men's and women's race pace as a percent of CS for any race distance ($p = 0.24 - 0.55$).

CONCLUSIONS: As CS represents the greatest wholly oxidative metabolic rate, men's faster CS is likely due to their known ability for greater oxygen delivery and consumption compared to women. The lack of difference in $D′$ may be due to similar phosphocreatine stores (per kg dry muscle mass) between sexes. Additionally, coaches and athletes that want to know CS for training design or race pacing applications may be able to utilize the prediction equations if data on a full range of performances is not available.

3152   Board #21   June 2 8:00 AM - 9:30 AM

Heart Rate Variability in middle-aged Sprinters and Endurance Runners

Lysleine Alves de Deus, Thiago dos Santos Rosa, Caio Victor de Sousa, Samuel da Silva Aguiar, José Morais Souto Filho, Patrick Anderson dos Santos, Lucas Duarte Barbosa, Herbert Gustavo Simões. *Universidade Católica de Brasília, Brasília, Brazil.*
(No relevant relationships reported)

Aging is associated with decreased autonomic balance which could be assessed by Heart Rate Variability (HRV). Exercise training improves autonomic balance, but there is a lack in the literature regarding the HRV profile of middle-aged sprinters and endurance runners. **PURPOSE:** The effects of lifelong endurance and sprint training on cardiac autonomic balance were assessed in middle-aged master athletes, and compared with age-matched controls and young untrained individuals. **METHODS:** Participants (n=81) were 8 master sprinters (MS; 51.75±11.08yrs), 8 endurance runners (EN, n=8, 51.14±5.36yrs), 17 age-matched untrained (CON, 47.47±6.00yrs) and 48 young controls (YC, 25.40±3.87 yrs). For the acquisition of RR intervals (iRR) (Polar RS800X Heart Rate Monitor®) the participants remained seated for 15-min, with the final 10-min being considered for analysis. HRV was measured using Kubios software. A two-way ANOVA with repeated measures was applied. **RESULTS:** All studied parameters did not differ between MS and EN {Time Domain [HR (bpm) 59.00±6.13 vs. 58.94±12.75], [R-R (ms) 1030.45±107.45 vs. 1068.77±206.17], [SDNN (ms) 57.35±20.07 vs. 80.66±71.07], [RMSSD (ms) 40.88±20.07 vs. 38.93±20.44]; Non-linear domain [SD1 (ms) 28.93±14.20 vs. 27.56±14.46]}, whose demonstrated a reduced HR and elevated mean R-R intervals in comparison to both YC [(HR (bpm) 69.64±9.81) and (R-R 883.93±124.11)] and age-matched individuals [(HR (bpm) 70.06±6.63) and (R-R (ms) 865.11±78.39)]. It was observed a lower HRV for middle-aged CON {[RMSSD (ms) 20.23±5.87], [SDNN (ms) 37.79±10.15] and [SD1 (ms) 14.31±4.15]} compared to YC {[RMSSD (ms) 43.33±26.41], [SDNN (ms) 67.07±28.77] and [SD1 (ms) 30.66±18.69; p<0.05]}. These last age-related changes were not observed for MS and EN. **CONCLUSION:** For the master athlete, regardless of being endurance runner or a sprinter, both training modes are similarly beneficial, attenuating the effects of aging on the autonomic balance.

3153   Board #22   June 2 8:00 AM - 9:30 AM

A Comparison of Two VO$_{2max}$ Treadmill CPETs in Highly Trained Distance Runners

Ryan A. Vanhoy[1], Stephanie A. Sullivan[2], Claudio L. Battaglini, FACSM[2]. *[1]University of Mississippi, University, MS. [2]University of North Carolina at Chapel Hill, Chapel Hill, NC.* (Sponsor: Claudio Battaglini, FACSM)
(No relevant relationships reported)

Measuring maximal oxygen consumption (VO$_{2max}$) via treadmill testing is a popular procedure for testing aerobic power and subsequently developing exercise prescriptions. Previous studies have produced conflicting results when comparing horizontal and incline graded treadmill protocols designed to assess VO$_{2max}$, and the variability may be due to the heterogeneity of subjects, having different fitness levels and backgrounds. **PURPOSE:** To prospectively compare the VO$_{2max}$ value attained during a horizontal (increment in speed only) (SOVO$_{2max}$) and an inclined (constant speed with increment in grade only) (GOVO$_{2max}$) cardiorespiratory exercise tests (CPETs) in highly trained distance runners. A secondary purpose examined if the ventilatory threshold (VT) determined from the SOVO$_{2max}$ and GOVO$_{2max}$ CPETs occurred at the same percent of VO$_{2max}$ (% VO$_{2max}$ @ VT). **METHODS:** After a familiarization session performing the Bruce Protocol, VO$_{2max}$ and % VO$_{2max}$ @ VT were evaluated in 16 male distance runners, some who preferred hilly terrain and some who preferred flat or track running, using the SOVO$_{max}$ and GOVO$_{max}$ CPETs. Dependent samples t-tests were used to compare the VO$_{2max}$ and % VO$_{2max}$ @ VT results between the SOVO$_{2max}$ and GOVO$_{2max}$ CPETs. **RESULTS:** VO$_{2max}$ values were significantly higher from the GOVO$_{2max}$ in comparison to the SOVO$_{2max}$ protocol (76.1 and 71.2 mLO$_2$/kg/min, p=. 005); however, the % VO$_{2max}$ @ VT was not significantly different between the GOVO$_{2max}$ and SOVO$_{2max}$ protocols (77.5% and 77.2%, p=.825). **CONCLUSION:** Higher VO$_{2max}$ values were attained on the GOVO$_{2max}$ CPET, even on those who reported they were track athletes and favored running on the flat surfaces. These results agree with previous research that found athletes who train and compete on an exclusively flat surface or hilly terrain both tend to produce higher VO$_{2max}$ values on CPETs that include changes in treadmill grade. However, due to the non-significant difference in % VO$_{2max}$ @ VT observed between the SOVO$_{2max}$ or GOVO$_{2max}$ CPETs,

for the determination of training thresholds, runner specialty (flat versus hill runners) should therefore be considered when selecting the most appropriate CPET in this athletic population.

Effects of Hip Strengthening on Running Mechanics and Chronic Leg Pain in Recreational Athletes

Jennifer Bossi[1], Samantha Everett[2], Vanessa Rettinger[1], Adam Keath[1]. *[1]Anderson University, Anderson, SC. [2]Elon University, Elon, NC.*

(No relevant relationships reported)

PURPOSE: The effects of a hip strengthening protocol on posterior hip running mechanics and Functional Movement Screen scores were examined in recreational athletes with chronic leg pain.
METHODS: Subjects ($n = 12$) were instructed to run at a self-selected pace on a treadmill, while a two-dimensional video was recorded to assess posterior hip drop. Posterior hip drop angle was defined as the alignment of the PSIS during the stance phase as indicated by reflective markers. Subjects were also assessed using the Functional Movement Screen. A treatment group ($n = 7$) was then instructed to complete an 8 week hip abductor strengthening protocol in addition to their normal training routine, while a control group ($n = 5$) resumed normal training without a hip abductor strengthening protocol. Both groups were reassessed after 8 weeks to determine changes in posterior hip drop angles and FMS scores. Chronic leg pain was assessed using a 10 point visual analogue scale pre and post treatment.
RESULTS: A two-way mixed ANOVA revealed a significant interaction between the treatment group and time on hip drop measurement, $F(1, 10) = 6.383$, $p = .03$, partial η2 = .390. Hip drop showed a statistically significantly improvement in the treatment group (M = 0.43, SE = 0.17, $p = .03$) compared to the control group. No statistically significant interaction effects were observed for pain (F(1, 10) = .278, $p = .60$, partial η2 = .027) or FMS (F(1, 10) = .310, $p = .59$, partial η2 = .03). Follow-up within subjects univariate analysis showed significant mean improvements for the treatment group in pre and post ratings for hip drop (m= -.89, $p = .04$) and FMS (m = -1.28, $p = .03$) and no significant differences in pain.
CONCLUSIONS: Hip abductor strength training was observed to reduce hip drop angles and increase FMS scores which may lead to better posterior hip mechanics. These improvements alone however, will not reduce pain in recreational runners with chronic leg pain. Given the limited sample size, further research is warranted to identify what factors contribute to chronic pain reduction in recreational runners.

Relationship between Daily Mileage and Upper Respiratory Illnesses in Collegiate Cross Country Runners

Joshua S. Hogg, Keith D. Randazzo, Suzanne L. McDonough, Michael C. Washam. *Mississippi College, Clinton, MS.*

(No relevant relationships reported)

The incidence of upper respiratory illnesses (URI) within endurance sports is commonplace and often results in decreased athletic performance. For this reason, avoidance of these illnesses is of utmost importance to the athlete. Previous research has identified a positive relationship between running mileage and frequency of URI; however, defining this threshold in terms of intensity and duration of exercise has not been well established. Little is known about underlying factors influencing this relationship. Greater insight into the relationship between mileage and URI will allow for better training and can help establish best practices for creating programs that can reduce the occurrence of URIs. **PURPOSE:** The purpose of this study was to investigate the relationship between endurance training and immune function. **METHODS:** Participants (N = 25, 13 females, 12 males; mean age 19 ± 3 years) were college undergraduate students. A survey consisting of the Wisconsin upper respiratory system measure (WURSS-21), Daily mileage, sleep, and diet logs were kept by each of the cross country athletes throughout the duration of this study. **RESULTS:** Correlations revealed a significant relationship between daily mileage and frequency of URI ($r = .10$, $p = .05$). Additionally, sleep and diet were significantly correlated with both mileage and URI frequency, which fulfilled prerequisites to test for moderation (Aiken & West, 1991). However, when sleep and diet were added to the model, neither was found to moderate the relationship between mileage and URI. **CONCLUSION:** Results suggest that as daily mileage increases there is a greater likelihood of URI. It was also revealed that vitamin C intake and hours of sleep did not affect this relationship. Future research on this should explore other factors that could potentially influence the relationship between miles run per day and URI.

The Effect of Workload on Exercise Volume during Exhaustive Anaerobic Treadmill Running

Taylor Kennon, Taylor Bloedon, Boe Burrus, Young Sub Kwon. *Humboldt State University, Arcata, CA.*

(No relevant relationships reported)

Anaerobic capacity has implications in health and sport performance. Sprint interval training improves anaerobic capacity, aerobic factors as well as performance. Optimal durations for taxing anaerobic capacity have been shown to be 60 seconds, and have been elicited using Anaerobic Speed Test (AST). In order to maintain this optimal duration for multiple sets, a decreasing workloads method must be used as fatigue increases following each set. These workloading methods must be compared to determine which protocol allows for the maximum exercise volume to be achieved. **PURPOSE**: The purpose of this study was to compare the effects of three different workload protocols on exercise volume completed during multiple sets of exhaustive anaerobic running on a treadmill. **METHODS**: Twelve male subjects (mean ± SD; age = 22.7 ± 4 yr, height:172.9 ± 6.9 cm, weight:75.9 ± 10.3 kg, VO$_2$ max: 57.3 ± 6 ml/kg/min) completed three sessions of high intensity running on a graded treadmill with three different protocols using parameters adopted from the AST (20% grade, 8 mph to exhaustion). Four sets were completed during each protocol. Protocols included: 1) constant sets (CS): no descending workload in all four sets, 2) descending speed (DS): the speed is decreased by 10% for each subsequent set, 3) descending grade (DG): the grade is decreased by 10% for each subsequent set. **RESULTS**: Total exercise volume achieved during the four sets of the DS protocol was significantly higher than both the CS (p<0.01) and DG (p<0.01) protocols. Time to exhaustion achieved during the 2nd, 3rd and 4th sets of the DS protocol were significantly higher than the 2nd, 3rd and 4th sets of the CS protocol, all under p<0.01. Cadence during the 3rd set of the DS protocol was significantly lower than the 3rd set of the CS protocol (p<0.01). Additionally, cadence during the 4th set of the DS protocol was significantly higher than the 4th sets of the CS and DG protocols (p<0.01). **CONCLUSIONS**: The longer times per set and greater volume achieved during the DS protocol, in comparison to the DG and CS protocols, suggests the potential for a greater training effect. Differences in cadence values among the protocols could help explain differences in performance implicating muscle fiber type recruitment and fatigue.

The Acute and Chronic Effects of Highly Cushioned Shoes on Loading Characteristics in Recreational Runners

Jessica L. Corkin[1], Sarah Clarke[1], Michael J. Bohne[2], Michael Stoolmiller[3], Scott N. Drum, FACSM[1]. *[1]Northern Michigan University, Marquette, MI. [2]Utah Valley University, Orem, UT. [3]Michigan State University, East Lansing, MI.* (Sponsor: Scott Drum, FACSM)

(No relevant relationships reported)

Highly cushioned shoes (HCS) are a popular choice for road and trail runners. Manufacturers suggested extra cushioning potentially reduces injury rates through superior shock absorption, implying less impact upon foot strike versus standard cushioned shoes (SCS). **PURPOSE:** To examine the effects of a 4-week HCS intervention on running-related impact forces in adult recreational runners. **METHODS:** Twenty-nine healthy runners (18-60 yrs of age) who had never worn HCS were randomized to either HCS intervention (INV) or SCS control (CON) groups, and wore HCS or SCS a majority of each training week. During pre and post-tests in a lab, all participants wore SCS first, followed by HCS, while running overground at a self-selected, monitored pace and striking embedded force plates in up to 30 total trials/session, at least 10 trials/shoe, to obtain impact peak (PK1) and active peak (PK2) forces, instantaneous loading rate (ILR), average loading rate (ALR), and contact time (CT). Runners recorded daily training data for 4-weeks. A repeated measures, mixed ANOVA was utilized to detect differences between shoes and groups. **RESULTS:** At pretesting, when comparing pooled data in SCS to HCS, no significant differences were found and all effect sizes were small. The acute (i.e., at baseline testing) response to the shoes yielded no statistically significant difference between shoe types. Additionally, there was no statistically significant difference between shoes over time (p >0.05) or between the groups over time (p>0.05). ILR was the variable closest to significance (p=0.066) with a small effect size (0.120). **CONCLUSION:** HCS do not cause alterations in ground reaction forces over a short-term (4-week) habituation period in recreational runners. Interestingly, there was a high drop-out rate in the HCS group of 18% due to self-reported adverse reactions (e.g., numbness, bruising, pain), but results indicated no differences in loading characteristics between shoe types. Still, transitioning to HCS should be a gradual process; however, more research is warranted in long-term HCS usage.

Association Between Race Time, Body Mass, and Total Body Water in Ultramarathon Runners

Julie M. Cousins, Heather H. Betz. *Albion College, Albion, MI.* (Sponsor: Helaine Alessio, FACSM)

(No relevant relationships reported)

Acute bouts of prolonged endurance exercise have been found to significantly decrease body mass. Some researchers suggest that a decrease in body mass may improve performance in weight-bearing exercise. Yet, other researchers suggest the decrease in body mass may impair exercise performance. **PURPOSE:** The purpose of this study was to investigate the association between race time with changes in body mass (BM) and total body water (TBW) in ultramarathon runners. **METHOD:** 10 ultramarathon runners (age = 36.4 (10.0) years, race time = 5.7 (1.5) hours) were assessed with the InBody 270 bioelectrical impedance analysis (BIA) before and after a 50k race. The InBody 270 BIA measured BM, skeletal muscle mass (SMM), fat mass (FM), and total body water (TBW). Race time was recorded as the runners crossed the finish line. Statistical analysis was performed using paired t-test, multiple linear regression, and Pearson product-moment correlations. Significance was set to $p < 0.05$. **RESULTS:** BM significantly decreased by 2.15 (1.44) kg (p=0.001) while TBW showed a nonsignificant increase of 0.93 (1.79) kg (p=0.134). SMM decreased by 1.1 (1.24) kg (p=0.023) and FM decreased by 3.67 (1.83) kg (p<0.001). There was a positive correlation between race time and age (r =0.676, p=0.032). Multiple linear regression suggested that change in BM and TBW predicted 10% of the variance in race time. **CONCLUSIONS:** Change in BM and TBW were not significantly associated with race time. BM was significantly decreased following the ultramarathon race. A limitation of the study is the small sample size. Therefore, additional research is needed to examine the relationship between performance and changes in BM in a larger sample size of ultramarathon runners.

3159   Board #28   June 2 8:00 AM - 9:30 AM

Does Stance Time Predict Running Economy at Relative Speeds in Highly Trained Distance Runners?

Stephen T. Hammond, Timothy R. Lindsay, Stephen J. McGregor. *Eastern Michigan University, Ypsilanti, MI.* (Sponsor: Andrew Coggan, FACSM)

(No relevant relationships reported)

Running economy (RE) is an important component of distance running performance. Recent evidence suggests shorter stance times (ST) are related to superior RE and practitioners often recommend shorter ST for this benefit. However, overall, reports are equivocal, perhaps because comparisons are usually made at absolute running speeds, which fails to account for differences in relative fitness. To date, this relationship has not been explored at relative intensities. **PURPOSE:** To determine the relationship of ST and RE at absolute and relative running speeds. **METHODS:** 20 highly trained distance runners (13 M, 7 F; VO_{2max} = 67.6 vs 53.5 ml/kg/min) consented to procedures approved by EMU-HSRC. Session 1 included a critical speed (CS) field test to determine relative fitness and establish relative testing speeds. Session 2 included two treadmill tests for kinematic and metabolic measurements. For both tests, subjects ran at 10, 12, 14, and 16 km/h (absolute speeds) and at 75, 85, and 95% CS (relative speeds). Kinematic data were collected for 60 sec using lower-body optical motion capture (Plug-In-Gait; Vicon, Centennial, CO). Metabolic data were collected using open circuit spirometry (TrueOne 2400, ParvoMedics, Sandy, UT) during three-minute trials, where the last 60 sec of each stage was used to calculate RE. Linear regressions were used to determine the relationship between ST and RE expressed as mL/kg/km, $\%VO_{2max}$, and kcal/kg/km, done separately for absolute and relative speeds. α was set at .05. **RESULTS:** For absolute speeds, significant negative relationships were found between ST and RE expressed as mL/kg/km (β = -.374), $\%VO_{2max}$ (β = -.461), and kcal/kg/km (β = -.459) (all p < .01). For relative speeds, a significant negative relationship was found for RE expressed as $\%VO_{2max}$ (β = -.318) (p < .05) but not mL/kg/km or kcal/kg/km (p > .05). **CONCLUSION:** Contrary to some reports and recommendations, for comparisons using absolute speeds, shorter ST was related to inferior RE. Comparisons using relative speeds showed weaker or non-significant relationships. Therefore, changes in RE mediated by ST may depend more on individual exercise strain than absolute speed. Future investigations should consider using relative intensities for a more appropriate comparison between individuals.

Run Performance is the Primary Factor in Determining Olympic Distance Triathlon Performance

Tyler J. Noble, Robert F. Chapman, FACSM. *Indiana University-Bloomington, Bloomington, IN.*

(No relevant relationships reported)

Introduction: Triathlon is a unique athletic event, given that it requires athletes to be proficient in three distinct disciplines: swimming, cycling, and running. Often, high achieving athletes in one of these disciplines are recruited to the triathlon event, but it is unknown as to which event proficiency is most important to triathlon performance. As a result, National Governing Bodies (NGBs) tasked with maximizing performance on the international stage may stand to benefit from the optimization of talent identification procedures. **Purpose:** To assess the relationship between discipline specific performance and overall triathlon performance. **Methods:** Performance data from all three disciplines (swim, cycle, run) were collected on each athlete (n = 430) for Olympic distance races (1.5k swim, 40k cycle, 10k run) contested during both the 2016 and 2017 World Triathlon Series (WTS, n=12). Performance in each discipline was ranked versus other competitors in the same race, based on time. Spearman rank-order correlations were then used to explore the relationship between discipline performance rank and overall performance rank. **Results:** Run rank was shown to have a strong, linear correlation with overall rank (r_s = 0.90, p < 0.01) while both swim (r_s = 0.37, p < 0.01) and cycle (r_s = 0.43, p < 0.01) ranks were shown to have mild linear relationships with overall rank. **Conclusion:** The strong linear relationship experienced between run rank and overall rank suggests that NGBs interested in maximizing triathlon performance at the Olympic distance may be best suited to engage in talent identification processes that place an emphasis on running ability.

3161   Board #30   June 2 8:00 AM - 9:30 AM

Acute:Chronic Workload Ratio is a Better Predictor of Running Injury than Average Weekly Running Volume

Allison H. Gruber, Emily G. Wagoner, Jacob E. Vollmar, Ashley B. Nguyen, Andrea K. Chomistek. *Indiana University, Bloomington, IN.* (Sponsor: Joseph Hamill, FACSM)

(No relevant relationships reported)

An acute:chronic workload (AC) ratio between 0.8-1.3 was shown to be protective against injury among athletes in rugby, cricket, and other sports but has yet to be applied to runners. **PURPOSE**: To assess AC ratio as a predictor of running-related overuse injury (RROI). **METHODS**: To date, 36 runners have been enrolled in a prospective injury for a minimum of 6 months. An average of 1.2 ± 0.8 injuries have been sustained by 19 runners. Weekly running volume (Rvol), running time, non-running exercise time, and RROI were recorded in a weekly online survey. RROI was defined as pain resulting in any reduction or stoppage of planned running. For each week of enrollment, AC ratio was calculated for running mileage (AC-vol), running time (AC-RT), and all-type exercise time (AC-ET) as the current week value divided by the mean of the previous four weeks. The average AC ratio was calculated across weeks from enrollment to date of injury for members of the injured group. AC ratio was calculated for all weeks of enrollment for members of the uninjured group. Univariate tests were used to assess the differences between injured and uninjured groups (α = 0.05). All variables were entered into a stepwise logistic regression model to determine the explanatory variables related to RROI incidence (α = 0.15). **RESULTS**: Significant differences between injured (I) and uninjured (U) groups were found for Rvol (I = 12.9 ± 8.9; uninjured 19.7 ± 14.4, P=0.011), AC-vol (I = 0.86 ± 0.26; U = 1.01 ± 0.09, P<0.001) and AC-RT (I = 0.94 ± 0.46; U = 1.06 ± 0.13, P=0.036). No other variables were significant between groups (P>0.05). Stepwise logistic regression identified that number of RROI, age, and mass were significant predictors of AC-vol (P<0.131) and that years running, height, and BMI were significant predictors of AC-RT (P<0.030). No significant predictors were identified for AC-ET (P>0.15). **CONCLUSIONS**: AC ratio using running time was a better predictor of RROI incidence than average miles/week, years running, and other common training variables. Reducing mileage or infrequent running training may increase the risk of RROI. AC ratio should be above 0.86 to prevent RROI, which is similar to the minimum threshold value for other sports reported in previous studies. Further study is needed to assess a maximum and minimum AC ratio that is considered 'safe' to prevent RROI.

Generalized Assessments of Mobility in Professional Soccer Athletes: Should Other Physiologic Characteristics Be Considered?

Bradley Lambert[1], Tyler Heimdal[1], Justin Vickery[1], Corbin Hedt[1], Joshua Harris[1], Michael Moreno[2], Stephen Crouse, FACSM[2], Patrick McCulloch[1]. [1]Houston Methodist Hospital, Houston, TX. [2]Texas A&M University, College Station, TX. (Sponsor: Stephen Crouse, FACSM)
(No relevant relationships reported)

The influence of body composition (Bcomp), and skeletal dimensions (SkD) on mobility screening conclusions is unknown. **PURPOSE:** Determine if each are correlated with balance, range of motion (ROM), and Functional Movement Screen (FMS) scores in professional soccer athletes (M&F). **METHODS:** Athletes provided informed consent to participate (♂18, 27±5 y, 79±9 kg | ♀16, 25±3 y, 63±4 kg). Bcomp and SkD were assessed using DXA. Balance and ROM were assessed via Y-balance (Y-bal) testing. FMS was used for movements listed in table. A two-tailed t-test and Chi-square were used for gender comparison of Y-bal and FMS respectively. Correlational analysis and Spearman's Rank Order were used to determine if Bcomp and/or SkD correlated with Y-bal or FMS measures. Correlations were defined as weak (r>0.4), moderate (r = 0.4-0.7), and strong (r>0.7). Type I error; α=0.05. **RESULTS:**

MEAN Y-BALANCE SCORE (reach / limb length)			
	Anterior	**Posteromedial**	**Posterolateral**	-
Men	0.65 ± 0.05	1.13 ± 0.08	1.06 ± 0.09	
Women	0.69 ± 0.07	1.20 ± 0.19	1.10 ± 0.08	
Sig.	NS	NS	NS	

FUNCTIONAL MOVEMENT SCREEN (1-3 Scale, % of Athletes Scored In Each Category)				
FMS SCORE	**Deep Squat**	**Hurdle Step**	**Inline Lunge**	**Shoulder Mobility**
Men 1	33%	8%	0%	14%
2	67%	75%	100%	50%
3	0%	17%	0%	36%
Women 1	0%	0%	0%	0%
2	94%	63%	28%	44%
3	6%	38%	72%	56%
Sig. Gender Diff.	p<0.05	NS	p<0.05	NS
FMS SCORE	**Straight Leg Raise**	**Trunk Stability Pushup**	**Rotary Stability**	
Men 1	6%	6%	6%	
2	47%	56%	94%	
3	47%	39%	0%	
Women 1	0%	22%	11%	
2	16%	44%	79%	
3	84%	22%	0%	
Sig. Gender Diff.	p<0.05	NS	NS	

Table 1. Values are presented as means ± SD for Y-balance scores. Y-balance scores represent averaged means of left and right limbs. For FMS scores, the proportion of each gender that scored 1 (worst), 2, or 3 (best) for each test was calculated based on range of motion. Type I error set at α=0.05

Y-balance: Weak correlations were found between anterior reach and height (r = -0.36), total lean mass (TLM) (r = -0.39), leg LM (r = -0.39), and trunk LM (r = -0.39) (p<0.05). Moderate correlations were found between posterolateral reach and pelvic width below the femoral head (r = 0.42), femur length (r = 0.44), and tibia length (r = 0.51). FMS: Moderate correlations were found between height and both; deep

squat (r = -0.400) and inline lunge (r = -0.63). Weak correlations were found between deep squat and both; TLM (r = -0.43) and trunk LM (r = -0.40). Strong correlations were found between inline lunge and TLM (r = -0.77), trunk LM (r = -0.73), and leg LM (r = -0.70). Pelvic width below the femoral head was found to be moderately correlated with deep squat (r = 0.40), straight leg raise (r = 0.45), and inline lunge (r = 0.60). **CONCLUSION:** Factors such as Bcomp and SkD likely influence diagnostic conclusions of commonly generalized mobility assessments in men and women soccer athletes. Further study is needed to determine if these variables could be used to improve testing value for improving performance and assessing injury risk.

3163   Board #32   June 2 8:00 AM - 9:30 AM

Profiles And Correlation Between Sprint And Agility K-test Of Elite Young Soccer Players As A Function Of Age

Lee Cabell[1], Frantisek Zahalka[2], Tomas Maly[2], Lucia Mala[2], Michal Dragusky[2], Arnold Baca[3]. [1]Arkansas Tech University, Russellville, AR. [2]Charles University, Prague, Czech Republic. [3]University of Vienna, Vienna, Austria. (Sponsor: Kevin Ford, FACSM)
(No relevant relationships reported)

Agility, acceleration, change of direction, deceleration, and sprinting are critical technical skills in soccer. Sprint performance relative to a new Agility K-test (KT) required testing among four age groups. **PURPOSE**: To determine the profiles and relationship between linear running speed and agility KT of elite young soccer players. **METHODS**: Elite Czech national level young male soccer players volunteered for his study and were divided into four age groups (16 yr, n_1 = 22; 17 yr, n_2 = 18; 18 yr, n_3 = 26; 19 yr, n_4 = 20). The KT consisted of the participants running at maximum speed between cones positioned in a "K" pattern on a field with artificial grass. The participants started and ended running at the intersection of the "K" pattern. A contact switch for time measurement was placed on the top of each cone which participants touched with the hand. The participants performed two trials and the time of test execution was measured in seconds. Times were measured in a 5-m (S5) and 10-m (S10) dash from a static position. Two-way (4x2) ANOVA and post-hoc Tukey HSD were used for statistical assessment. Pearson correlation coefficient test was used to correlate two dependent variables. P<.05. **RESULTS:** Factorial ANOVA indicated no significant interaction between sprint distance and age, $F_{3, 164}$=0.15, p=.93, but significant main effect for sprint distance, $F_{1, 164}$=2142.61, p<.01, and age, $F_{3, 164}$=3.06, p<.05. The 19-year old group significantly improved both sprint times compared to the other age groups. The correlation between sprint times and KT for individual age groups primarily showed weak to moderate non-significant correlations: 16 yr: r_{S5}=-0.24, NS; r_{S10}=0.24, NS; 17 yr: r_{S5}=0.46, NS; r_{S10}=0.39, NS; 18 yr: r_{S5}=0.22, NS; r_{S10}=0.46, p<.05; 19 yr: r_{S5}=0.36, NS; r_{S10}=0.36, NS. The correlation between sprint times for S5 and S10 for the individual age groups: 16 yr: r = 0.64, p<.01; 17 yr: r = 0.76, p<.01; 18 yr: r = -0.06, NS; 19 yr: r = 0.97, p<.01. **CONCLUSION**: The sprint distance main effect indicated that sprint times improve with participants' ages. The weak correlation between sprint and KT may suggest a different training program for young soccer athletes or individual training program for different ages. The significant correlation between the linear sprint distances shows a good choice for speed training.

3164   Board #33   June 2 8:00 AM - 9:30 AM

Changes in Lower Extremity Musculoskeletal Characteristics Associated with Ankle Sprain History in Intercollegiate Soccer Athletes

Mallory Faherty[1], Jennifer Csonka[2], Karl Salesi[2], Tara Moore[1], Robert Zarzour[1], Timothy Sell, FACSM[1]. [1]Duke University, Durham, NC. [2]University of Pittsburgh, Pittsburgh, PA. (Sponsor: Timothy Sell, FACSM)
(No relevant relationships reported)

Ankle sprains (AS) result in persistent neuromuscular deficits and increased risk of re-injury. Examining the effect of AS on lower extremity (LE) flexibility, strength, static balance (SB), and dynamic postural stability (DPS) may aid in the development of injury prevention and rehabilitation programs. **PURPOSE:** Determine side-to-side differences in LE flexibility, strength, SB, and DPS in intercollegiate soccer athletes with a history of ankle sprain (HAS). **METHODS:** Fifteen intercollegiate male and female soccer athletes with a HAS participated (Age:20.2±1.3years, Height:175.3±9.9cm, Weight:68.7±10.2kg). LE flexibility tests included weight-bearing and active ankle dorsiflexion, active knee extension, and straight leg raise. LE strength tests included ankle dorsiflexion/plantarflexion, ankle inversion/eversion, hip abduction/adduction, hip internal/external rotation, and knee flexion/extension. LE SB and DPS were assessed with a force plate collecting ground reaction forces (GRF). Single-leg SB was assessed under eyes-open and eyes-closed conditions. DPS was assessed during a single-leg landing task. Side-to-side differences were assessed using T-tests, Wilcoxon Signed-Ranks or Mann-Whitney U tests, as appropriate. Significance for all tests was set at p<0.05, a priori. **RESULTS:** Athletes with a HAS demonstrated significant side-to-side differences for weight-bearing ankle dorsiflexion

(p=0.044), ankle dorsiflexion strength (p=0.006), and knee flexion strength (p=0.023). No other significant differences were observed. **CONCLUSION:** Athletes with a HAS demonstrated persistent side-to-side differences despite returning to competition. These differences, including weight-bearing ankle dorsiflexion flexibility, ankle dorsiflexion strength, and knee flexion strength may predispose these athletes to re-injury. The results of this study should guide AS rehabilitation programs in an effort to mitigate these persistent changes in an attempt to prevent re-injury.

Knee Alignment And Muscle Strength Ratios In Division III Female Soccer Players With Reconstructed Anterior Cruciate Ligament

Nina M. Robinson, Ana B. Freire Ribeiro. *Augsburg University, Minneapolis, MN.* (Sponsor: Dr. Mark Blegen, FACSM)

(No relevant relationships reported)

Intro: Anterior cruciate ligament tears are very common in sports that require contact, hard landing from jumps, or cutting, like soccer. Analyzing an athlete's knee valgus and muscle strength ratios may help reduce their risk for injury.
Objective: To compare knee valgus angles and the hamstring to quadriceps femoris strength ratio between healthy female Division III soccer athletes and athletes with ACL reconstruction, as surrogates for knee (re)injury risk.
Methods: Thirteen non-injured and three injured athletes completed a vertical drop jump (VDJ) from a 31 cm box and 1 Repetition Maximum tests (1RM) using seated knee curl and seated knee extension machines. Baseline and landing knee valgus angles (KVA) were measured using Dartfish software.
Results: There was a significant difference in quadriceps to hamstring ratio between injured and non-injured athletes (*p*=0.03), with injured individuals having an average ratio of 0.89 and non-injured 0.71. No significant difference was found in KVA from VDJ between injured and non-injured subjects (*p*=0.87). No significant relationship was found between KVA and quadriceps to hamstring ratios.
Conclusion: There are significant differences in hamstring to quadriceps strength ratios in injured female DIII soccer players compared to non-injured, suggesting it is a better screening than VDJ. KVA cannot be predicted by quadriceps to hamstring ratio and injury history.

Knee Biomechanics in Division III Female Soccer Players with Reconstructed Anterior Cruciate Ligament (ACLR)

Marissa Guillou, Ana B. Freire Ribeiro. *Augsburg University, Minneapolis, MN.* (Sponsor: Dr. Mark Blegen, FACSM)

(No relevant relationships reported)

PURPOSE: To compare knee valgus angles (KVA) between healthy athletes and athletes with reconstructed ACLs in vertical drop jump and soccer specific drills.
METHODS: Sixteen NCAA Division III (DIII) female soccer players, ages 20.94 (±1.29), thirteen athletes with healthy ACL and three with an ACL reconstruction (ACLR). Knee Valgus Angles (KVA) were measured during vertical drop jump, ladder drill, dribbling drill and shooting drill using Dartfish. Paired t-tests compared the groups.
RESULTS: There were no differences in KVA between groups in any of the drills. Drop Jump KVA mean was 12.9± (SD±11.8)(p=0.87). Mean right leg KVA on ladder drill was 19.1±(SD±9.6)(p=0.95) and 17.2± (SD±8.3)(p=0.3) for left leg. Mean right leg dribbling drill average KVA was 15.8± (SD±8.5)(p=0.11) and 12.7±(SD±7.5) (p=0.16) for left leg. Mean right leg shooting drill average KVA was 19.9± (SD±7.3) (p=0.08) and 15.2± (SD±7.2)(p=0.29) for left leg.
CONCLUSIONS: Although there were no significant differences, between the injured and non-injured athletes for any drills, KVA in the injured athletes tended to be larger in game-like drills, suggesting they could be more meaningful in injury prevention assessment.

Sweat Loss in Association With Measures of External Load in Adolescent Soccer Players

Timothy J. Roberts, Melissa L. Anderson, Tina L. Bonsignore, Kortney J. Dalrymple, Khalil A. Lee, Lindsay B. Baker, FACSM. *Gatorade Sports Science Institute, Bradenton, FL.* (Sponsor: Lindsay Baker, FACSM)

Reported Relationships: T.J. Roberts: *Salary; This study was funded by the Gatorade Sports Science Institute. The views expressed in this abstract are those of the authors and do not necessarily reflect the position or policy of PepsiCo, Inc.*

BACKGROUND: The use of technology to track workload and measurements of sweat loss to prescribe hydration strategies are now common practice. No study has explored the association of load variables to sweat loss in soccer athletes.
PURPOSE: To determine the association of load measures (total distance (TD), energy expenditure (EE)), body mass (BM), and sweat loss in adolescent soccer athletes during organized practice.
METHODS: Thirty-two adolescent soccer athletes (Male: n=16, 17 ± 1 y, 71.4 ± 6.7 kg; Female: n=16, 18 ± 1 y, 64.0 ± 8.4 kg) had workload measured during 3 in-season practices (21.9-25.4°C WBGT) using GPS/accelerometer technology. Total sweat loss was calculated from pre- to post-exercise change in BM, corrected for fluid/food intake (ad libitum), urine output, metabolic mass loss, and respiratory water loss. Practice type was assessed subjectively and categorized as small or large-sided games/drills based on the activities athletes engaged in during the majority (>50%) of the practice time. Girls practice 1 and 2 and boys practice 2 were small-sided. Girls practice 3 and boys practice 1 and 3 were large-sided. Multiple linear regression analyses were used to model the effects of independent variables (BM, EE, and TD) on total sweat losses. Data are shown as mean ± SD.
RESULTS: Boys covered 4.7 ± 1.4 km and expended 1595 ± 481 KJ (381 ± 115 kcal) in 81 ± 13 min practices. Girls covered 4.4 ± 0.9 km and expended 1310 ± 299 KJ (313 ± 72 kcal) in 81 ± 7 min practices. Total sweat loss was 1.3 ± 0.3 L in boys and 0.8 ± 0.2 L in girls. Models to predict sweat loss included: 1) BM and EE; and 2) BM and TD. Model 1 was significant in boys during practice 1 (r^2=0.73, p<0.001) and 3 (r^2=0.60, p<0.01), but not practice 2 (r^2=0.38, p=0.06). Model 1 was significant in girls during practice 3 (r^2=0.57, p<0.01), but not practice 1 (r^2=0.36, p=0.11) or 2 (r^2=0.32, p=0.12). Model 2 (not reported) was largely identical. **CONCLUSION:** The association between total sweat loss, BM, and workload was inconsistent among practices, which may be explained in part by practice type. Significant prediction models were found during practices that consisted of predominantly large-sided game/drill scenarios. This work provides a literature base for the exploration of associations between workload measures and physiological/metabolic variables.

Effect of Maturation on Heart Rate During a Six-Week Plyometric Training in Female Soccer Players

Christina M. Mullen, Jeffrey B. Taylor, Michelle A. Aube, Audrey E. Westbrook, Anh-Dung Nguyen, James M. Smoliga, FACSM, Kevin R. Ford, FACSM. *High Point University, High Point, NC.* (Sponsor: Kevin R. Ford, FACSM)

(No relevant relationships reported)

Implementation of an anterior cruciate ligament (ACL) injury prevention program (IPP) has been recommended to coincide with the adolescent growth spurt as risk factors increase during and following this phase of maturation. Physiological responses to load during this stage of growth may result in a differing maximum heart rate (HR_{max}) during intense exercise. Understanding the relationship between physiological responses to load and maturation stage may result in more effective IPP in youth athletes. **PURPOSE**: To examine the effects of maturation on HR_{max} in adolescent soccer players over a six-week training program. **METHODS**: 34 female soccer players participated in a 6-week training study (age 13.3±1.5yrs; height 158.7±6.9cm; mass 50.0±9.6kg). Maturation groups were determined based on percent of adult stature (PAS) with 88-94% representing pubertal (n=9, PAS 91.6±2.0%) and 95-100% representing post-pubertal (n=25, PAS 97.7±1.7%). Three 30 minute sessions, separated into plyometric, resistance, and core strength training, were completed each visit for a total training time of 90 minutes three times per week. Participants wore HR monitors during each plyometric session. The initial exercises were adapted from ACL IPP, and intensity of each exercise was progressed weekly following the second week of training (5 total phases). HR_{max} was calculated for each participant during each session and averaged weekly. A linear mixed model (p<0.05) was used to determine the effects of HR_{max} over the six-week intervention in pubertal and post-pubertal female soccer players. Average HR during the first week of training was used as a covariate.
RESULTS: A significant interaction of maturational group and training week was found (p<0.04) with HR_{max}. A main effect of training week was found in both pubertal (p<0.001) and post-pubertal (p<0.01) groups. HR_{max} was significantly increased in both groups (week 1 to week 3, p<0.05) following the first two technique focused weeks of plyometric program with the pubertal group (184.3±4.7 BPM) having greater HR_{max} compared to the post-pubertal group (172.7±2.2 BPM) during week 3.
CONCLUSIONS: Physiologic responses to load was dependent on maturation stage and should be further examined in relation to reduced risk of injury following IPP. Funding supported by NIAMS/NIH R21AR069873

Comparison of Pre And Postseason FMS Individual Test Scores In DIII Male Soccer Players

Ana B. Freire Ribeiro[1], Darby R. Lindgren[2], Jide Ifonlaja[1], Stuart Borne[3]. [1]Augsburg University, Minneapolis, MN. [2]North Dakota State University, Fargo, ND. [3]University of Saint Thomas, Saint Paul, MN. (Sponsor: Mark Blegen, FACSM)

(No relevant relationships reported)

The Functional Movement Screen (FMS) is a battery of seven tests scored on a 0-3 scale that aims to identify imbalances and asymmetries in the body (Cook, 2014). Within the FMS, the deep squat (DS) and active straight leg raise (ASLR) are good predictors of injury (Hotta et al, 2015, Hammes et al, 2016, and Zalai et al, 2014); therefore they were tracked pre and postseason, along with shoulder mobility (SM). Given that most soccer injuries occur during preseason (Hootman et al., 2007, NCAA 2017), it is hypothesized that athletes would have lower scores at preseason. **PURPOSE**: To compare pre and postseason DS, ASLR, and SM scores in NCAA DIII male soccer players. **METHODS**: Sixteen collegiate players were assessed in mid-August and late March. They completed the DS, ASLR, and SM tests and were rated by one athletic trainer certified in FMS. A paired t-test compared the pre and postseason scores. **RESULTS**: The mean preseason total score was 6.62 (SD=0.89), while the postseason mean was 6.88 (SD=1.15). Scores between the two seasons were not different (p=0.21). From pre to postseason, DS scores increased by 21% (p=0.059), ASLR scores increased by 5.8% (p=0.054), but SM scores decreased by 7% (p=0.18). **CONCLUSIONS**: DS, ASLR, and SM scores did not significantly change from pre to post-season. Sport-specific tests and a more sensitive rating scale could have yielded different results and should be further investigated.

Differences Between the Bilateral and Ipsilateral Strength Asymmetries With Respect to Age, Contraction Velocity and Limb Preferences in Female Soccer Players.

Lucia Mala, Tomas Maly, Frantisek Zahalka, David Bujnovsky, Mikulas Hank, Michal Dragijsky. *Charles University, FPES, Prague, Czech Republic.*

(No relevant relationships reported)

During the soccer match, strength and power movements are accumulated on both lower extremities. This occurs in an asymmetrical manner and may gradually leads to higher shifts of myodynamic characteristics and strength asymmetries (SA). There are limited investigations of a combination of muscle SA and different age groups in female soccer players.
PURPOSE: To investigate of differences bilateral and ipsilateral SA in female soccer players of four age categories.
METHODS:
Elite female players (n=67) of 4 age categories (U17=13, U19=18, U18=20 and U19=15) performed isokinetic strength testing (Cybex NORM®, Humac, USA) for knee extensors (KE) and flexors (KF) at three angular velocities (AV: 60, 180, 300 °·s^{-1}). Bilateral strength ratios (Q:Q, H:H) and ipsilateral strength ratios (H:Q) were evaluated. Three-way Mixed-design ANOVA with two between subject effect (Age, Limb) and one within subject effect (AV) were used for evaluation. Bonferonni's *post-hoc* test and partial eta square (η_p^2) were also used for data analysis.
RESULTS:
We found a statistically significant effect of AV on bilateral ($F2,123$ = 5.52; p<.01; Wilk's Λ = 0.92; ηp^2 = .08) and ipsilateral ($F2,123$ = 4.87; p<.01; Wilk's Λ = 0.93; ηp^2 = .07) SA in four age groups. We found a significant higher SA between KF compare to KE (F1$_{,124}$ = 23-89, p<0.00, η²=0.16). With increasing AV from 60 to 180°·s^{-1}, significant changes in H:H appeared (H:H$_{60}$ = 7.81±0.60 % vs. H:H$_{180}$ = 11.03±0.73 %, p<0.01). The factor "Age" did not significantly affected SA in players (Bilateral: F$_{3,124}$ = 1.10, p>0.05, η²=0.03; Ipsilateral: F$_{3,124}$ = 1.85, p>0.05, η²=0.04). The interaction between "Age" and "Leg" had not significant effect (p>0.05) on SA for groups. Post-hoc analysis showed in dominant leg a significant difference in H:Q$_{60}$ = 54.73±0.92 % vs. H:Q$_{180}$ = 57.61±1.17 (p<0.01). Totally, 17 (~25%) risk results (>20%) of H:H was found in players in comparison to 3 (~5%) risk results in Q:Q.
CONCLUSION
The KF demonstrated a higher degree of the bilateral ratio in comparison to KE. Seventeen players (25%) had SA in KF higher than 20% at least at one AV. More attention should be paid to KF, where a higher percentage of SA was observed. Higher percentage of SA was seen at higher AV. The results may be beneficial for fitness coaches, physiotherapists, doctors and other clinical staff of female soccer players.

High Intensity Interval Training Does Not Improve Cardiorespiratory Parameters In Trained Young Soccer Players

Stelios Poulos, Ilias Zacharogiannis, Giorgos Paradisis, Fotini Dagli, Maria Maridaki. *National and Kapodistrian University of Athens, Athens, Greece.*

(No relevant relationships reported)

Soccer performance is the result of technical, tactical, physiological and psychological attributes of the players. **PURPOSE**: The present study investigated the effect of high-intensity interval training (HIIT) and continuous moderate intensity training (CONT) on selected parameters of the cardiorespiratory function in young soccer players. **METHODS**: Thirty Greek amateur soccer players (mean ± sd, age 19 ± 2,21y, Body mass 71.19 ± 2.5 kg) were randomized into a high-intensity interval training group (HIIT, n = 10), a continuous moderate intensity training group (CONT, n = 10) and a control group (Control, n = 10). The intervention for HIIT and CONT groups was 16 more training sessions, 2 per week while CONTROL group continued regular soccer training routine. The HIIT group training sessions consisted either of 15s sprints interspersed by 15s of recovery at 120%VO$_2$max with 8 min total exercise time or they played 4x4 min (16 min total time) small-sided games (4v4) followed by 2 min recovery interval. The CONT group training sessions consisted either of 40 min continuous running at 70% VO$_2$max or 10v10 full field soccer game for 40min. **RESULTS**: Mean values ± sd pre and post-training for Body weight, (HIIT: 69.49 ± 8.39 v 69.0 ± 8.8; CONT: 71.2 ± 10.93 v 70.2 ± 11.01 kg), %fat, (HIIT: 13.02 ± 2.41 v 12.12 ± 2.49, CONT: 13.75 ± 2.19 v 13.82 ± 2.21), VO$_2$max, (HIIT: 55.08 ± 4.43 v 57.75 ± 5.63, CONT: 56.46 ± 4.61 v 58.41 ± 5.24 ml.kg^{-1}.min^{-1}), vVO$_2$max (velocity at VO$_2$max, HIIT: 15.9 ± 0.70 v 16.5 ± 0.52, CONT: 16.5 ± 1.51 v 16.7 ± 1.19 km.h^{-1}) and vVT (velocity at ventilatory threshold, HIIT: 11.8 ± 0.87 v 12.5 ± 0.69, CONT: 12.4 ± 1.03 v 12.5 ± 1.13 km.h^{-1}). VO$_2$max, vVO$_2$max and vVT improved 4.6, 3.6 and 5.6% only after HIIT training but the difference didn't pass statistical significance due to large sd of the sample. **CONCLUSIONS**: In conclusion, the combination of the training regiments of this study did not improve cardiorespiratory parameters of endurance performance in already trained young soccer players. There was, though, a tendency for better adaptations favors the time efficient HIIT training.

3172   Board #41   June 2 8:00 AM - 9:30 AM

Performance Differences Between Home And Away Fixtures And Halves In NCAA DI Women'S Soccer

Mikaela C. Gabler[1], Gavin Connolly[1], Shane F. O'Riordan[2], Tomas Barrett[1], Naveen Sharma[1], Paul L. O'Connor[1]. [1]Central Michigan University, Mount Pleasant, MI. [2]Australian Sports Commission, Canberra, Australia.

Reported Relationships: M.C. Gabler: *Consulting Fee; CMU women's soccer.*

PURPOSE: It is well documented that there is an advantage when playing games at home. The influence of home advantage on performance measures are not fully understood. The current study compared performance variables between wins and losses, home and away fixtures and also first and second halves to explore potential performance differences.
METHODS: 12 Division I female soccer players (19.5 ± 1.5 yrs, 166 ± 3.5 cm, 61.4 ± 4.8 kg) were included based on playing time criteria (≥ 60% total game time). Global positioning system (GPS) data was collected for conference games for one season (11 total games). Total distance (TD), distance covered (m·min^{-1}), high speed distance (HSD: 15.5 - 19.9 km·h^{-1}), and average player passes were recorded. Data was analyzed using Two-Way ANOVAs in Sigma Plot.
RESULTS: There were no differences in any measured variable between games won and games lost. TD was significantly greater for the first half compared to the second half (4632.5 ± 368.8m vs 4045.2 ± 364.6m; P = 0.002). TD was also significantly greater for the first half compared to the second half for both home (H) and away (A) games (P < 0.05). M.min^{-1} was significantly greater for the first half compared to the second half (119.9 ± 5.8m vs 113.1 ± 5.5m; P = 0.015). M.min^{-1} was also significantly greater for the first half compared to the second half for H games (P = 0.037). HSD was significantly greater in the first half compared to the second half (585.16 ± 75.3m vs 499.9 ± 71.9m; P=0.016). There was no difference in HSD between home and away games. Average passes were significantly greater for the H compared to A games (11.7 ± 2.6 vs 9.3 ± 1.7; P = 0.015). They were also significantly greater for the first half compared to the second half (P = 0.049). Additionally, average passes were significantly greater for the first half for H compared to A games (P = 0.036).
CONCLUSIONS: Game result had no effect on the measured variables. TD, m·min^{-1}, and HSD were greater for the first half compared to the second half regardless of location. Average passes were greater for the first half compared to the second half and for H compared to A games. This information could influence coaches' decision making.

3173   Board #42   June 2 8:00 AM - 9:30 AM

Match-Play Analysis Of Physiological And Movement Variables In Men's And Women's Division I Soccer Players

Ashley N. Triplett, Michael Vorkapich, James M. Pivarnik, FACSM. *Michigan State University, East Lansing, MI.*

(No relevant relationships reported)

HR monitoring, accelerometers, and GPS tracking have become popular tools to quantify activity intensity during soccer matches. Limited research has examined differences between men and women collegiate players using these tracking modalities. **PURPOSE**: To quantify the activity profile of Division I collegiate soccer players during games using HR response and GPS and to examine differences based on gender and position. **METHODS**: A team HR monitoring system was used to evaluate in-game HR response and quantify match-play movement patterns of 21 men and 21 women NCAA Division I soccer players who played >70 min in each of 3 games. Players were divided into 3 groups based on position (defender, midfielder, forward). Percentage of playing time spent above 80% of HR max and average %HRmax was calculated. Total distance/playing time and number of sprints above sprint threshold (men: accelerations >2.8m/s^2, women: accelerations >2.4m/s^2) were also calculated. ANOVA and student's t-test were used to determine differences. **RESULTS**: Forwards and midfielders had significantly greater distance/playing time and sprints/playing time than defenders (F: 115.2m/min, M: 115.7m/min, D: 103.0m/min) (F: 0.38sprints/min, M: 0.33sprints/min, D: 0.26sprints/min) (p<0.05). No positional differences were observed in average %HRmax or % of game time >80% of HRmax. Men had a greater average distance/playing time than women (113.0m/min vs 105.6m/min) (p<0.05). Men had significantly fewer average sprints/min above threshold than women (0.18/min vs 0.42/min) (p<0.05). No differences were observed in average %HRmax (M: 85.6%HRmax, W: 87.7%HRmax) or % of game >80% of HRmax (M: 80.6%, W: 88.3%) between genders. **CONCLUSIONS**: HR data illustrate that elite level soccer is a highly aerobic sport. Differences in distance/playing time and sprints based on position may be explained by positional requirements, with more constant movement required for midfielders and explosiveness for forwards. Men's soccer moves at a faster pace, explaining the difference in distance/playing time by gender; however, relative activity intensity (%HRmax) was similar between positions and gender. The gender difference in number of game sprints may be at least partially related to the threshold differences determined by the GPS system.

The Effect of High Intensity Interval Training on Planned Agility Performance in Soccer Players

Tal Amasay, Sofia Jakobsson, Constance M. Mier, FACSM. *Barry University, Miami Shores, FL.* (Sponsor: Constance M. Mier, FACSM)

(No relevant relationships reported)

Inducing fatigue prior to agility training through high intensity interval training (HIIT) has shown to yield greater agility improvements compared to agility training alone. However, high levels of neuromuscular fatigue can impair the ability to implement proper technique and may increase injury risk associated with the explosive neuromuscular demand of agility performance. **PURPOSE:** To investigate the fatiguing effects of HIIT on agility performance, and determine if performance can be fully recovered following a short rest period. **METHODS:** Nineteen collegiate level soccer players participated in the study, nine men (22 ± 2 yrs) and ten women (20±2 yrs). Agility T-test were performed before (PRE), and twice following (POST 1 and POST 2) the completion of four 4-seconds cycle ergometer sprints. The four sprint intervals were separated by 25 s active recovery. POST 1 was performed immediately following the final cycle sprint whereas, POST 2 began two minutes after completion of POST 1. Repeated measures ANOVA and Bonferroni post hoc tests were used to determine significant differences in the time to complete the T-tests. **RESULTS:** During HIIT, average power from the first sprint to the last declined by 30.7 ± 9%. Time to complete the agility T-test significantly differed among the three tests (PRE: 10.46 ± .17 s; POST 1: 11.67 ± .33 s; POST 2: 10.96 ± .19 s; F(2, 54) = 6.174, p = .003). Post hoc test revealed an increase in time from PRE to POST 1 (p = .002), but no difference between PRE and POST 2 (p =. 473). **CONCLUSION:** These results show that acute fatigue from HIIT impairs planned agility, but performance can be recovered within a few minutes. Coaches can safely combine fatigue-inducing drills and planned agility training into same sessions with rest interval.

Acute Hypoxic Exposures On Submaximum And Maximum Physical Performance In Soccer Players

rungchai C. chaunchaiyakul. *mahidol university, Nakonpathom, Thailand.* (Sponsor: Professor Chia-Hua Kuo, FACSM)

(No relevant relationships reported)

Acute hypoxic exposures on submaximum and maximum physical performance in Soccer Players.
Rungchai Chaunchaiyakul[1,*] Panik Avirutakan[2], Chusak Pattanamontri[2], Somporn Wannasiri[2] and Salinee Chaiyakul[3]
[1] College of Sports Science and Technology, Mahidol University, Thailand.
[2] Sports Authority of Thailand,
[3] Faculty of Allied Health Science, Walailak University, Thailand.
Purpose: This study was aimed to investigate cardiorespiratory and metabolic changes during acute hypoxic exposures on physical performance in soccer players. **Materials and method:** Male football players, who currently trained, participated. This study was approved by the Human Research Committee of Ethical Reinforcement for Human Research, Mahidol University, Thailand (MU-CIRB 2015/075 1905). A hypoxic chamber was used to simulate normobaric-normoxic (NOR, $F_1O_2 = 0.21$) and hypoxic (HYP, $F_1O_2 = 0.15$) condition. Cardiorespiratory and metabolic functions at rest and during exercise were monitored using an impedance cardiography (PhysioFlow®) and telemetry gas analyser (Oxycon Mobile®). Variables including heart rate (HR) stroke volume (SV), cardiac output (), respiratory rate (RR), tidal volume (V_T), ventilation ($\dot{V}_E$), oxygen consumption ($\dot{V}O_2$), carbon dioxide production ($\dot{V}CO_2$) and respiratory exchange ratio (RER), were monitored. Two separated progressive exercise tests were conducted on a cycle ergometer. **Results:** At submaximum exercise, no significant different of all resting variables between two groups were detected. HR, SV, VT, RR, VE, SaO2 and VO2 remarkably increased in the stepwise pattern ($p<0.05$) in parallel with all workloads. EDV, ESV, CO and VCO2 in both groups progressively increased ($p<0.05$) at the moderate to high workloads (90, 120 and 150 W). HYP showed the significantly higher HR ($p<0.05$) for all workloads, and significantly lower EDV and ESV at 150 W. At maximum exercise, HYP showed significant reductions in maximum values of HR, SV, EDV, ESV, CO, WR and VO2 ($p<0.05$), with increasing in RR, VE, VCO2, and RER ($p<0.05$). **Conclusion:** Hypoxic condition declines performance, VO2 and cardiac function at maximum exercise. Physiologic responses are mostly derived from respiratory compensation for all workloads. Thus, respiratory adjustment plays major role in acute normobaric-hypoxic condition.

3176   Board #45   June 2 8:00 AM - 9:30 AM

Unstable Surface Training Effects on Balance and Lower Limb Power in Adolescent Female Soccer Players

Ieng Si Chan, Li-Lan Fu. *National Taiwan Sport University, Taoyuan City, Taiwan.*

(No relevant relationships reported)

Soccer is a moderate contact sport and has a higher injury rate in female adolescent. Previous researches demonstrate the unstable surface training (UST) could improve the body's stability and movement control, thereby reducing the risk of injury during exercise. **PURPOSE**: The purpose of this study was to determine the effect of a 6-week unstable surface training program on dynamic balance and lower limb power in adolescent female soccer players. **METHODS**: Twenty female soccer players (age: 14.9 ± 0.75 yrs, height: 160 ± 6.02 cm, weight: 50.6 ± 6.5 kg) from a local Junior School were randomly divided into control group (n = 10) and exercise group (n = 10). All players underwent a regular soccer training 5 times per week. Participants in the exercise group received extra UST program (6 weeks, 3 times per week, 20 min per session). The training program included core muscle, lower limb strength and balance training by using the BOSU ball as a training tool. Vertical jump, 30 meters dash and the dynamic balance (Star Excursion Balance Test, SEBT) before and after the training program were assessed for all players. Paired sample t-test was used to analyze the difference between pre and post-tests in two groups. The significant level was set at α = .05.
RESULTS: In the exercise group, the SEBT scores significantly increased after UST ($p = .000$, pre 294 ± 23 % vs. post 332 ± 30 %). No significant difference was found in the control group ($p = .823$, pre 301 ± 17 % vs. post 299 ± 16 %). The time of 30 meters dash in exercise group was significantly improved after UST ($p = .047$, pre 5.38 ± 0.3 s vs. post 5.27 ± 0.27 s). No significant differences were found in control group ($p = 0.17$, pre 5.45 ± 0.21 s vs. post 5.61 ± 0.38 s). The vertical jump height in exercise group was significant increased after UST ($p = .008$, pre 30.88 ± 3.82 cm vs. post 32.1 ± 4.2 cm), but no significant difference in control group ($p = 0.405$, pre 31.08 ± 2.12 cm vs. post 30.36 ± 3.19 cm).
CONCLUSIONS: Six weeks UST could improve the dynamic balance, vertical jump and 30 meters dash performance in adolescent female soccer players. Incorporation of UST into the routine training of female adolescent soccer players is important for the development of sports fitness and possibly exercise performance.

Heart rate Variability, Stress Tolerance and Performance Outcomes to Intensification and Tapering in Soccer Players

Luiz Claudio Reeberg Stanganelli, Diego H. Figueiredo, Diogo H. Figueiredo, Helcio R. Gonçalves. *State University of Londrina, Londrina-Parana, Brazil.*
(No relevant relationships reported)

PURPOSE: The aim of this study was to examine the effect of intensification weeks (IT) followed by a 1-week tapering (TP) phase leading up to a major competition, on heart rate variability (HRV), stress tolerance (ST) measures, and physical performance in sixteen male U19 soccer players.
METHODS: The study comprised 1 baseline week, 2 weeks of intensified training followed by a 1-week taper. Daily measures of HRV, ST (DALDA questionnaire) and internal training load (ITL) were collected through the training phases. Mean values of lnRMSSD (lnRMSSD$_{mean}$) and the coefficient of variation (lnRMSSD$_{cv}$) were determine on a weekly basis for each training phase. At the end of each training phases, the athletes performed the Yo-Yo Intermittent Recovery level 1 (Yo-Yo IR1) test, Counter movement jump, Squat jump, speed tests and a running anaerobic sprint test (Rast test).
RESULTS: A decrease in lnRMSSD$_{mean}$ with an increase in lnRMSSD$_{cv}$ were observed during the IT with an opposite response observed during TP. No difference was found for the Rast test among training phases (p>0.05). During IT all remaining performance variables decline (p>0.001) with a supercompensation during TP (p>0.001). A decrease in stress tolerance were found during IT (p>0.001) with a reduction during TP (p>0.001).
CONCLUSIONS: The present results suggest that decreases in vagal-related HRV with greater daily fluctuations during peak volume-based training loads may be a sign that the athletes are not 'coping' with the applied training load and may reflect the initial stage of physiological stress.

Training Strategies Maintain Performance Characteristics in Marines Selected for Marine Corps Special Operations Individualized Training Course

Scott D. Royer[1], Joshua D. Winters, FACSM[1], Kathleen Poploski[1], John Abt, FACSM[1], Andrejs Zalaiskalns[2], Scott Lephart, FACSM[1]. [1]*University of Kentucky, Lexington, KY.* [2]*United States Marine Corps Forces Special Operations Command, Camp Lejeune, NC.* (Sponsor: John Abt, FACSM)
(No relevant relationships reported)

Marines must complete an intensive Assessment and Selection (A&S) course prior to becoming a United States Marine Corps Forces Special Operations Command (MARSOC) Raider. Following selection, Marines are given training recommendations designed to maintain performance characteristics deemed relevant to successfully complete a rigorous nine-month Individualized Training Course (ITC). However, the time between the two courses is highly variable and training strategies are individually implemented by the Marine. **PURPOSE:** To evaluate the effectiveness of current training strategies following A&S and prior to ITC. **METHODS:** Fat free mass (FFM), fat mass (FM), anaerobic power (AP), anaerobic capacity (AC), aerobic capacity (VO$_2$max), knee flexion (KF), knee extension (KE), shoulder internal rotation (SIR), shoulder external rotation (SER), trunk extension (TE) and trunk flexion (TF) isokinetic strength were collected on 27 Marines (Age: 25.6 ± 2.9 years, Height: 1.78 ± 0.05 meters, Mass: 83.0 ± 8.4 kg, Post A&S to ITC Start: 183.8 ± 68.2 days) following A&S and directly prior to ITC. **RESULTS:** No significant changes were found in Marines between A&S and the start of ITC in FFM (*p=0.852*), FM (*p=0.119*), AP (*p=0.569*), AC (*p=0.388*), VO$_2$max (*p=0.594*), KF (*p=0.855*), KE (*p=0.843*), SIR (*p=0.868*), SER (*p=0.710*), TE (*p=0.590*), and TF (*p=0.971*). **CONCLUSION:** Performance characteristics were similar following selection and prior to the start of ITC, suggesting the current training strategies, as implemented and adopted for the varying time gaps post A&S, were effective at maintaining performance between courses. Although effective at sustaining performance levels, Marines still demonstrated deficits in AP (13.0 W/kg vs 12.65 W/kg respectively) compared to previous studies on MARSOC Raiders. Future training strategies may further benefit from an increased emphasis on AP in conjunction with current recommendations. Additionally, further research is needed to determine how performance characteristics are effected by variance in time between courses.

The Influence Of Four-week Of Endurancetraining With Periodic CO Inhalation On Aerobic Capacity

Jun WANG, Yang HU. *Beijing Sport University, Beijing, China.*
(No relevant relationships reported)

PURPOSE: Altitude training is commonly used to enhance aerobic capacity in competitive athletes. The rationale is hypoxic stimulation of EPO to raise blood Hb mass and concentration and therefore also O$_2$ transport capacity. We hypothesized that periodic inhalation of low levels of CO at sea level might be an easier method to achieve the same outcome.**METHODS**: 12 non-smoking male well trained football players volunteered to participate in this study. In a preliminary experiment in resting subjects, the concentrations of CO in exhaled gas and of CO and EPO in venous blood were measured before and then at 1h, 2h, 4h, 6h, 8h after inhaling a bolus of CO (1ml/kg BW) through a spirometer. For the main experiment, the subjects were divided into two groups (one group given inhaled CO (INCO) and a control group not given CO (NOCO)). All subjects participated in a four-week treadmill training program, running for 50 minutes at a speed of 90% of that producing each individual ventilation threshold, 3 times a week for 4 weeks. Prior to each training session, INCO inhaled a mix of CO (1ml/kg BW) and O$_2$ (4L) over two minutes, while NOCO inhaled a bolus of O$_2$(4L) over two minutes. Before and after 4 weeks of training, total hemoglobin mass (tHb), blood parameters (RBC, Hct, [Hb], MCVC), and VO$_2$ max were measured. **RESULTS**:In the first experiment, HbCO% increased from 0.7% to 5.81% (p<0.05) 1 hr after CO inhalation, decreasing gradually to 1.48% after 8 hours; EPO increased significantly 2 hours (p<0.05) after CO inhalation, peaking (42.3% higher than pre 1.912 **mIU/mL**) at 4 hours, and then decreasing gradually at 6 (2.465 **mIU/mL**) and 8 hours (1.759 **mIU/mL**); (2) tHb and VO$_2$max in INCO increased significantly after training (5.9% higher and 6.7% respectively, each p<0.05). However there were no such changes in NOCO; Oxygen uptake at a given submaximal intensity declined slightly both in INCO and NOCO, with the changes being more obvious in INCO. At 8, 10 and 12km/h, VO2 decreased by 7.08%, 2.13% and 3.43% respectively in INCO and by 1.56%(p=0.057), 5.74%(p=0.081) and 0.66%(p=0.059) in NOCO.
CONCLUSIONS:Circulating EPO increases sharply after a bolus of CO (1ml/kg BW), peaking at 4 hours after inhalation; Endurance training with CO inhalation increases tHb and VO2max and slightly reduced the energy cost of submaximal running.

3180   Board #49   June 2 8:00 AM - 9:30 AM

Prescription of Dry-land Resistance Training by Elite Swimming Strength and Conditioning Coaches.

Emmet Crowley, Andrew J. Harrison, Mark Lyons. *University of Limerick, Ireland, Limerick, Ireland.* (Sponsor: Giles Warrington, FACSM)
(No relevant relationships reported)

Purpose: No research to date has investigated the current practice of prescription of dry-land resistance training by elite swimming strength and conditioning (S&C) coaches. The aims of this study were to examine the prescription of dry-land resistance training modalities and exercises among elite swimming S&C coaches and explore coach's rationale and justification for prescribing dry-land resistance training modalities and dry-land exercises. **Methods:** Twenty-three (n = 21 males, n = 2 females) elite swimming strength and conditioning coaches from Ireland (n = 7), Great Britain (n = 5), Australia (n = 6) and the United States (n = 5) were recruited through their specific national governing bodies. Coaches completed an online questionnaire consisting of seven sections; participant information, informed consent, coach's biography, coach education, current training commitments, dry-land resistance training modalities exercises and additional information. **Results:** Results showed that coaches had varying levels of experience, education and worked with swimmers at regional (4.6 %), national (59.1 %) and international (36.4 %) levels. The most popular S&C accreditations were; National S&C Association (29.2 %), United Kingdom S&C Association (22 %) and Australian S&C Association (7.3 %). S&C coaches reported that their primary sources of information were their own experience (52.4 %), S&C coaches (14.3 %) and academic journals (9.5 %). In total four different resistance training modalities were reported and these included 95 dry-land resistance training exercises. **Conclusion:** Traditional resistance training was the most commonly practiced dry-land training modality with the pull up and squat reported as the most popular exercises prescribed by elite swimming S&C coaches. Future research should focus on exploring the specificity and transfer of specific exercises to swimming performance. This study highlighted that coaches need to have a clear understanding of the mechanisms that occur during sport specific movements such a swimming. Furthermore, there is a need for coaches to perform detailed needs analysis before prescribing dry-land resistance training programs as aquatic sports provide a unique challenge to the s S&C coach.

Changes in Muscular Strength and Endurance Following Various Resistance Training Frequencies and Protocols in Untrained Females

Murat Karabulut[1], P. Gage Murphy[1], Ulku Karabulut[1], Michael G. Bemben, FACSM[2]. *[1]University of Texas Rio Grande Valley, Brownsville, TX. [2]University of Oklahoma, Norman, OK.* (Sponsor: Michael G. Bemben, FACSM)
(No relevant relationships reported)

PURPOSE: To determine the impact of various resistance training protocols and frequencies on isometric and isokinetic strength and endurance in sedentary and recreationally active females.
METHODS: Forty-six female subjects (age= 22.7 ± 4.1) were randomly assigned to one of four groups that trained the knee flexors and extensors for 6 weeks. Training groups included a traditional group (TRAD) [3 sets (10, 10, 10 reps), 3x/wk at 70-80% of one repetition maximum (1RM)], two blood flow restriction groups [(BFR-1) 4 sets (30, 15, 15, failure), 1x/wk at 20-50% 1RM; and (BFR-2) 4 sets (30, 15, 15, failure), 2x/wk at 20-50% 1RM], and a one set to failure group (FAIL) [1x/wk at 75-80% 1RM]. Subjects fasted (for at least 8 hours) and were hydrated for pre and post testing sessions that included assessing isometric maximum voluntary contraction (MVC) of the knee extensors (60° of knee joint flexion), 10 repetitions of isokinetic knee extensions at 60°/s (ISO-60), and 10 reps at 180°/s (ISO-180), and 50 maximal knee extensions (50 REP) at 180°/s.
RESULTS: One-way ANOVA found no between-group differences in any of the outcome measures of interest at baseline. Repeated measures ANOVA found a significant time main effect for MVC ($p < 0.01$). There was also a significant time main effect ($p < 0.01$) and time*condition interaction ($p < 0.05$) for ISO-60 as well as a significant time main effect ($p < 0.01$) for ISO-180, with post torque values being greater than baseline. There was a significant time*condition interaction ($p < 0.04$) for percent decline in torque for the 50 REP test. All training groups had increases in strength (peak torque) following each training program, but the TRAD group had greater percent declines in torque from the average of first 3 reps to last 3 reps of the 50 contraction test on the posttest compared to the pretest (58% pre-training vs. 60% post-training) while the BFR-1 groups improved their ability to maintain torque over the 50 reps (63% pre-training vs. 59% post-training).
CONCLUSIONS: Findings indicate that the FAIL, BFR-1, and BFR-2 training programs can be as effective as the TRAD training program to improve isometric and isokinetic strength, but the BFR-1 group appeared to be able to maintain muscular endurance better than the TRAD group.

3182   Board #51   June 2 8:00 AM - 9:30 AM

The Relationship Between Macronutrient Consumption and an Off-Season Training Program in Female Athletes

Yvette Figueroa[1], Arlette Perry, FACSM[2]. *[1]Augusta University, Augusta, GA. [2]University of Miami, Coral Gables, FL.*
(No relevant relationships reported)

Sports performance and training are impacted by energy provisions. Adequate caloric and carbohydrate intakes are necessary for positive adaptations to exercise training, yet there is limited research examining dietary intake in relation to strength and power in female athletes. **PURPOSE:** To determine whether there are significant changes in weekly total caloric and macronutrient consumption, strength, and power and to determine whether changes in caloric and macronutrient consumption are significantly and positively related to changes in strength and power across a controlled eight-week, off-season resistance training program. **METHODS:** Eleven female volleyball players were examined on macronutrient consumption, strength, and power every two weeks over a period of eight weeks. A total of 5 assessments were conducted per subject. Anthropometric measures were taken to evaluate pre- and post-test measures of body mass index (BMI), lean body mass (LBM), and body fat (BF) percentage. Macronutrient consumption was measured using a three-day food log. Strength was assessed using a 3-repetition maximum (RM) bench press for upper body strength and a 3-RM back squat for lower body strength. A vertical jump was used to assess lower body power. Repeated-measures ANOVA and weighted regression analysis was used to compare assessments across time. **RESULTS:** Back squat and vertical jump significantly increased across the training program ($p<0.05$). Changes in caloric and carbohydrate intake were significantly related to the changes in vertical jump ($p<0.05$). Significant improvements were seen in BMI, LBM, and BF percentage ($p<0.05$). Bivariate correlations showed significant inverse relationships between pre-test BMI and pre-test caloric intake ($p<0.05$), as well as between post-test LBM and post-test carbohydrate intake ($p<0.05$). **CONCLUSION:** Changes in caloric and carbohydrate intake positively contribute to lower body strength and power in female athletes.

Cardiometabolic Responses Of Body-weight Exercises With And Without Vibration

Jie Kang, FACSM, Nicholas A. Ratamess, Jeremy Kuper, Elizabeth O'Grady, Nicole Ellis, Ira Vought, Jill A. Bush, FACSM, Avery D. Faigenbaum, FACSM. *The College of New Jersey, Ewing, NJ.*
(No relevant relationships reported)

Purpose: This investigation examined cardiometabolic responses of body-weight (BW) exercises with and without concurrent vibration. **Methods**: Eight men and six women performed a BW exercise protocol either on the floor (BW–V) or with a vibration platform (BW+V) in a randomized order. The BW exercise protocol consisted of three circuits of eight calisthenics-based exercises performed using Tabata intervals. Vibratory frequency and amplitude were set at 40 Hz and 4 mm, respectively. Oxygen uptake (VO_2), heart rate (HR), expired ventilation (V_E), and respiratory exchange ratio (RER) were measured throughout the protocol and during 30 min recovery. Blood lactate concentrations ([La]) were determined at rest and at the end of BW-V and BW+V. **Results**: The mean ($\pm$SE) VO_2 reached 22.11 (±0.51) and 23.28 (±0.82) ml·kg^{-1}·min^{-1} or 48% and 50% of VO_2max in BW-V and BW+V, respectively. The mean HR reached 156.63 (±4.15) and 162.22 (±4.40) beats·min^{-1} or 80% and 83% of HRmax in BW–V and BW+V, respectively. During the protocol, while the mean V_E was greater (p=0.031) in BW+V than BW-V, no differences were seen for VO_2, RER, and HR between the two conditions. During recovery, while mean VO_2 was greater (p=0.002), and RER was lower (p=0.033) in BW+V than BW-V, no differences were seen for V_E and HR between the two conditions. [La] were significantly elevated, but remain similar between the two conditions. **Conclusion**: Performing three circuits of eight BW exercises using Tabata intervals produces a sufficient increase in cardiometabolic responses. Metabolic potentiation associated with combining vibration with BW exercises seems to be influenced by how the exercises were carried out on a vibration platform.

3184   Board #53   June 2 8:00 AM - 9:30 AM

Single-joint Eccentric Knee Extension Training Induces Selective Hypertrophy: A Potential Preventive Measure Against Strain Injuries

Sumiaki Maeo[1], Xiyao Shan[1], Shun Otsuka[1], Hiroaki Kanehisa[2], Yasuo Kawakami[1]. *[1]Waseda University, Tokorozawa, Japan. [2]National Institute of Fitness and Sports in Kanoya, Kanoya, Japan.*
(No relevant relationships reported)

It is known that eccentric muscle action-induced strain injuries during sports activities (e.g. American football, soccer, etc.) often occur in the rectus femoris (RF). By using magnetic resonance imaging (MRI)-based transverse relaxation time (T_2) as an index of exercise-induced muscle edema, we recently reported that acute (unaccustomed) single-joint eccentric knee extension exercise specifically induced muscle damage in RF. **PURPOSE:** To test hypotheses that 1) single-joint eccentric knee extension training would induce greater hypertrophy in RF than its synergists, and 2) training-induced changes in muscle activity [i.e. increased electromyogram (EMG) amplitude] would be also greater for RF. **METHODS:** Twelve young males conducted single-joint isokinetic (180°/s) maximal eccentric contractions of the knee extensors 5-10 repetitions/set, 6 sets/session (3-5 sets in the initial 1-3 sessions), 2 sessions/week for 10 weeks. MRI-based anatomical cross-sectional area (ACSA) and T_2 of the quadriceps muscles [RF, vastus lateralis (VL), vastus medialis (VM) vastus intermedius (VI)] and EMG of the superficial muscles (RF, VL, VM) were measured weekly throughout the training period and pre- and post-training. Whole muscle volume of each muscle was also assessed pre- and post-training. **RESULTS:** ACSA significantly ($P < 0.05$) increased after week (W)4 or W9 in RF, VL, and VI but not in VM, without significant T_2 changes in all muscles throughout. Percentage change (%Δ) in muscle volume was significantly ($P = 0.01−0.02$) greater for RF (7.3 ± 4.5%) than VM (3.7 ± 2.9%) and VL (2.9 ± 3.0%). Agonist EMG amplitude significantly ($P < 0.05$) increased after W4 or W7 in all muscles, without significant differences in %Δ among muscles ($P = 0.292$, RF: 58.8 ± 35.0%, VL: 64.4 ± 62.0%, VM: 91.9 ± 97.3% at post). **CONCLUSIONS:** These results suggest that single-joint eccentric knee extension training induces greater hypertrophy in RF, while increases in muscle activity (i.e. neural adaptations) are similar among the synergists. Single-joint eccentric knee extension training would be a strong preventive measure against strain injuries in RF. Supported by JSPS KAKENHI (JP15J03228).

3185 Board #54 June 2 8:00 AM - 9:30 AM

Evaluation Of The LaxPrep ACL Injury Prevention Program

Kelly Comolli[1], Andrew E. Lincoln[2], Lisa Hepburn[2], Justin Cooper[2], Carissa Colangelo[2], Bruce Griffin[3]. [1]*Georgetown University School of Medicine, Washington DC, DC. [2]MedStar Health, Baltimore, MD. [3]US Lacrosse, Sparks, MD.*
(No relevant relationships reported)

Title: Evaluation of the LaxPrep ACL Injury Prevention Program
Neuromuscular-based warm-up programs are effective at reducing risk of lower extremity injury, but more research is needed on the perspective of the program instructor. LaxPrep is a lacrosse-specific, progressive 3-phase program that combines neuromuscular control, core strength, and balance training. Each phase features a series of 9-10 exercises that are to be practiced 2-3 times per week for a period of 3-6 weeks. Resistance bands are implemented in advanced phases of the program. The online training is based on the US Lacrosse website and takes 45-60 minutes to complete. **PURPOSE:** To characterize respondents who completed and implemented the LaxPrep training, which program phase was reached, and common barriers to implementation.
METHODS: A web-based survey (Tonic Health) was created and sent to 390 trainees who completed the online education course and intended to implement the LaxPrep program with their team.
RESULTS: 64 trainees (16%) responded to the survey. They included coaches, athletic trainers, and others for youth, high school, and college athletes across 27 states. 28% of respondents completed Phase 1, 28% completed Phase 2, 25% completed Phase 3, and 19% did not implement the program. Program instructors for youth teams cited 2 barriers to full implementation: the inability of young athletes to perform some of the exercises in advanced phases, suggesting the need for age-specific programs; and the accessibility and expense of resistance bands. High school and collegiate players were not as willing as youth players to participate and implement the program.
CONCLUSION: Challenges to program implementation were associated with the team's age group and included finding practice time, athlete willingness, and resistance band expense. These observations support the implementation of age-specific neuromuscular–based warm-up programs, starting at the youth level.
FUNDING: This research was supported by the US Lacrosse Center for Sport Science and the Georgetown University School of Medicine's MedStar Health Research Scholarship.

3186 Board #55 June 2 8:00 AM - 9:30 AM

The Effects Of A Shoulder Stretching And Strengthening Intervention On Shoulder Benchmarks And Disability In Collegiate Softball Players

Alicia M. Montalvo[1], Brianne Kimura[2]. [1]*Florida International University, Miami, FL. [2]Wake Forest University, Winston-Salem, NC.* (Sponsor: Greg Myer, FACSM)
(No relevant relationships reported)

PURPOSE: To investigate the effects of a shoulder strengthening and stretching program on shoulder internal rotation (IR) and shoulder external rotation (ER) range of motion, throwing speed, and disability in collegiate softball players. **METHODS:** Eighteen Division I softball players (age=19.5±1.3 yrs, height=65.3±2.6 in, weight=148.4±20.8 lbs) completed a four week arm care intervention two to three days per week before practice during the preseason. The intervention consisted of two sets of eight repetitions of five resistance band exercises (shoulder horizontal abduction, shoulder scaption-flexion, shoulder extension, and shoulder IR and ER in abduction) and three sets of a 30 second shoulder IR stretch (sleeper stretch). Bilateral shoulder IR and ER were measured by cell phone inclinometer app, throwing speed was measured by radar gun, and shoulder disability was measured by the Disability of Arm, Shoulder, and Hand form. All outcomes were measured at pretest and posttest. Paired t-tests were used to compare athletes at pretest and posttest and significance was established at p≤0.05. **RESULTS:** The mean overall compliance rate was 95.3% ±12.4. The maximum compliance rate was 100% (n=14). The minimum compliance rate was 50% (n=1). Dominant shoulder IR increased significantly (54.7±13.6° vs 60.7±12.3°, p=0.011) and throwing speed decreased significantly (53.4±4.4 mph vs 51.8±4.3 mph, p=0.005) from pretest to posttest. There were no changes in non-dominant shoulder IR (67.6±12.8° vs 74.9±15.1°, p=0.052), dominant shoulder ER (90.9±14.8° vs 86.9±16.2°, p=0.481), non-dominant shoulder ER (83.9±12.7° vs 86.1±11.6°, p=0.413), or shoulder disability (9.1±5.7 vs 12.7±10.4, p=0.871) from pretest to posttest. **CONCLUSION**: The sleeper stretch increased shoulder IR without changing shoulder ER. Four weeks' time may have been insufficient to increase strength in the newly acquired shoulder range of motion, which may have resulted in a decrease in throwing speed. Disability did not change following the intervention, though disability may have been low at the start of the preseason.

3187 Board #56 June 2 8:00 AM - 9:30 AM

Salivary Testosterone-to-Cortisol Ratio in Collegiate Gymnasts over a Competitive Season

Scott K. Crawford, Jessica L. Calvi, Jack W. Ransone, FACSM. *University of Nebraska-Lincoln, Lincoln, NE.*
(No relevant relationships reported)

Scant empirical literature can be found regarding female gymnasts' physiological hormonal responses to training and competition, especially at the collegiate level. **PURPOSE:** To understand the long-term physiological effects of a full competitive season of NCAA Division-I female gymnasts on hormonal responses. **METHODS:** Participants were 8 female athletes (ages 18-22) on the active roster of a university women's gymnastics team. Saliva samples were taken approximately 24 hours pre-competition at approximately the same time of day as schedules permitted. Saliva samples were collected via unstimulated passive drool. Salivary cortisol (C) and testosterone (T) concentration levels were determined using an enzyme immunoassay kit (Salimetrics, State College, PA, USA). Given the nested nature of the data, hierarchical linear regression models examining individual-level and team-level variables on testosterone:cortisol ratio (T:C) were conducted. **RESULTS:** The initial, simplified model indicated that T:C decreased over a competitive season ($p = 0.003$). Specifically, it was observed that T did not change over the competitive season, but C significantly increased. To examine alternative predictors over the season, other variables were examined in a second model, namely the number of events in which an athlete competed and whether the competition was a conference or non-conference competition. Conference competitions predicted significantly higher T:C than non-conference competitions ($p < 0.001$), and the number of events in which individuals competed predicted significantly higher T:C ($p = 0.001$). Surprisingly, the interaction between time and conference showed a significant decrease in T:C ($p < 0.001$), and the main effect of time became non-significant ($p = 0.186$). **CONCLUSION:** This is the first study of its kind to examine hormonal changes over a competitive season in female gymnasts. These findings indicate that the athletes had significant increases in cortisol without a corresponding increase in testosterone throughout the season, resulting in a decreased anabolic-catabolic balance. This perhaps contributed to an overtrained state as the season progressed. Further research should be conducted with this athlete population to optimize training and competition stress and recovery periods.

3188 Board #57 June 2 8:00 AM - 9:30 AM

The Effects Of The Alchemy Philosophy On Cardiovascular Health, Flexibility, And Strength

Chloe Tuma, Lana Prokop, Mark Blegen, FACSM, Joshua Guggenheimer. *St. Catherine University, St. Paul, MN.*
(No relevant relationships reported)

Various styles of fitness training target different aspects of health. By utilizing different modalities of fitness, overall health can be improved. Alchemy is a relatively new type of exercise class that offers a blend of flexibility, strength, and cardiovascular training in a group fitness setting. Little research has been done to examine the effectiveness of the Alchemy approach on fitness outcomes. **PURPOSE**: To examine the effects of eight weeks of Alchemy training on flexibility, strength, and cardiovascular performance in healthy adults. **METHODS**: 12 men and 20 women were recruited to participate in this study. The pre-intervention protocol included testing peak torque of the knee joint and examining the strength of the hamstrings and quadriceps. A Vo2max test was completed to examine cardiovascular health. Flexibility was tested by examining ROM of hip flexion, ankle arc flexion, knee hyperextension, and closed dorsiflexion. Participants height and weight were also recorded. The eight-week intervention instructed participants to attend at least two Alchemy classes per week. All classes include disciplines of yoga, strength and cardiovascular training. After the intervention, participants return for post-intervention testing to examine changes in fitness areas. **RESULTS**: 32 participants (age 31.7 ± 8.9 yrs, weight 67.9 ± 13.4 kg, height 168.2 ± 7.5 cm) completed a battery of fitness tests, which included average peak torque (APT) of the quadriceps and hamstrings of both legs (APT right extension 106.7 ± 26.6, APT left extension 105.4 ± 24.3, APT right flexion 53.8 ± 14.8, APT left extension 50.9 ± 13.3). Mean Vo2max was 50.1 ± 10.5. Flexibility as measured by right and left hip flexion, right and left ankle arc, right and left closed dorsiflexion, and right and left knee hyperextension, was 106.1 ± 13.12, 106.5 ± 13.9, 74.8 ± 10.8, 78.5 ± 10.8, 35.2 ± 5.4, 34.1 ± 6.2, 7.9 ± 2.6, 8.3 ± 3.0, respectively. **CONCLUSIONS**: These results suggest that the participants are in good physical health, which may lead to small changes from an Alchemy-based training intervention. However, there did appear to be a bilateral discrepancy in quadricep and hamstring torque production which may be worth further examination in the future.

3189   Board #58   June 2 8:00 AM - 9:30 AM

Muscle Activation of Palmaris Longus and Flexor Carpi Radialis Muscles in Different Rock Climbing Holds

Kacey Savage, Kade Worton, Nathan Stevenson, Austin Jenson, Devin Ashby, Ellis Jensen. *Utah Valley University, Orem, UT.*
(No relevant relationships reported)

Rock climbing is a popular sport with very dedicated athletes and fan base. Climbing performance, especially for new climbers, should increase when climbers develop the appropriate muscle strength to execute a variety of different climbing holds. **PURPOSE:** This study investigated which of four popular rock-climbing holds caused the greatest recruitment of the Palmaris Longus (PL) and the Flexor Carpi Radialis muscles (FCR). **METHODS:** Muscle activation was measured in eleven experienced rock climbers: seven males and four females. Electromyography (EMG) sensors were placed on PL and FCR muscles. Participants performed four different types of rock climbing holds in random order. The PL activation, in all holds, was greater than the FCR activation. **RESULTS:** The Sloper hold caused greater PL activation than the Jug, Crimp, or Pinch holds as well as greater activation for the FCR in the Crimp and Pinch holds.

Muscle Activation While Performing Climbing Holds				
Muscle Type	**Climbing Hold Type**			
	SLOPER	**JUG**	**PINCH**	**CRIMP**
Palmaris Longus m.	108.468	69.7*	77*	82.243*
Flexor Carpi Radialis m.	26.1	19.6	13.7[+]	13.53[+]
* = p<.05 compared to SLOPER in Palmaris Longus				
+ = p<.05 compared to SLOPER in Flexor Carpi Radialis				

CONCLUSION: Developing rock climbers should be able to increase their physical capacity to climb more quickly if they supplement their training with exercises aimed at increasing the strength and endurance of their PL muscle as it is highly recruited when executing holds. Ability to climb more difficult routes may advance quickly by training the Sloper hold as its performance required the greatest recruitment of both the PL and FCR muscles.

Intra-day And Inter-day Reliability Of A Combined Pre-planned And Reactive Agility Protocol

Khalil A. Lee[1], Justina L. Bonsignore[1], Timothy J. Roberts[1], Lindsay B. Baker, FACSM[2], Melissa L. Anderson[1]. *[1]Gatorade Sports Science Institute, Bradenton, FL. [2]Gatorade Sports Science Institute, Barrington, IL.*
(No relevant relationships reported)

PURPOSE: To evaluate the reliability of a novel agility protocol using a wireless light system, consisting of pre-planned and reactive agility components. **METHODS**: Seventeen male athletes (19 ± 1 yrs; 85.1 ± 9.4 kg) completed 3 sessions, each separated by 3-7 days. Each session consisted of a standardized warm-up followed by 5 trials of the protocol, assessing time to complete each trial. Subjects reported to the laboratory at the same time of day for all 3 sessions to avoid differences in circadian rhythm. Pre-trial urine specific gravity measurements, 24-h dietary recalls (to assess macronutrient intake), and visual analogue ratings (to assess physical and mental fatigue) were measured, and results suggested no baseline differences between sessions (p>0.05, ANOVA). A two-way (day x trial) repeated measures ANOVA was used to assess differences in completion times, followed by Tukey's post hoc test where main effects were found. Reliability was determined using coefficient of variation (CV). **RESULTS**: Main effects were evident for day (p<0.0001) and trial (p<0.0001), yet no interactions were present. Post-hoc results revealed significantly slower completion times during day 1 (27.76 ± 1.33 sec), but no significant difference between day 2 (27.17 ± 1.38 sec) and day 3 (27.13 ± 1.18 sec). Completion times (intra-day) were significantly slower during trial 1 (28.07 ± 1.26 sec) and trial 2 (27.49 ± 1.37 sec), but no differences existed between trials 3, 4, and 5 (27.25 ± 1.30 sec, 26.91 ± 1.27 sec, and 27.04 ± 1.16 sec, respectively). The reliability analyses suggested a high consistency (for mean of trials 3-5) within each day (CV = 2.2%, 2.2%, and 1.3% for days 1, 2, and 3, respectively) as well as between days 1-3 (CV = 1.8%). **CONCLUSIONS**: The evaluated protocol is a reliable tool that may be used for future research investigating agility performance. An initial familiarization session is warranted, followed by a minimum of two familiarizations (or warm-up trials) prior to performing an initial test trial in each successive visit. This study was funded by the Gatorade Sports Science Institute. The authors are employed by the Gatorade Sports Science Institute, a division of PepsiCo, Inc. The views expressed in this abstract are those of the authors and do not necessarily reflect the position or policy of PepsiCo, Inc.

Effects of Manipulating Stride Length on Ground Reaction Form and Wrist Velocity During Baseball Pitching.

Kevin Ritsche, Garrison Roy, Wendt Christoper, Kurt Kornatz. *Winston-Salem State University, Winston-Salem, NC.* (Sponsor: Michael McKenzie, FACSM)
(No relevant relationships reported)

PURPOSE: Stride-leg ground reaction forces have been used to predict wrist velocity during baseball pitching and are likely influenced by stride length. The purpose of this study is to determine the effect of stride length on peak vertical ground reaction forces (Fzpeak) of the stride leg and wrist velocity in skilled baseball throwers. **METHODS**: Ten collegiate baseball pitchers (6 right-handed, 4 left-handed) completed one laboratory testing session in which they were instructed to throw a baseball as fast and accurately as possible. After a standardized warmup, a total of 15 throws (5 Normal-stride [NS], 5 Over-stride (NS +10% [OS]), and 5 Under-stride (NS -10% [US]) were performed on a dimensionally correct pitching mound equipped with a force platform (1200 Hz). Marker trajectory data (32 reflective markers) was tracked from 10 high-speed cameras at 240 frames/sec. Fzpeak was normalized for body weight (N/BW) and wrist velocity (m/s) was measured at ball release. **RESULTS**: When all stride lengths were combined, significant correlations were found between Fzpeak and wrist velocity (r=0.47; p<0.01). However there was no effect of stride length on either Fzpeak (NS=1.63±0.20, OS=1.59±0.19, US=1.60±0.22; p>0.05) or wrist velocity (NS=18.27±1.03, OS=17.95±1.00, US=18.12±0.85; p>0.05). **CONCLUSIONS**: These results confirm the relation between Fzpeak and wrist velocity. However, the data indicate that skilled throwers are able to compensate for changes in stride length up to 10% to maintain performance.

Six-week Pilates Program Improves Postural Stability, Balance, And Isometric Back Strength In College-aged Athletes

Melinda B. Smith, Tyler Mitcheltree, H. Scott Kieffer, FACSM, Douglas K. Miller. *Messiah College, Mechanicsburg, PA.* (Sponsor: Dr. Diane Gill, FACSM)
(No relevant relationships reported)

Pilates training engages core musculature and utilizes controlled repetitions of various movements to improve muscular strength and endurance, flexibility, balance, and posture. Although a growing body of research identifies the benefits of Pilates training for middle-aged and older adults, little emphasis has been placed on evaluating athletic populations. **PURPOSE:** To determine the effects of a short-term Pilates training program on postural stability, balance and core isometric back strength in NCAA DIII and competitive club sport athletes. **METHODS:** The experimental group of 16 off-season college-aged female athletes participated in a supervised Pilates training program, which took place two times each week for six weeks. The 30-minute Pilates sessions consisted of body weight training that progressed to the incorporation of dumbbells. Pre- and post-test measurements were taken in three functional tests, which included Force Plate Tandem Balance (FPTB), Limits of Postural Stability (LPS), and Biering-Sorensen Back Extension (BSBE). A control group of 10 college students, who maintained their normal physical activities, but were not involved in the Pilates training program, completed pre- and post-testing for comparison. **RESULTS:** There were no significant differences between the experimental and control groups at baseline testing. The control group did not show any significant changes between pre- and post-test measurements. The experimental group decreased path length in the FPTB assessment (39.8 inches vs. 36.5 inches, p<0.05). The experimental group also exhibited significant improvement in postural control score on the LPS assessment (37.1 vs. 47.4, p<0.001). Finally, there was a significant increase in seconds held during the BSBE assessment among the experimental group (172.4 seconds vs. 187.7 seconds, p<0.05). **CONCLUSION:** A six-week progressive Pilates program contributed to significant decreases in single-foot sway, increases in postural stability, and increases in isometric back strength in female college-aged athletes.

Effect of Suspension Training on Selected Health Related Fitness and Functional Movement

Kelsey D. Bryan, A Tamlyn Shields, Alex T. McDaniel, Rachel E. Williams, Ryan Swiezy, Adrian Gonzalez, Andrew L. Ortiz, Brad R. Hollingsworth, Sarah A. Noland, Christa Douros, Raechel M. Santee, Phillip V. Morie, Lauren A. Ackerman, Emma C. Schmid, Tiago V. Barreira, Wayland Tseh. *University of North Carolina Wilmington, Wilmington, NC.* (Sponsor: Robert Wilkes Boyce, FACSM)

(No relevant relationships reported)

Although body weight training is included in the 2017 ACSM Top Fitness Trends, there is relatively little research quantifying the effects of suspension training on health-related fitness and functional movement. **PURPOSE:** To examine the impact of suspension training on selected health-related fitness variables and functional movement. **METHODS:** Fifteen individuals (11 females; 4 males; Age = 22.2 ± 3.2 yrs; Height = 172.0 ± 11.4 cm; Body Mass = 69.8 ± 19.2 kg) in a suspension training course completed 11 workout sessions over a 6-week period. Throughout each 30-minute exercise session, six body positions were utilized across push, pull, rotational, squat and lunge movements. Pre- and post-health-related fitness assessments included body composition, muscular endurance, flexibility, and a functional movement screen. Dependent t-tests were used to determine if there were mean changes in health-related fitness and functional movement. Due to multiple comparisons, Bonferroni correction was used, therefore, alpha level was set at .008. Cohen's Delta effect size was calculated for functional movement. **RESULTS:** There were no significant changes in mean fat mass, percent body fat, and push-ups. There were, however, positive changes in mean lean body mass (55.5 ± 18.4 kg to 56.3 ± 18.6 kg), sit and reach (42.2 ± 8.5 to 45.5 ± 8.3 cm, p= .004), and functional movement screen score (15.7 ± 2.1 to 17.7 ± 2.0). A large effect size was present for functional movement (Cohens' Delta = 0.98). **CONCLUSION:** Suspension training had a significant impact on lean body mass, flexibility and functional movement in as few as 11 thirty-minute sessions.

The Effects of Ballistic Exercise on Cognitive Function

Allan Shook, Joshua A. Logan, Toria A. Crispin. *Slippery Rock University, Slippery Rock, PA.*

(No relevant relationships reported)

A strong connection between physical activity and cognition has been well documented in health science. Prior research suggests a strong relationship between both aerobic exercise training and slow-controlled resistance training with improvements in cognitive function (CF). Little research exists on the influence of high-force production (ballistic) strength training on CF. **PURPOSE:** To determine the effects of ballistic strength training on CF in an apparently healthy, college-aged population. **METHODS:** 21 low-risk participants (age 18-25 years) who had refrained from any ballistic strength training for at least six months were recruited to the treatment group. 19 individuals (age 18-25 years) served as controls. Treatment and control groups continued previous aerobic and traditional (slow-controlled) resistance training during the study. Both groups completed congruent (CONG) and incongruent (INCONG) sections of The Stroop Test, and the Trail Making Test, Part B (TMT-B), at baseline, and eight weeks later. The Stroop Test assessed the number of correct answers on CONG and INCONG questions and the completion time of the test. The TMT-B measured the correct completion time of the test. The treatment group met twice weekly for eight weeks and completed a ballistic training protocol. Pre- and post-test comparisons within and between subjects on CF were assessed. **RESULTS:** Completion time for both CONG and INCONG sections of The Stroop Test significantly improved from baseline to post-test for all participants (1.65 ± 3.59, p = .006; 2.17 ± 4.60, p = .005, respectively); however, there was no significant difference in between groups (F = .921, p = .847; F = 2.696, p = .450, respectively). All participants significantly improved from baseline to post-test on the TMT-B (9.74 ± 10.48, p < .001); however, there was no significant difference between the treatment and control group from baseline to post-test (1.82 ± 3.08, p = .564). **CONCLUSION:** CF improved in the treatment and control group but was not statistically different. Future research could investigate if ballistic strength training influences CF in sedentary individuals.

The Effects of Pilates Training on Functional Movement Screen and Muscle Endurance for Cheerleaders

Yu-chen Chung, Nai-Jen Chang. *Kaohsiung Medical University, Kaohsiung City, Taiwan.*

(No relevant relationships reported)

Pilates provides a way to train core muscles. However, most researches in Pilates focus on how Pilates releases back pain. Functional movement screen (FMS) is a simple tool to assess a player's movement dysfunction. Nevertheless, there is no related research to investigate the efficacy on movement change and trunk muscular endurance after Pilates training of cheerleading dancers. **PURPOSE:** To investigate cheerleading dancers' capability of movements and muscular endurances after eight-week Pilates training. **METHODS:** Thirty cheerleading dancers were divided randomly into two groups, training (TRN: n= 15) and control (CTL: n= 15). TRN group had a regular practicing program which includes Pilates training with a licensed Pilates instructor. This training course was held three times a week, 50 minutes each course, for a total of 8 weeks. On the contrary, CTL group only maintained regular practicing. Functional movement screen (FMS) was adopted to assess capability of movements and body asymmetry, which includes seven fundamental movements (deep squat, hurdle step (HS), active straight leg raise, in-line lunge (ILL), active straight leg raise, trunk stability push up (TSPU), and rotary stability (RS). The test trunk extension, plank, and side plank were adopted to measure isometric endurance of abdominal and trunk muscles. **RESULTS:** After 8-weeks training, TRN group had significant improvements in FMS, indicating in HS (pre-test: 2.00 ± 0.53 vs post-test: 2.73 ± 0.46, p < .001), TSPU (pre-test: 1.73 ± 0.46 vs post-test: 2.2 ± 0.41, p = .004), RS (pre-test: 2 vs post-test: 2.67 ± 0.49, p < .001), totally FMS scores (pre-test: 16.40 ± 1.24 vs post-test: 19.00 ± 1.13, p < .001). Furthermore, the asymmetrical ratio on HS and ILL were improved by 67% and 100%, respectively. However, CTL group obtained few improvements. Regarding trunk endurance, TRN group had significantly increased isometric contraction time on trunk extension (p= .025), plank (p= .001), and side plank (p= .007) compared to CTL group. **CONCLUSION:** Eight-week Pilates training can significantly enhance FMS scores (movement function) and improve body asymmetrical problem. Moreover, Pilates is also helpful for increasing isometric endurance of abdominal and trunk muscles.

Assessing Changes in Absolute and Relative One-repetition Maximum Bench Press After a Six-week Blindfolded Training

Ali Boolani[1], Masoud Moghaddam[2], Timothy Baghurst[2], Timothy Jones[3], Essameldin Hamido[3], Bert Jacobson, FACSM[2]. [1]*Clarkson University, Potsdam, NY.* [2]*Oklahoma State University, Stillwater, OK.* [3]*Tennesee State University, Nashville, TN.* (Sponsor: Bert Jacobson, FACSM)

(No relevant relationships reported)

PURPOSE: This study investigated changes in one-repetition maximum (1-RM) strength on the bench press following 6 weeks of vision-deprived resistance training in college-aged individuals. **METHODS:** Fifty-three resistance-trained individuals (males = 40, females = 13; age = 19.67 ± 1.12; height = 174.25 ± 9.58 cm; weight = 85.89 ± 22.18 kg; body fat % = 13.98 ± 10.54) were recruited to participate in a 6-week resistance training intervention. Testing procedures were completed pre- to post-training intervention, including the 1-RM bench press and body composition using BODPOD. Participants were matched by 1-RM/lean mass relative bench press strength and randomly assigned to either the experimental (E) or control group (C). Both groups completed 3 sets of the following upper-extremity exercises: barbell bench press, lat pull-down. standing shoulder press. overhead triceps extension, and biceps curl) 2 days a week for 6-weeks. The experimental group performed the exercises blindfolded and the C group were visually unimpaired. The participants progressively increased the loads and decreased the repetitions every 2 weeks (weeks 1-2 = 12-15 reps; weeks 3-4 = 8-12 reps; weeks 5-6 = 6-8 reps). A repeated-measures ANOVA was used to assess changes in 1-RM bench press between the groups. **RESULTS:** Statistical analysis yielded a significant ($p < .001$) improvement in absolute (E pre= 73.9±34.3kg, post=79.5±33.8kg, C pre=84.2±35.2kg, post=87.7±35.93kg), relative to body weight (E pre=0.9±0.3, post=0.9±0.3, C pre=1.0±0.4, post=1.0±0.4), and relative to lean mass (E pre=1.1±0.3, post=1.2±0.3, C pre=1.1±0.4, post=1.2±0.4) 1-RM bench press between the pre- to post-testing. However, there were no significant differences between groups ($p > .05$). **CONCLUSION:** Although there were no statistically significant differences between groups, there was a 7.6% change for the blindfold group compared to a 4.2% change for the blindfold group compared to the control group. The large standard deviations may explain why a statistical significance was not found. Further research needs to be conducted with better matching criteria.

Cardiovascular Adaption From Altitude 3500-6400m Among Trekkers With Different Endurance Genotype Scores

Yutao Du, Lei Kuang, Jun Cao, Meng Li. *Sport Genomics Institute, BGI, Shenzhen, China.*

(No relevant relationships reported)

Purpose: to explore if and how the endurance genotype score would affect the cardiovascular adaption under reduced oxygen caused by the altitude elevation. **Method:** All 9 trekkers who participated in a 8000 meter peak climbing is studied. Nine genes (ADRB2,AQP1,COL5A1,NRF2,HFE,KCNJ11,PPARD,UCP3,HIF1A) that reported to be associated with endurance performances were measured and the total genotype score were obtained by adding up the genotype score of each genes. The trekkers were divided into two groups according to their genotype scores as high endurance group (score>0) and low endurance group (score<0). We defined cardiovascular adaption as the changes of morning pulse, systolic blood pressure and blood oxygen concentration. These parameters for cardiovascular adaptions were measured every 300-400 elevation of the altitude from 3500 m to 6400 m. Mean changes for each of parameters were compared for the two groups during the whole course.

Results: There were four trekkers in the low endurance group and five trekkers in the high endurance group (score: -2.5 vs.1.0). Due to small study sample, none of the comparison show statistical significance at 0.05 level. However, we were able to find that the high endurance score group maintained a higher blood oxygen level and smaller oxygen fluctuation as the altitude elevation. Though the systolic blood pressure showed higher fluctuation in the high endurance score group, mean systolic blood pressure were 3-13 mmHg lower at different altitudes. We also viewed that morning pulse increased as the altitude increased in both groups. However, compared to low endurance group, the mean pulses were lower for the high endurance group for each altitude from 3800m and above.

Conclusion: Different genotypes scores may indicate different oxygen carrying and utilizing ability which resulted in different cardiovascular adaptation manifestation among the trekkers.

Figure 1. Comparison of the Blood Oxygen Concentration Fluctuation from Altitude 3500 to 6400 meter

Figure 2. Comparison of the Systolic Blood Pressure Fluctuation from Altitude 3500 to 6400 meter

Figure 3. Comparison of the Morning Pulse Fluctuation from Altitude 3500 to 6400 meter

Optimal Load For High-Speed Exercise

Ling Bai, Ema A. Selimovic, Rebecca Mueller, Samantha Beatty, Kathy A. Carter, Thorburn B. Symons, George Pantalos, John F. Caruso, 40292. *University of Louisville, Louisville, KY.*

(No relevant relationships reported)

PURPOSE: Identify an optimal load for knee extensions done on an exercise device called the Impulse (Impulse Technologies; Newnan GA). **METHODS**: Subjects (29 women, 15 men) made six laboratory visits. The first two visits entailed familiarization to the knee extension exercise. For their last four visits they did four 30-second knee extension sets with different loads (0, 3.4, 5.7, 8.0 kgs.) added to the Impulse weight sled per set. A Latin Squares design counterbalanced the set sequence, which limited the risk of an order effect and fatigue's impact on our results. Subjects rested 120 seconds between sets and were told to exert maximal effort. Average and peak force (AF, PF) data were each analyzed with a 2 (gender) x 4 (load) ANOVA, with repeated measures for load. Alpha = 0.05 and T-tests served as our post-hoc. **RESULTS**: AF and PF results (mean ± sem) appear below:

Average force (N)	0 kgs.	3.4 kgs.	5.7 kgs.	8.0 kgs.
Women	38.4 ± 1.5	70.1 ± 2.8	84.3 ± 3.5	92.8 ± 3.5
Men	44.5 ± 2.2	76.2 ± 4.4	85.9 ± 7.3	101.5 ± 6.2

Peak force (N)	0 kgs.	3.4 kgs.	5.7 kgs.	8.0 kgs.
Women	400.4 ± 21.8	708.1 ± 39.8	810.1 ± 44.9	857.3 ± 47.7
Men	529.5 ± 38.5	936.2 ± 69.3	1100.8 ± 77.2	1174.3 ± 76.7

Analysis of AF yielded a load effect, while PF produced a two-way interaction, in which men produced higher values than women for each load.
CONCLUSIONS: Results show significant inter-gender PF, but not AF, values per load examined.

A Preceding Bout of Endurance Exercise Decreases Peak Power of the Arm Extensor Muscles

Luke Olsen[1], Bjorn Hansson[2], Tommy R. Lundberg[3]. [1]*University of Kansas, Lawrence, KS.* [2]*The Swedish School of Sport and Health Sciences (GIH), Stockholm, Sweden.* [3]*Karolinska Institute, Stockholm, Sweden.*

(No relevant relationships reported)

The combination of aerobic exercise (AE) and resistance exercise (RE) within a given training protocol, termed concurrent training (CT), lacks sufficient analysis concerning the upper body. In the lower body knee extensor muscles, we have previously demonstrated reduced peak power when AE precedes RE. However, postural requirements of the lower body, as compared to the upper body, may give rise to unique responses following CT. Thus, further investigation as to specific peak power alterations of the upper body muscles are warranted. **PURPOSE**:To investigate the effects of a preceding AE bout on muscle strength to subsequent RE of the arm extensors. **METHODS**: Healthy men (*n*=8) performed AE+RE (CT) for the elbow extensors in one arm, while the contralateral arm performed RE only. The AE consisted of unilateral, moderate endurance exercise (43±2 min of repeated elbow extensions) using an isokinetic dynamometer. After 15-min rest, subjects performed unilateral RE (4x7 iso-inertial RE) with a flywheel device for both arms targeting the arm extensor muscles. Work produced during AE and peak concentric power during RE were recorded. **RESULTS**: The AE bout resulted in a gradual increase in heart rate (126±12 bpm) with a parallel increase in RPE reaching the termination threshold (18±0.5 RPE). The implementation of AE prior to RE led to a 21% decrease (*p*=0.045) in arm extensor peak concentric power from 98W to 78W, respectively. There was no change in performance from pre- to post in the RE-only arm (94W to 89W). **CONCLUSIONS**: These results demonstrate that the implementation of AE prior to RE, as compared to RE alone, compromises peak concentric power adaptations of the arm extensors. The noticeable decrement in peak concentric power between pre- and post from the CT intervention (21%), relative to a similar study with the same testing protocol which targeted the lower body (10%), gives credence to the possibility that upper and lower body muscles respond differently to concurrent training.

Quality of LifeImproved by Adequate Physical ActivityLevels Among University Employees

Gustavo Mendoza, Kenneth R. Ecker, FACSM. *University of Wisconsin, River Falls, WI.* (Sponsor: Kenneth Ecker, FACSM)

(No relevant relationships reported)

PURPOSE: The purpose of this study was to determine if quality of life is affected through different levels of physical activity and compare those to the national norms. This study also looked at the number of ACSM cardiovascular disease risk factors and different physical activity levels among university faculty.
METHODS: An SF-36, I-PAQ, and Health Questionnaire form was handed out to the participants to complete to the best of their knowledge.
RESULTS: Comparative analysis showed that there was a significant positive difference among the participants who were HEPA active in general health (p = 0.0354) and the active group in comparing emotional well-being (p = 0.0346) and physical functioning (p = 0.0498) when using one-way ANOVA. A Tukey-Kramer post hoc test was performed to prove honestly significant difference.
CONCLUSION: The results indicate that the university faculty had better quality of life scores in certain parts of the SF-36 sub-scales when being active and HEPA active. The university faculty seem to be at risk for some cardiovascular disease risk factors in which the need to reduce the risks by implementing an exercise-based health and wellness program within the university workplace should be considered in university workplace policies.

Lower VO$_2$max In Individuals With A Family History Of Diabetes is normalized After 8-weeks Exercise

Mario Garcia[1], Manuel Amador[1], Cesar Meza[1], Christopher Figueroa[1], Andrew McAinch[2], Sudip Bajpeyi[1]. [1]University of Texas at El Paso, El Paso, TX. [2]Victoria University, St. Albans Campus, Melbourne, Australia.

(No relevant relationships reported)

A family history of type 2 diabetes (FH+) is considered a risk factor for insulin resistance and poor cardiorespiratory fitness. However, it is not known if exercise induced improvement in maximal aerobic capacity (VO$_2$max) is impeded by a FH+. **PURPOSE**:The purpose of this study was to determine if normoglycemic, sedentary, Hispanic men with FH+ have a lower VO$_2$max compared to those without a family history of type 2 diabetes (FH-) and if the improvement in VO$_2$max after 8-weeks of combined exercise training is comparable between FH- and FH+.**METHODS**: 19 participants (mean ± SEM: age:23±0.56 years; BMI: 26.9±0.98 kg/m^2) underwent 8 weeks of combined exercise training (35 min aerobic at 60-75% VO$_2$max followed by 6 full-body resistance exercises (3x/week)). VO$_2$max was measured using ParvoMedics 2400 metabolic measurement system during a standardized graded exercise test performed on a treadmill. Body composition was assessed by DXA. **RESULTS**: VO$_2$max was significantly lower in FH+ compared to FH- at baseline (3.57 ± 1.7 vs. 4.08 ± 0.15 L/min; p=0.04). After 8 weeks of combined exercise training FH+ significantly improved VO$_2$max (3.57 ± 0.17 to 3.82 ± 0.16 L/min; p=0.002), whereas no improvement was observed in FH- (4.08 ± 0.15 to 4.21 ± 0.17 L/min; p=0.16). There was no difference in VO$_2$max between groups after 8 weeks of exercise training (p=0.67). Lean body mass significantly improved in both groups (FH- 56.6 ± 2.1 to 58.5 ± 2.1 kg; p=0.01; FH+ 51.8 ± 1.95 to 53.4 ± 1.79 kg; p=0.01) and fat mass remained unchanged (p=0.38). **CONCLUSIONS**: A family history of diabetes may negatively impact cardiorespiratory fitness in a normoglycemic, sedentary, Mexican American population. A combined exercise training program (8 weeks) is effective in normalizing this defect.

Effects of chronic endurance exercise training on serum 25(OH)D concentrations in elderly Japanese men

Xiaomin Sun [1, 2, 7], Zhen-Bo Cao [3, 7*], Kumpei Tanisawa [4, 7], Hirokazu Taniguchi [5], Takafumi Kubo [6], and Mitsuru Higuchi FACSM [7]

[1] School of Public Health, Xi'an Jiaotong University, [2] Global Health Institute, Xi'an Jiaotong University, [3] School of Kinesiology, Shanghai University of Sport,[4] National Institutes of Biomedical Innovation, Health and Nutrition,[5] Faculty of Agriculture, Ryukoku University, [6] Graduate School of Sport Sciences, Waseda University,[7] Faculty of Sport Sciences, Waseda University

Higher levels of physical activity and cardiorespiratory fitness are positively related to serum 25-hydroxyvitamin D [25(OH)D] concentrations; however, the response of 25(OH)D concentrations to chronic endurance exercise training is unclear. **PURPOSE:** To elucidate whether serum 25(OH)D concentrations were directly increased by 5 weeks of endurance exercise training and influenced by changes in body fat in elderly men. **METHODS:** Twenty elderly Japanese men were randomized to either the 5-week endurance exercise training group (ET group; N=10) or the sedentary control group (SC group; N=10). Fasting blood samples were collected to determine serum 25(OH)D and other blood parameters. The visceral fat area and hepatic fat content were assessed by magnetic resonance imaging and proton magnetic resonance spectroscopy, respectively. **RESULTS**: After 5 weeks of endurance exercise training, the levels of maximal oxygen uptake (VO$_2$max) were significantly increased from 23.3 at baseline to 28.1 mL/kg/min at the endpoint for the ET group; levels were unchanged for the SC group. A significant seasonal reduction in serum 25(OH)D concentrations was observed in the SC group (P<0.05), while no change was found in the ET group. The results may be

partly attributed to the slight decrease in intrahepatic fat in the ET group. No changes were observed in percent body fat or visceral fat area. **CONCLUSIONS:** The results of our study suggest that 5 weeks of endurance training could inhibit the seasonal reduction in serum 25(OH)D concentrations without changes in body fat.

The Effect of Hyperthermic Whole Body Heat Stimulus (Sauna) on Heat Shock Protein 70 and Skeletal Muscle Hypertrophyin Young Males

Brandon Jones, Scott Drum, FACSM. *Northern Michigan University, Marquette, MI.* (Sponsor: Scott Drum, FACSM)

(No relevant relationships reported)

PURPOSE: The aim of this study was to investigate if stimulating HSP70 by using a sauna (45 - 50◦C, 80% Humidity) three times per week, for 15 minutes, could aid skeletal muscle hypertrophy during six weeks of resistance training in a young (21.38 ± 1.9 yrs.), recreationally trained male population. **METHODS**: Thirteen subjects were randomly distributed into 3 groups [resistance Training + sauna (RT+S, n=5), RT + Relaxation (RT+R, n=5), and complete control (CON, n=3) or no training]. Primary dependent variables, observed in a pre- and post-test format, included: lean body mass (LBM), HSP70 concentration, and a 5 repetition maximum (5RM) back squat. **RESULTS**: When comparing groups (i.e., RT+S, RT+R, and CON), no significant main effects or interactions were observed (p > 0.05) over the 6-week intervention period for LBM, HSP70, and 5RM. The hypothesis that HSP70 would be upregulated to a greater extent with concurrently larger LBM and 5RM improvements in RT+S vs. the other groups was not supported. **CONCLUSIONS**: Although HSP70 and LBM were highest in RT+S after 6-weeks of heavy resistance training, RT+R improved the most on 5RM. Sauna use in combination with resistance training does not appear to augment muscle hypertrophy or strength. Despite this, it appears using sauna post RT does not hinder muscle growth and may be a viable strategy for maintaining muscle mass.

3204 Board #73 June 2 8:00 AM - 9:30 AM

Cost-Effective Personal Training Aid to Improve Leg Function Using Smart Exercise Application: Pilot Study

Byungjoo Noh, Eric Vasey, Kevin Phillips, Derek Verbrigghe, Myounghoon Jeon, Tejin Yoon. *Michigan Technological University, Houghton, MI.* (Sponsor: Sandra Hunter, FACSM)

(No relevant relationships reported)

As a personal training aid, a smart exercise application (SEA) has been developed to improve leg function such as balance and endurance.**PURPOSE**: The purpose of this study was to evaluate the functionality of SEA and validate the data output. **METHODS**: Thirteen healthy young adults (25.4 ± 8.3 years) attached an inertial measurement unit sensor (IMU; MetaWear C; mbientlab, Portola, San Francisco) and a research level accelerometer (ACC; Trigno wireless, Delsys Inc., Boston) on their thigh. Subjects sustained a one-leg half squat posture with 45 degrees of knee flexion as steady and accurate as possible. During the experiment, 3-axis acceleration data were collected using an IMU and ACC at 100 Hz and 1000 Hz respectively. The vertical direction acceleration was displayed as visual feedback on three different zones such as safety, warning, and failure. In addition to visual feedback, SEA created no sound, a warning sound at 1 Hz, and a high-frequency warning sound at 3 Hz on each zone respectively. As the acceleration exceeded a particular threshold value or passed the failure zone for a certain amount of time, the task was terminated and the time was logged as endurance time. The accuracy of IMU was assessed through Pearson's correlation between two data sets obtained from two systems. Bland-Altman plot was used to evaluate the discrepancy between measurements. **RESULTS**: Our application provided visual/auditory feedback as required and determined the task failure objectively. Our application was able to collect acceleration data accurately, as assessed by correlation and Bland-Altman plot. Correlations (r = 0.90 to 0.99, P < 0.001) between the output from the IMU and the reference output from the ACC were high. Bland-Altman plot also showed a low discrepancy between each of the two measures. The mean bias across all axes was -0.01 ± 0.01 m/s^2 with 95% LOA ranging from -0.14 to 0.13 m/s^2 (x-axis: 0.01 ± 0.04 m/s^2 (95% LOA: -0.07 to 0.09 m/s^2), y-axis: -0.02 ± 0.10 m/s^2 (95% LOA: -0.21 to 0.18 m/s^2), and z-axis: -0.01 ± 0.06 m/s^2 (95% LOA: -0.13 to 0.11 m/s^2)). **CONCLUSIONS**: These results suggest that there is potential for the application as a cost-effective personal training aid in the future. It may be useful in long-term interventions such as home-based training aimed at increasing balance and endurance in a healthy or clinical population.

Changes In Upper-body Strength Are Dependent On Training Mode And Independent Of Strength Level

Jerry L. Mayhew[1], Jensynn Kasper, 63501[1], William F. Brechue, FACSM[2], Jana L. Arabas[1]. *[1]Truman State University, Kirksville, MO. [2]A. T. Still University, Kirksville, MO.*

(No relevant relationships reported)

Previous research has shown upper-body muscular strength gains are independent of fat-free mass (FFM) in men. Further, initial strength is typically higher when evaluated with machine weights (MW) than with free weights (FW). Lacking is information comparing the training effects of FW versus MW in men with comparable initial strength levels. **PURPOSE**: To evaluate the effect of resistance training (RT) using different modes on changes in upper-body muscular strength when controlling mode-specific initial strength.
METHODS: College men (n = 1,331) enrolled in a RT course volunteered to participate and initially performed 1RM bench press using free-weights (FW), seated horizontal press (SHP) or supine vertical press (SVP). FW (n = 218), SHP (n = 270), and SVP (n = 208) groups were matched for mode-specific initial strength. Groups were further divided into low, average, and high strength based on the bottom, middle, and top one-third of mode-specific 1RM. Each participant performed 12 weeks of linear periodization mode-specific RT using progressively heavier loads and reduced repetitions designed to achieve maximum strength improvement. Each participant performed auxiliary upper- and lower-body supplemental exercises in 3 sets of 6-10 repetitions.
RESULTS: A mode x strength level ANOVA noted significantly greater improvement with SHP (12.5 ± 7.0 kg) than with SVP (10.7 ± 7.0 kg) which was greater with FW (6.8 ± 5.9 kg) but no significant difference among low (10.3 ± 7.4 kg), average (10.4 ± 6.2 kg), and high (9.8 ± 7.9 kg) strength levels. The interaction was not significant (p = 0.45). The relationships between initial strength and strength change was nonsignificant and similar in SHP (r = 0.01), FW (r = -0.05), and SVP (r = 0.06).
CONCLUSIONS: Men of differing strength levels gain similar amounts of upper-body strength when training with different RT modes. In participants with equal initial strength, training with one mode does not appear to offer any significant advantage over training with a different mode.

3206   Board #75   June 2 8:00 AM - 9:30 AM

Testosterone Response Following Five Crossfit® Open Workouts

Paul Serafini[1], Trisha VanDusseldorp[1], Yuri Feito, FACSM[1], Alyssa Holmes[1], Adam Gonzales[2], Gerald Mangine[1]. *[1]Kennesaw State University, Kennesaw, GA. [2]Hofstra University, Hempstead, NY.* (Sponsor: Yuri Feito, FACSM)

(No relevant relationships reported)

PURPOSE: To determine the effect of sex and lean mass (LM) on the testosterone (T) responses to five unique CrossFit® Open (CFO) workouts. **METHODS:** LM was measured via Dual-Energy X-Ray Absorptiometry (DXA) within two weeks of the onset of the 2016 CFO in recreationally-trained adults (males-n=5, 34.4±3.8 yrs, 175.5±5.1cm, 80.31±9.7kg; females-n=5, 35.5±7.0yrs, 159.0±7.1 cm, 76.93±21.4kg). During each week of the 5-week competition, saliva samples were collected prior to (PRE) the competitors' warm-up, immediately (IP), 30- (30P), and 60 min post-exercise (60P) and analyzed for concentrations of T. All workouts were completed at the same gym; mid-day during the first four weeks (WK1-WK4) and on the night of the final challenge's release (WK5). Separate two-way (sex x time) repeated measures analyses of variance were performed to assess the percent change from PRE-values in T during each week. Pearson's correlation coefficients were calculated between all LM measures and T responses, quantified as the area under the curve, of each week. **RESULTS:** Although no (sex x time) interactions were found, significant (p<0.05) main effects for time were observed on WK2-WK4 where T was elevated from PRE at IP (162.1-191.7%, p≤0.015) and 30P (40.2-59.8%, p≤0.040). T was also elevated at 60P on WK3 (62.8%, p=0.015). Additionally, a trend (p<0.01) was noted for elevated T at IP (p=0.077) and 30P (p=0.033) on WK1. The T response was not related to any LM measure **CONCLUSION:** The majority of the CFO events observed in this study elicited an elevation in salivary T from PRE-values. These elevations were not affected by the athlete's sex or quantity of LM.

A Preliminary Investigation of the Relationship Between Training Volume and Body Fat in Triathletes

Barbara S. McClanahan[1], Michelle Stockton[1], Christopher Vukadinovich[2]. *[1]University of Memphis, Memphis, TN. [2]St. Jude Children's Research Hospital, Memphis, TN.* (Sponsor: Lawrence Weiss, FACSM)

(No relevant relationships reported)

PURPOSE: Appropriate levels of body fat are critical to optimal health and athletic performance, particularly for endurance athletes such as the triathlete. Therefore, the purpose of this study was to explore the potential relationship between body fat percent and training volume in triathletes over a competitive season while controlling for caloric intake.
METHODS: Participants were 12 male and 13 female triathletes. Body fat percent, determined through dual-energy x-ray absorptiometry, for male and female triathletes was 13.3% (±4.63%) and 21.4% (±6.12%) respectively. Training volume was determined by exercise duration and intensity over 24 weeks. Caloric intake was assessed through a seven-day dietary recall.
RESULTS: Average daily energy intake was 2,366 (±714) kcals/day for all participants, males reported consuming an average of 2,776 (±774) kcals/day and females reported consuming 1,987 (±386) kcals/day. Overall training volume (Intensity*min) for the 25 participants over the 24-weeks was 37,661 (±16,478), with males averaging 44,948 (± 18,433) and females averaging 30,934 (± 11,377). For males, a bivariate correlation revealed that total training volume (r = -0.66) was significantly associated with body fat percent. However, total training volume was not statistically significantly related to body fat percent for females. Preliminary analyses using multiple linear regression indicated that for males the independent variable (total training volume) explained 49% of the variance in body fat percent (p < .05) while controlling for total kcals. Training volume was a significant predictor of body fat percent for males (β = -0.976; t = -2.40; p = 0.04). For females, the multiple regression indicated that there was not a significant amount of the variance explained in body fat percent by training volume while controlling for kcals.
CONCLUSIONS: Given its potential impact on athletic performance and overall health and wellness it is important to consider possible contributors to body fat. It was surprising to document a significant influence of training volume on body fat percent in men but not women in this study. Further studies are needed to better understand the current findings.

3208   Board #77   June 2 8:00 AM - 9:30 AM

The Effects of Gender and Training Status on Optimal Loads for Developing Muscular Power

Ryan M. Miller, Eduardo D.S. Freitas, Aaron D. Heishman, Japneet Kaur, Karolina J. Koziol, Bianca A.R. Galletti, Michael G. Bemben, FACSM. *University of Oklahoma - Department of Health& Exercise Science, Norman, OK.* (Sponsor: Michael G Bemben, FACSM)

(No relevant relationships reported)

Muscular power is required in varying degrees for differing situations (fall prevention, sport performance, etc.) and populations (athletes, elderly, clinical populations, etc.). Generally, greater muscular power is achieved at lower percentages of maximal strength (1RM); however, these intensities have not been evaluated based on gender or training status. **PURPOSE**: To determine the optimal loading intensity for developing maximal lower and upper body muscular power for trained and untrained men and women. **METHODS**: Forty-one men and women (resistance trained or untrained) completed a 1RM test for the leg press and barbell bench press. Following at least 48 hours, subjects returned to perform single repetitions, in randomized order, at 20, 30, 40, 50, 60, 70 and 80% of their 1RM for each exercise to determine lower and upper body muscular power. Mixed-model ANOVAs were used to determine if there were any significant differences between the within-subject variable (intensity or %1RM) and between-subject factors (gender and training status). **RESULTS**: Significant main effects were observed for intensity (F=44.2, p<0.001) and gender (F=31.3, p<0.001) for the leg press with males producing more power at each intensity with maximal power output occurring at 60% 1RM (which was significantly different (p<0.001) from 20, 30, 40% 1RM but not different from 70 or 80% 1RM). The bench press analyses revealed significant main effects for intensity (F=54.7, p<0.001), gender (F=101.9, p<0.001) and training status (F=17.5, p<0.001), as well as significant interactions for %1RM X gender (F=10.2, p<0.001) and %1RM X training status (F=3.2, p<0.001). Males produced more power (p<0.001) at each intensity with maximal power output occurring at 50% 1RM compared to females who produced maximal power at 40% 1RM. Trained subjects had significantly higher power outputs (p<0.001) at each intensity with the greatest power produced between 40-60% 1RM, while untrained subjects achieved maximal power between 40-70% 1RM. **CONCLUSION**: In order to obtain maximal power outputs for large lower or upper body muscle groups, relatively low intensities ranging between 40-70% 1RM depending on gender and training status should be used.

Abstracts were prepared by the authors and printed as submitted.

Influence of Psychosocial Wellness Factors on Training Duration in Triathletes

Michelle B. Stockton[1], Barbara McClanahan[1], Christopher Vukadinovich[2]. *[1]University of Memphis, Memphis, TN. [2]St. Jude Children's Research Hospital, Memphis, TN.* (Sponsor: Lawrence Weiss, FACSM)

(No relevant relationships reported)

PURPOSE: Training duration is an important factor in athletic performance, especially long endurance events such as triathlons. While the majority of attention in training duration has focused on physical factors, psychosocial wellness factors may also influence training duration. Therefore, the purpose of this study was to explore the influence of psychosocial wellness on triathlete training duration.
METHODS: Participants established their own training regimen and recorded training duration (minutes) for each sport. Total training duration was calculated by summing training duration for each sport across six months. Participants also completed a multi-dimensional wellness assessment during the laboratory visit. The 70-item self-report assessment consisted of seven subcategories with Likert scale responses 1-5. Total scores were calculated for each category as well as a composite wellness score.
RESULTS: Participants were 14 male and 9 female triathletes. Total training duration for all participants was 12,880 (±5536) minutes over 6-months with males reporting an average of 13,435 ($\pm$ 5990) total minutes, and females reporting 12, 017 ($\pm$ 4961) total minutes. Preliminary analyses using multiple linear regression indicated that the multiple-dimensions of psychosocial wellness (drugs and driving, social, emotional awareness, emotional control, intellectual, occupational, and spiritual) explained 73.8% of the variance in total training duration for all the participants (p = .002). Social (β = .804), intellectual (β = -.757), occupational (β = 1.091), and spiritual (β = -.749) were significant predictors at the univariate level. For males, the multiple-dimensions of wellness explained 94.3% of the variance in total training duration (p = .002) with social (β = 1.226), intellectual (β = -.650), occupational (β = 1.332), and spiritual (β = -.914) being significant predictors. For females, the psychosocial wellness factors did not significantly influence training duration.
CONCLUSIONS: Study results illustrate the importance of understanding potential psychosocial influences on training duration for triathletes. Further research is needed to determine the multiple dimensions of psychosocial wellness on all aspects of training in order to develop ideal strategies for optimal performance.

Effects Of High Concentration Oxygen Intervention On Physiological Recovery From High Intensity Hammer Throwing Training

Chung-Wen Chen[1], Szu-Kai Fu[2], Jen-Chun Lo[2], Kuo-Wei Tseng[2], Chang-Chi Lai[2]. *[1]National Taiwan Sport University, Taoyuan City, Taiwan. [2]University of Taipei, Taipei City, Taiwan.*

(No relevant relationships reported)

Purpose: To investigate the effects of high-concentration oxygen inhaled on repeated hammer throwing efficiency and the recovery of physiological fatigue. **METHODS**: Five hammer players completed 10 throws with both normobaric oxygen and high-concentration oxygen interventions with a 7-day interval. Each bout consisted of 10 repeated throws with a 5-minute rest between each throw. For high-concentration oxygen intervention, each subject was given 5 minutes of highly concentrated oxygen inhalation after each throw; no specific application for normobaric oxygen intervention. Distance, blood lactate (La), rating of perceived exertion (RPE), heart rate (HR) and recovery heart rate were measured at baseline (pre-exercise) and after each throw.
Results: All variables were changed significantly after the 1st-10th throws ($p < .05$) following high-concentration and normobaric oxygen intervention, but no significant intervention × times was found in all dependents variables (Distance, La, RPE, HR and recovery heart rate) during the repeated throws. **Conclusion:** The results suggested that high-concentration oxygen inhalation intervention did not improve the rate of blood lactate metabolism, and the recovery of heart rate and rating of perceived exertion after high intensity throws.

Effects Of A Caffeine-carbohydrate Mouth Rinsing On Sprinting Kinetics And Kinematics In Fasted Athletes

Jad-Adrian Washif[1], Christopher Martyn Beaven[2]. *[1]national Sports Institute Of Malaysia, Kuala Lumpur, Malaysia. [2]university Of Waikato, Hamilton, New Zealand.*

(No relevant relationships reported)

Carbohydrate mouth rinsing during an intermittent fasting has been reported to be advantageous for endurance performance; however, there appears to be no clear effect on repeated sprints. What has not been investigated previously is the effects of combined caffeine and carbohydrate (CAF-CHO) mouth rinsing on speed-endurance performance commonly performed by track and field athletes during a fasted state.
PURPOSE: To determine the influence of CAF-CHO mouth rinsing on sprinting kinetics and kinematics, as well as subjective exertion during a speed-endurance bout performed in a fasted state. **METHOD:** In a counterbalanced, single-blind random order design, eleven (n = 11) well-trained National level male sprinters and middle-distance runners performed three 15-sec all-out sprints on a Woodway nonmotorized force treadmill, interspersed with 2-min active recovery between sprints. Athletes rinsed 25 ml of CAF-CHO (4g carbohydrate, 5 mg caffeine), or a similarly coloured placebo solution (PLA) prior to warm-up (30-min pre-trial), 1-min pre-trial, and the mid-way of each period of active recovery. On one occasion, no mouth rinse (NMR) was administered. The study was conducted within the second and third quarters of Ramadan, and each session separated by at least 72 hours. **RESULTS:** At the start of each trial, the rating of perceived exertions (RPE), readiness to train, blood glucose, and lactate concentrations were similar (p > 0.05). A significant primary effect of trial (3 x 15 seconds sprint) was observed for the distance (p = 0.019), revealing a longer average distance achieved in the CAF-CHO compared to PLA trial (69.80 $\pm$ 3.57 vs. 68.08 $\pm$ 3.22; p = 0.026; EF: 0.5), and NMR (69.69 $\pm$ 3.82; p = 0.680; EF: 0.2). The difference between NMR and PLA also approached significance (p = 0.073; ES: 0.5). The CAF-CHO intervention also obtained better results in all other sprint measures such as average velocity, peak acceleration, and peak horizontal force, although these differences were not significant. Post-trial RPE was higher during NMR (7.23 $\pm$ 1.92) as compared to CAF-CHO (6.54 $\pm$ 2.15) and PLA (6.38 $\pm$ 1.94) (p = 0.247).
CONCLUSION: In challenging metabolic conditions, CAF-CHO mouth rinsing might have potential to improve measures of sprint training performance with a positive ergogenic effect on speed endurance performance.

Association of Performance Physiology Measures with Sports Performance Tests

Therese Wichmann, Marissa Burnsed-Torres, Michael Hahn. *University of Oregon, Eugene, OR.*

(No relevant relationships reported)

PURPOSE: Common fitness tests such as the Yo-Yo Intermittent Recovery Test and the Beep Test have previously been validated against laboratory-based assessments and shown to be accurate. The purpose of this study was to assess whether the Gauntlet, an unexplored fitness assessment, was an accurate assessment of individual fitness compared to standard laboratory-based physiological tests. The Gauntlet test requires athletes to complete a set of maximal effort runs, with a one-minute break in between each stage (Stage 1: 814.6m, Stage 2: 907.3m, Stage 3: 453.7m, Stage 4: 226.8m, Stage 5: 100m) with the goal of achieving the best overall time. **METHODS:** Subjects (n=18) first completed a lactate threshold test and VO_{2max} test in the laboratory. After four to fourteen days, subjects then completed the Gauntlet on an outdoor track. Lactate, VO_{2max} and heart rate were recorded during the laboratory session, and heart rate, lactate, and time of completion per stage and overall time to completion were recorded during the Gauntlet test. **RESULTS:** Preliminary correlation analyses showed a positive relationship between VO_{2max} (ml·kg^{-1}·min^{-1}) to Time to Completion of the Gauntlet (r = 0.89, P= 1.29E-15), VO_{2max} Maximum Heart Rate to Gauntlet Maximum Heart Rate (r = 0.80, P= 0.0011), and VO_{2max} 3-min Post Lactate to Gauntlet 3-min Post Lactate (r = 0.66, P= 0.0188). **CONCLUSION:** These results indicate that the Gauntlet is an accurate estimate of aerobic fitness when compared to laboratory-based physiological tests. Therefore, the Gauntlet could be implemented into common exercise programs or sport specific training to assess an individual's level of fitness without the need for laboratory testing.

Effects of Depth Jump Implementation on Sprint Performance in Collegiate and Club Sport Athletes

Ryan Bean, Michael Lane, Aaron Sciascia, Matthew Sabin.
Eastern Kentucky University, Richmond, KY.
(No relevant relationships reported)

Introduction; Depth jumps (DJ) are popular high-intensity plyometric exercises typically reserved for highly-trained individuals. DJs cause an individual to undergo high amounts of stress during the eccentric and concentric phase. This extreme loading allows individuals to increase lower body strength and power output. Muscular strength and power have a transfer effect to sprint speed; however, few have examined if implementing DJs into training can increase sprint speed.
Purpose; The purpose of this study was to determine if the implementation of DJs into a sprint training program would increase sprint speed more so than sprinting alone.
Methods; 5 collegiate level and 13 club level athletes participated in this study (6 males and 13 females). Subjects performed 3 maximal 40-yard sprints with 3 to 5 minutes of rest between sprints. Subjects were randomized into either a control group, a sprint training group, or a DJ group. The DJ and sprint group performed 2 training sessions/week, with both groups performing the same sprint training protocol. The DJ group had DJs of varying intensities. Following 6 weeks of implementation, subjects were retested on the 40-yard sprints in the same manner as before.
Results; One-way ANOVA were conducted using paired comparisons to determine significance. Significant differences were observed after implementation for the 40-yard sprint (-.24±.43s) (P<.01), 20-30yard split (-.13 ± .11s) (P<.05), and a 20-40yard split (-.20 ± .18s) (P<.01). No differences were observed between groups. The DJ group changes showed the largest effect sizes of any group in these measures; 1.12, 1.6, and 2.5 respectively.
Discussion; The effect sizes of the changes in sprint speed demonstrate that DJs may benefit sprint speed. It can be concluded from this study that maximal sprint speed was improved more so than acceleration due to the improvements observed from 20-30yards and 20-40yards. These indicate the maximal speed phase of sprinting. Further research is needed to determine if DJs can improve sprint performance in highly-trained athletes.

Comparison Of The Effects Of A Novel Structured Nanotechnology Water On Physical Performance.

ALI K. M. SAMI[1], Gary Liguori, FACSM[2]. *[1]College of Medicine/University of Sulaymany, Sulaymany, Iraq. [2]University of Rhode Island/College of Health Sciences, Kingston, RI.*
(No relevant relationships reported)

Purpose
A new type of water that uses nanotechnology to alter the physical and chemical properties of water molecules to enhance its bioavailability was compared to other commonly consumed beverages for the effect on physical performance.
Methods
Thirty male college athletes (21-23 y) were randomly divided into three groups, nanotechnology structured water (N), Gatorade (G), ordinary water (W) for a 3-month training program. Participants were blinded to their beverage and were instructed to consume their respective beverage at 500 ml/kg body weight over the course of each day during the 3-month training period, with other fluids consumed ad libitum. All participants completed the same set of pre-post physical tests: resting heart rate (RHR); sprinting; jumping, in which participants jumped 10 consecutive times with the difference in height jumped between the first and last jump recorded; obstacle course, which measured for accuracy in completing the course; and peak exercise heart rate on a 60-min steady-state treadmill run (EHR).
Results
Post-training test results were analyzed for differences among groups using an ANCOVA, which accounted for any baseline differences among groups. All significant results were then subjected to a post-hoc analysis to determine specific differences. For sprinting, the N group (10.0s) was faster than both G (11.5s; p=0.025) and W (13.5s; p<.001). The N group had lower EHR (112.6bpm) compared to G (138bpm; p<.001) and W (157bpm; p<.001). The N group had a lower jump differential (25cm) then G (41cm; p<.001) and W (59cm; p<.001). In the obstacle course, N had a mean score of 86.6, which was higher than G (70; p<0.001) and W (63; p<0.001). The only variable that was not different among groups on the post-test was RHR (p=0.33).
Conclusions
This is the first known study to measure the effect of structured nanotechnology water magnalife on physical performance, and these results indicate that participants consuming nano-water performed better on a series of physical tests compared to other beverages. However, this study had used a small population of male athletes only. Future studies should be larger and include a variety of populations to gain a better understanding of the possible ergogenic effects of nano-water.

The Effects Of A Six-week Ketogenic Diet On The Performance Of Short-duration, High-intensity Exercise: A Pilot Study

Emily M. Miele[1], Steven Vitti[1], Laura Christoph[2], Elizabeth C. O'Neill[1], Tracey D. Matthews[1], Richard J. Wood[1]. *[1]Springfield College, Springfield, MA. [2]Holyoke Community College, Holyoke, MA.*
(No relevant relationships reported)

There is much controversy surrounding the use of very high fat, low carbohydrate ketogenic diets and athletic performance. Specifically, it has been hypothesized that anaerobic activity, which is primarily fueled by ATP that is formed through the metabolism of carbohydrate sources, may be hindered when utilizing a ketogenic dietary approach. PURPOSE: The current study was designed to investigate how switching from a habitual diet to a ketogenic diet for 6 weeks would affect the performance of short-duration, high-intensity exercise. METHODS: Eight men and seven women (N = 15; 30.2 yr ± 4.11) were randomly assigned to either the ketogenic diet (KETO; n = 8) or the control group (CON; n = 7). All subjects were trained in CrossFit for at least 3 months prior to the study. Several measures of anaerobic performance were assessed at baseline and following 6 weeks utilizing the following series of standardized exercise tests: timed 500m row, Wingate Anaerobic Test, and 3-repetition maximum (3RM) deadlift. Aerobic capacity was also assessed by measuring VO2peak. Subjects continued their regular CrossFit training during the 6 week period and dietary intake was recorded. RESULTS: A significant increase (p < .05) in mean power output (MPO; W/kg) from baseline (M = 8.24 ± 1.15) to 6 weeks (M = 8.70 ± .82) was found the CON group. No significant interactions (p > .05) were found between diet and test time for any of the other measured exercise variables. No significant differences (p > .05) were found in the KETO group from baseline to 6 weeks in any of the measured exercise variables. No significant differences in body weight (lbs) were found from baseline to 6 weeks in either group (KETO; 183.8 ± 31.71 vs. 181.03 ± 30.28, CON; 166.38 ± 35.77 vs. 166.88 ±37.28). Attrition rate was 33% in the KETO group and 30% in the CON group. CONCLUSION: A 6-week ketogenic diet did not affect the performance of short-duration high-intensity exercise. Our data does not support the hypothesis that ketogenic diets induce detriments in the performance of activity that is anaerobic in nature. The current study took place over a 6 week period, allowing for keto-adaptation to occur; results may be different if a shorter time period were utilized.

Inconsistency of Bilateral Asymmetry BetweenSprinting and Jumping Performance: Rethinking Leg Dominance

Nathan T. Gorman[1], Jerry L. Mayhew[2], William F. Brechue, FACSM[3]. *[1]Rocky Vista University College of Osteopathic Medicine, Parker, CO. [2]Truman State University, Kirksville, MO. [3]A.T. Still University, Kirksville, MO.* (Sponsor: William F. Brechue, Ph.D., FACSM, FACSM)
(No relevant relationships reported)

The concept of leg dominance is complicated as bilateral muscular strength/power asymmetry is linked to poor performance and/or injury risk. Bilateral asymmetry during 2-leg (2L) jumping appears to define performance, rather than limit it. During 2L jumping, the leg that developed the greatest torque/velocity is defined as dominant. **PURPOSE**: to investigate the relationship between apparent leg dominance in jumping and sprinting. **METHODS:** Men (n=18; football, basketball) and women (n=17; basketball, soccer, volleyball) athletes competing in intercollegiate sports completed repeat trials of sprint and jump testing. Sprint: three trials of a 12-m sprint with step-by-step kinematic data collected with an infrared timing system. Jump: repeat trials of 2L and single-leg (1L- left leg; 1R-right leg) squat jump without countermovement conducted on individual force plates to determine jump impulse (IMP$_J$). Jump height (JHt) was calculated from flight time (Δt). Data were averaged across trials. Asymmetry index was calculated as (L-R)/(0.5*(L+R)). Bilateral facilitation/deficit was determined from jump performance as (1L+1R)/2L. Differences were tested with ANOVA; p<0.05. **RESULTS:** Men (1.70±0.17 s) were faster than women (1.82±0.11 s). Horizontal acceleration (a) decreased from the first to last stride while, horizontal velocity (v) increased throughout. In contrast, step-by-step a was asymmetric while v increased linearly. a and v were always greater in men. There were no differences in 1L and 1R JHt (left & right: men: 22.0±11.7 & 21.5±11.6 cm;women: 12.4±2.7 &12.7±2.9 cm, respectively). 1L and 2L (men: 39.6 ± 3.6 cm; women: 26.4.± 4.2 cm) JHt was greater in men. Bilateral asymmetry (AI range 40 to -58%) was noted in IMP$_J$ during 2L; both groups produced a greater jump impulse in one leg (men: 135±18 & 110±13.2 N; women: 92±18 N & 74±15 N). 2L performance was associated with a bilateral deficit (n=12) or facilitation (n=19) and was unrelated to JHt (r=-0.25). There was no relationship between the dominant leg during 2L jumping and sprinting. **CONCLUSION:** There is a non-linear, asymmetric acceleration pattern associated

SATURDAY, JUNE 2, 2018

with short distance sprinting which appears to define leg dominance in sprinting. There appears to be a dominant leg during sprinting and 2L jumping, which is not consistent across performance.

3217   Board #86   June 2 8:00 AM - 9:30 AM

Acute Effects of Beta-Alanine on Exercise Performance Variables.

Emmanuel Lavarias, Zinong Li, Yunae Lee, E. Todd Schroeder, FACSM. *University of Southern California, Los Angeles, CA.*
(No relevant relationships reported)

Beta-Alanine (BA) is converted to carnosine which serves to lower acid levels in the muscle by acting as an intramuscular buffer to H+ ions. BA supplementation may increase carnosine synthesis in muscle, leading to reduced muscle fatigue with exercise. **PURPOSE:** To determine the effects of an acute dose of BA (4 grams, 30 min before testing) on muscular power, muscular endurance and aerobic performance. **METHODS:** 21 recreationally active men (24.5±1.5yrs, 1.8±0.1m, 79.2±9.3kg) and 15 women (25.7±2.2yrs, 1.6±.0.1m, 55.1±8.1kg) participated in a placebo controlled, double blind cross-over design study. Subjects were tested on 3 separate days with a 24-hour washout period between test visits. Visits consisted of 4 tests done in the following order: vertical jump on a jump mat, repetition of 70% leg press and chest press max until failure, and a 4-kilometer time trial (4km) on a cycle ergometer. The first testing visit established the 1-repetition maximum on the leg and chest press and familiarization with testing procedures. Subjects were randomized to BA or placebo on the 2nd and 3rd visit. Comparisons of the effects of BA and placebo on exercise test values were made using two-way ANOVA with repeated measures (p<0.05). **RESULTS:** BA showed a significant increase from baseline in the number of reps performed on both the leg press (15.7±5.5 vs. 22.9±7.3 repetitions, p<0.001) and chest press (12.0±5.8 vs. 17.7±5.4 repetitions, p<0.001). Placebo showed a small non-significant increase from baseline in the number of reps performed on both the leg press (15.7±5.5 vs. 17.3±5.3 repetitions, p=0.055) and chest press (12.0±5.8 vs. 12.6±5.6 repetitions, p=0.059). The increases in the BA group were statistically different from the change in the placebo group (leg press, p<0.001 and chest press p<0.001). BA showed a significant increase from baseline in aerobic power (132.0±49.1 vs 144.0±48.8 Watts, p<0.001) during the 4km. Placebo showed a small non-significant increase from baseline in aerobic power (132.0±49.1 vs 134.3±49.4 Watts, p=0.080) during 4km. The increase in aerobic power in the BA group was statistically different from the change in the placebo group (p<0.001). **CONCLUSION:** A single 4 gram dose of BA improves muscular endurance and aerobic power in recreationally active young men and women.

3218   Board #87   June 2 8:00 AM - 9:30 AM

The Influence of Different Walking Conditions on Walking Parameters

Tomoaki Sakai[1], Takahiro Nakano[1], Kosho Kasuga[2], Kazuo Oguri[3]. *[1]Nagoya Gakuin University, Seto, Aichi, Japan. [2]Gifu University, Gifu, Japan. [3]Gifu Shotoku Gakuen University, Gifu, Japan.* (Sponsor: Kiyoji Tanaka, FACSM)
(No relevant relationships reported)

PURPOSE: This study investigated the relationship between characteristics of walking parameters and walking parameters of different walking conditions. **METHODS**: The participants were 54 university students who had the habit of exercising (32 men and 22 women, 19.6 ± 0.7 years). Participants were asked to walk on flat and sloped ground. On the flat ground, they were asked to walk freely with a subjective intensity of "Light (ratings of perceived exertion (RPE) 11)" and "Somewhat hard (RPE 13)." The average slope was 4% for both upward and downward conditions and participants walked freely on both. Participants wore a wearable device attached to the left wrist that measured their walking speed, cadence, stride, and heart rate. **RESULTS**: On the flat ground, in all walking parameters, RPE 13 showed significantly higher values compared to RPE 11 (walking speed: 5.35 ± 0.49 versus 4.48 ± 0.43 km/h, cadence: 121.9 ± 8.8 versus 113.0 ± 7.3 steps/min, stride: 73.2 ± 6.8 versus 65.8 ± 6.8 cm, respectively; $P < 0.05$). On the sloped ground, walking speed on the upward slope showed significantly lower values compared to that on the downward slope and the free-walking speed on flat ground(upward slope: 4.85 ± 0.27 km/h, downward slope: 5.27 ± 0.38 km/h, flat ground: 5.25 ± 0.30 km/h). However, heart rate was significantly higher on the upward slope than in other conditions(118.8 ± 16.9 beats/min, 103.5 ± 14.0 beats/min, 107.8 ± 18.2 beats/min, respectively). Multiple regression analysis was performed with walking speed as the dependent variable and cadence and stride as independent variables. Results showed that for walking on the flat ground, the standardized coefficient for stride was higher than that for the cadence under all conditions. Although the same trend was found for walking on downward slopes, for walking on upward slopes, the standardized coefficient for cadence was higher than that for the stride. **CONCLUSIONS**: Walking parameters tended to be similar for walking on flat ground even when conditions changed; however, it became clear that characteristics of walking parameters on upward slopes varied from those of other conditions.

Physiological Performance Predictions Based on Simple Assessments

Lindsie S. Rogers, J. Mark VanNess, Roman Musselman, Courtney D. Jensen. *University of the Pacific, Stockton, CA.*
(No relevant relationships reported)

Muscular strength and cardiovascular capacity are important determinants of athletic performance. Fundamental assessments include lower body strength (e.g., squat max), upper body strength (e.g., bench press max), and aerobic capacity (VO_2 max). For coaches who lack equipment to measure these parameters, it is important to know if there are feasible alternatives to accurately evaluate their athletes. **PURPOSE**: To determine if simple strength and aerobic assessments can be used in the place of equipment-intensive testing to evaluate college athletes. **METHODS**: Fourteen collegiate male rugby players were recruited and tested. Independent variables were age, height, weight, vertical jump, and 10-yard dash. Dependent variables were body fat percent (BF%) via hydrostatic weighing, bench press max, squat max, and VO_2 max. Data were collected twice during the competitive season, one month apart. Multiple linear regression tested how well the simple assessments predicted the traditional performance measurements. **RESULTS**: On average, athletes were 19.6 years of age with a BMI of 25.2 kg/m², 13.4% body fat, VO_2 max of 45.5 ml/kg/min, bench press of 186.7lb, squat max of 269.5lb, 10-yard dash of 1.7 seconds, and vertical jump of 22.2 inches. At baseline, BMI (p<0.001) and 10-yard dash (p=0.023) predicted BF% (R²=0.881; p<0.001). Significance was preserved at follow-up (R²=0.751; p<0.001). At baseline, holding age constant, 10-yard dash predicted VO_2 max (β=-31.4; p=0.002); the model was significant (R²=0.714; p=0.004) and was strengthened at follow-up (R²=0.780; p<0.001). Holding age and BMI constant, 10-yard dash predicted bench press (β=-222.7; p=0.023); the model was significant (R²=0.732; p=0.011) and retained at follow-up (R²=0.750; p=0.009). At baseline, holding BMI constant, squat max was predicted by vertical jump (β=8.9; p=0.005) and 10-yard dash (β=-263.5; p=0.013). The model was significant (R²=0.923; p<0.001) and retained at follow-up (R²=0.913; p<0.001). **CONCLUSIONS:** In a sample of college rugby athletes, age, height/weight, vertical jump, and 10-yard dash were sufficient predictors of BF%, bench press, squat, and VO_2 max. Our results indicate that it may be reasonable for comprehensive athletic evaluation to be simplified to accommodate a lack of equipment.

Relationship Between Clock Gene Expression, MEQ Score, and Exercise Performance

Karina Ando[1], Masaki Takahashi[2], Shigenobu Shibata[2], Hideyuki Takahashi[1]. *[1]Japan Institute of Sports Sciences, Tokyo, Japan. [2]Waseda University, Tokyo, Japan.*
(No relevant relationships reported)

PURPOSE: To examine the relationship between human clock gene expression, chronotype, and morning/evening exercise performance. **METHODS**: Fifteen healthy young males were recruited for this study. The peak time of *Period 3 (PER3)* expression in hair follicle cells was evaluated as an indicator of the biological circadian rhythm and the Morningness-Eveningness Questionnaire (MEQ) score was used to determine the chronotype (morning, intermediate, or evening). Hair follicle cells were collected over a 24-h period at 4-h intervals from 06:00 hours by firmly holding and pulling the facial hair root. Morning and evening exercise performance was evaluated using a bleep test. The tests were performed at least one week apart using a cross-over design at 10:00 and 18:00 hours. As a physiological index, oral temperature was measured before exercise, and heart rate was measured before and during exercise. Partial correlation was used to examine the relationship between MEQ score and the peak time of *PER3* expression, exercise performance, and oral temperature. Paired *t*-tests were used to compare physiological variables between morning and evening performances. **RESULTS**: There was a moderate positive correlation between the peak time of *PER3* expression and evening performance (r = 0.700, P = 0.053). A significant correlation was found between the oral temperature at 10:00 and improvement in performance at 18:00 (evening performance) compared to that at 10:00 (r = 0.735, P < 0.05). There was no relationship between the MEQ score and performance. There was no significant correlation between the peak time of *PER3* expression and the MEQ score. **CONCLUSIONS**: The present study suggested that the internal clock time evaluated based on gene expression may affect exercise performance. When the peak time of *PER3* expression is late, performance may be higher at 18:00 compared to that at 10:00. Higher body temperature at 10:00 may be a good marker for higher performance at 18:00. Further research is required to investigate the relationships among circadian rhythm of clock genes expression, chronotype, and performance in competing athletes.

3221   Board #90   June 2 8:00 AM - 9:30 AM

Changes in Blood pH and Ammonia Following Repeat Sprint Performance

Greggory R. Davis, Jordan Perett, Danielle Rudesill, David Bellar. *University of Louisiana at Lafayette, Lafayette, LA.*
(No relevant relationships reported)

The relationship between relative intensity and changes in blood pH and ammonia are not well characterized. **PURPOSE:** The primary aim of the study was to determine how changes in relative exercise intensity following repeat sprint performance affect changes in blood pH and blood ammonia concentrations. **METHODS:** Healthy college-age males (n = 12) completed completed one 30 second Wingate cycle sprint test as a familiarization trial. A minimum of 48 hours after the familiarization trial, participants returned to the lab. Resting venous and capillary blood samples were obtained to determine blood ammonia, pH, and lactate levels. Participants then completed 3 Wingate sprint tests, separated by 5 minutes each. Finger capillary blood was immediately obtained after each test to determine lactate and pH values. After the final test, an additional venous blood sample was obtained to determine blood ammonia values. **RESULTS:** Data are shown as 1st vs. 2nd vs. 3rd tests, respectively. There was a significant effect for time for peak power (750.08 ± 39.55 vs. 675.42 ± 30.01 vs. 615.60 ± 37.72 Watts); F = 4.66, p = 0.05, mean power (632.67 ± 30.71 vs. 561.25 ± 22.16 vs. 524.40 ± 26.46 Watts); F = 5.04, p = 0.04, pH (7.72 ± 0.01 vs. 7.63 ± 0.02 vs. 7.62 ± 0.02); F = 70.18, p < 0.01, and lactate (12.36 ± 1.14 vs. 14.10 ± 1.13 vs. 16.95 ± 1.22 mg/dL); F= 42.02, p < 0.01. Blood ammonia values did increase from pre- to post-exercise (0.33 ± 0.09 vs. 1.07 ± 0.22 mg/dl); t = 3.62, p < 0.01, but there was no correlation between post-exercise ammonia values and change in peak or mean power. There was a weak, but significant correlation between change in peak power and change in pH ($R^2 = 0.34$, p = 0.05) and change in mean power and change in pH ($R^2 = 0.44$, p = 0.02). **CONCLUSIONS:** Greater reductions in peak power and mean power correlated with change in blood pH, but not post-exercise ammonia values.

3222   Board #91   June 2 8:00 AM - 9:30 AM

Impact of Calf Temperature Changes on Neuromuscular Function in Elite Taekowndo Athletes

Bo Geun Lee[1], Somi Yun[1], Yun Bin Lee[1], Mingi Jung[1], Dahye Lim[1], Ah Reum Jung[1], Woong Hee Lee[1], Eunjin Hwang[1], Ik Jin Kwon[2], Dae Taek Lee[1]. *[1]Kookmin University, Seoul, Korea, Republic of. [2]Chung-Ang University, Seoul, Korea, Republic of.*
(No relevant relationships reported)

PURPOSE: This study investigated the impact of lower body temperature changes on neuromuscular function in elite Taekowndo athletes.
METHODS: Eighteen Korean National Taekwondo Team athletes (10 men, 24 ± 2 yrs, 190 ± 5 cm, 77 ± 11 kg; 8 women, 24 ± 3 yrs, 174 ± 7 cm, 63 ± 10 kg) were recruited. They participated in two separate tests. In one test, their calf was cooled by ice packs. In another test, their calf was warmed by hot packs. Before and after each thermal treatment, Hoffmann reflex (H-reflex; Hmax, Mmax, H/Mmax ratio), static (eye-closed single leg balance, eye-closed single leg balance, in sec) and dynamic balance (leg reach to front, left-back diagonal, and right-back diagonal directions, in cm) and four different jumps (Counter Movement Jump, Counter Movement Jump Arm Throwing, Drop Jump, and Stiffness Jump) were tested. Test order was randomly assigned. The room temperature was maintained at 23-25°C and 60% relative humidity.
RESULTS: Calf skin temperature was 33.2 ± 1.1 and 33.2 ± 0.5°C before and 12.2 ± 1.5 and 40.1 ± 1.3°C after cooling and warming test, respectively. Hmax increased by cooling from 4.5 ± 1.9 at rest to 5.6 ± 1.7 mV (p<0.05) while no changes were noticed after warming (p>0.05). No changes were found in Mmax after both thermal treatments. H/Mmax ratio was increased after the cooling from 51.3 ± 9.6 to $65.3\pm17.8\%$ (p<0.05) while no changes were found in warming treatment (from 47.0 ± 28.5 to $65.3\pm17.8\%$, p>0.05). Dynamic balance significantly increased after warming (p<0.05), but static balance was not changed after warming (p<.05). Cooling decreased both static and dynamic balances. Drop Jump reduced by cooling from 53.3 ± 12.9 to 45.1 ± 11.0 cm, but other jump performances were not significantly changed after thermal treatments.
CONCLUSIONS: Hmax, which represents neural activation, was increased after cooling. Mmax, which is directly related to muscle neuron activation, was not significantly changed by thermal treatment. These explain an increase of H/Mmax ratio after cooling. Cooling impacts on motor neuron pool activation. Balance and jump performances decreased after cooling, and dynamic balance increased after warming.

3223   Board #92   June 2 8:00 AM - 9:30 AM

No Effects of Skin Pressure Depth on Reaction Time

Taylor L. Curtis, Landyn Van Overbeke, Antonio Meikel, Jeffrey W. Bell. *Southwest Minnesota State University, Marshall, MN.* (Sponsor: Serge P. von Duvillard, Ph.D., FACSM, FECSS, FACSM)
(No relevant relationships reported)

Depth of pressure on skin mechanoreceptors may affect reaction time. Athletes such as wrestlers that depend on skin proprioception for performance may utilize reaction time differences based on pressure differences. It is unknown whether training could affect this response. **PURPOSE**: The purpose of this study was to determine whether depth of pressure or athlete status affects reaction time. **METHODS**: Forty college students (20 wrestlers, 15 non-wrestling athletes, and 5 non-athletes) participated in a reaction time study where three weights (5 g, 10 g, and 30 g) were dropped from 50 cm onto the bicep while subjects were blindfolded and wearing earplugs. Each weight was dropped three times in a randomized order. All trials were recorded using a high-speed camera (Fastec IL3) at 1200 Hz and calculated as the time from skin deformation until first hand movement. After removal of outliers, 36 subjects' data for the average reaction time to the weight drops (29 wrestlers, 13 non-wrestling athletes, and 4 non-athletes) were analyzed using a 3x3 (weight x group) General Linear Model in SPSS v. 24. **RESULTS**: There were no main effects for athlete status group or weight ($p = 0.38$), even though heavier weights elicited a non-significant faster response (5 g = 140.28 ± 16.44 ms, 10 g = 136.75 ± 17.63 ms, 30 g = 128.86 ± 18.02 ms). **CONCLUSIONS**: There is no evidence to suggest that wrestlers should train to react to a variety of contact pressures on the upper arm.

3224   Board #93   June 2 8:00 AM - 9:30 AM

Acute Cognitive Anxiety is Positively Related to Maximal Strength Performance

Joseph P. Carzoli[1], Michael H. Haischer[1], Daniel M. Cooke[1], Amber M. Shipherd[2], Trevor K. Johnson[1], Edward P. Davis[1], Dan J. Belcher[1], Robert F. Zoeller[1], Michael Whitehurst, FACSM[1], Michael C. Zourdos[1]. *[1]Florida Atlantic University, Boca Raton, FL. [2]Texas A&M University-Kingsville, Kingsville, TX.*
(No relevant relationships reported)

A flexible program allows the athlete to choose the daily training session based upon their readiness prior to the session. There is no consensus regarding the best pre-training readiness assessment. One proposal has been that elevated acute anxiety would be related to performance, however, there are equivocal findings related to the benefit of high anxiety and strength performance. **PURPOSE**: Therefore, the purpose of this investigation was to examine the relationship between somatic and cognitive anxiety on acute one-repetition maximum (1RM) back squat performance. **METHODS**: Fifty-eight resistance-trained males (n=41) and females (n=17) (age: 23 ± 3yrs; body mass: 80.64 ± 16.49 kg) completed the Revised Competitive State Anxiety Inventory-2 (CSAI-2) questionnaire prior to performing a 1RM back squat. Additionally, participants completed a perceived self-efficacy (PSE) questionnaire in which participants stated what they believed they were 100%, 75%, and 50% confident they could squat for a 1RM. Next, following a 5-minute dynamic warm-up, subjects completed a validated 1RM back squat protocol. To provide the dependent variable the difference of each PSE value was taken from the 1RM (1RM-PSE). Pearson's product moment correlations were then utilized to determine the relationship between the somatic and cognitive anxiety subscales of the CSAI-2 and 1RM-PSE difference at each reported percentage of confidence. **RESULTS**: Participants squatted more than predicted at the 100% (13.25 ± 18.00 kg) and 75% confidence (3.5 ± 15.75 kg) and less than predicted at 50% confidence (-5.00 ± 15.25 kg). Cognitive anxiety was positively and significantly related to 1RM-PSE at all confidence levels: 100% (r=0.43, p<0.01), 75% (r=0.41, p<0.01), and 50% (r=0.37, p<0.01), while somatic anxiety was not significantly related to performance at any confidence level (100%: r=0.16, p=0.23; 75%: r=0.16, p=0.24; 50%: r=0.04, p=0.77). **CONCLUSIONS**: These results indicate that increased acute cognitive anxiety is associated with better than predicted squat strength, while increased acute somatic anxiety is not associated with acute strength. If utilizing a flexible training template, cognitive anxiety should be one of the pre-training readiness factors which is used to select resistance training load.

3225   **Board #94**   **June 2 8:00 AM - 9:30 AM**

A 3-year Analysis of Game Demands in Women's Division I College Basketball

Lynda B. Ransdell, FACSM[1], Teena Murray[2], Dierdra Bycura[1], Paul Jones[3]. *[1]Northern Arizona University, Flagstaff, AZ. [2]University of Louisville, Louisville, KY. [3]University of Louisville, Louisville, KY.*

(No relevant relationships reported)

Women's division I college basketball is demanding, thus non-contact injury rates are high, and key performance markers such as lower body power may decline at the end of the season due to high chronic training stress. Quantifying and monitoring athlete training loads is fundamental to managing injury risk, explaining acute changes in performance, increasing understanding of training responses, and planning and modifying training. Wearable devices using GPS and accelerometry (i.e., Catapult® OptimEye S5) provide new opportunities for advancing sport science in basketball. To date, no research has examined the game demands of women's division I college basketball using Catapult® technology.
PURPOSE: To quantify the game demands of 6 women's basketball players from a top Division I program (.781% win percentage) over a 3-year period, and to compare the positional differences of guards and posts during regular- and post-season games, and wins versus losses.
METHODS: Six female athletes (20.35 $\pm$ 1.6 yrs) wore Catapult S5® units in a garment resembling a sports bra during 89% of practices and games (Catapult Sports, Melbourne, Australia). Data were collected in real-time. Data, including Player Load (PL), Player Load per minute (PL/min), Inertial Movement Analysis (IMA), and Jumps (volume and intensity), were analyzed using Catapult OpenField Software (Version 1.14.1+).
RESULTS: For the 3-year period, average player load ranged from 613-642, and it increased each year. This indicates that athletes were able to continue to increase their average player load each season. Average player load and average player load per minute was higher for wins than for losses. High IMA was similar for wins and losses. When data were examined by player position, guards accumulated higher average player loads, and higher average player loads per minute than posts. Differences in IMA by player position were inconsistent from year to year.
CONCLUSIONS: Wearable devices such as Catapult ® provide important workload information that can be used to assess and guide player practice and game demands, including differences by player position. Future research should examine how player load relates to specific aspects of game performance (FT %, FG%) and to injury prevention.

3226   **Board #95**   **June 2 8:00 AM - 9:30 AM**

Assessing The Impact Of A Governed Focal Point On Broad Jump Performance In Collegiate Females

Madeline Phillips, Robert T. Sanders, Jared R. Feister, Andy M. Bosak, Hannah E. Nelson, Russell K. Lowell, Brandon M. Ziebell. *Liberty University, Lynchburg, VA.* (Sponsor: Dr. James Schoffstall, FACSM)

(No relevant relationships reported)

The broad jump (BJ) test is frequently utilized to evaluate how far a person can jump and what their resulting lower body power will be. Hence, it is important that the BJ test be administered correctly for a person to jump as far as possible. The standard BJ test has no set focal point for a subject which causes the subject to look wherever they choose. However, prior research with vertical jump performance suggests a set focal point contributes to higher jumps. Therefore, it is logical to assume that a set focal point may assist in greater BJ performance, but to the best of the researchers' knowledge, the impact of a governed focal point (FP) vs. non-governed focal point (NFP) on BJ performance has not been assessed. **PURPOSE:** To investigate the potential differences between a FP vs. NFP on BJ performance in no less than averagely fit college-age females. **METHODS:** After having descriptive data (Ht., Wt., BF%, age) recorded, 33 averagely fit college-age females participated in an 8 min dynamic warm-up. Subjects were then given a four minute passive recovery (PR) period after the warm up and then completed four familiarization jumps (ie. trials). After another 4 min PR period, subjects completed two series of jumps (ie. four trials apiece) in a counterbalanced order with either a FP or NFP for each jump. The FP and NFP jump series were separated by 4 min of PR. The farthest jump for FP vs. NFP was compared using Paired-Samples t-Tests with significant differences occurring at p $\leq$ 0.05. **RESULTS:** No significant differences (p = 0.291) occurred between FP (180.74 $\pm$ 19.9 cm) and NFP (179.63 $\pm$ 20.0 cm). **CONCLUSION:** The results suggest that FP has no significant impact on BJ performance using no less then averagely fit college-age females, yet 39.4% of the subjects did benefit from an FP. Future research may be required to assess the impact of FP vs. NFP on broad jump performance using no less than averagely fit college-age males as well as athletes who perform horizontal jumping actions (running long jump, triple jump, etc.). Additional research may be required to assess the impact of a sports specific focal point vs. non-governed focal point on broad jump performance with no less than averagely fit female and male population.

Effect Of Exercise On Cognitive Performance And Systemic Bdnf Levels In An Elderly Mexican Population

Ermilo Canton Martinez, Ivan Renteria, Patricia Garcia Suarez, David Martinez Corona, Alberto Jimenez-Maldonado. *Universidad Autónoma de Baja California, Ensenada, Mexico.*

(No relevant relationships reported)

The ageing is a progressive process that reduces the functional abilities that affect the life in humans. Furthermore, studies have indicated that the ageing is associated with morphological changes in the hippocampus, the last condition seem induces cognitive deficiencies. **PURPOSE**: To determine the effect of a functional exercise training on cognitive performance and systemic BDNF in an elderly Mexican population. **METHODS**: 19 elderly-healthy participants (Age = 69. 1$\pm$ 7.5 yr.; body weight (BW) = 74.3 $\pm$ 12.8 kg; height = 155 $\pm$ 0.7 cm; BMI = 29.7 $\pm$ 5.6 kg/m²) were recruited in this study. The subjects were randomly divided in two groups: Control (C; n=11; 10 women; 1 man) and Functional Exercise (FE; n=8; 6 women; 2 men). Before to start the FE program. The physical activity level (PA) and the years of education (YE) were determined in the groups. The PA was not statistically different in the groups (C: 6.24 $\pm$ 3.05 vs FE: 8.7 $\pm$ 1.49, p= 0.07). The YE was similar between the groups (C: 5.81 $\pm$ 1.5 vs FE: 6.9 $\pm$ 2.9 yr, p=0.3). After this, the FE program was applied. The protocol consisted in 36 sessions of aerobic and stretching exercises. 24 hours of finished, the exercise program the miminetal test and the 6-minute walking test (6 MWT) was applied in the two groups. The systemic BDNF levels at basal state also were evaluated. **RESULTS**: The FE walked more distance in the 6MWT compared with C (C: 329.1$\pm$ 39.6 m vs EF: 844.4 $\pm$ 172.6, p< 0.01). The cognitive performance was better in FE with respect to C (C: 21.18$\pm$4.2 vs FE: 27.44 $\pm$ 0.8 (p<0.01). There was a positive correlation between the distance walked in the 6MWT and the cognitive performance (r=0.68, p<0.01). Finally, FE showed lower systemic BDNF levels than C (C: 18 676 $\pm$ 2264 pg/ml vs FE 15 766 $\pm$ 2064 pg/ml, p=0.01). **CONCLUSION**: The data of the present study suggest that FE to long-term improved the cognitive performance in older people. However, the last effect was not accompanied with a higher BDNF concentration in the periphery at least in a Mexican population.

Associations Between Off-Season Player-Tracking Data and Changes in Vertical Jump Parameters in Female Basketball Players

Sandra Dahling, John Krzyszkowski, Marguerite Smith, Kristof Kipp. *Marquette University, Milwaukee, WI.* (Sponsor: Paula Papanek, FACSM)

(No relevant relationships reported)

Commercial player-tracking systems help quantify the volume and intensity of activity during practices and games. When combined with neuromuscular fitness testing data, longitudinal analysis of player-tracking data may provide insight into the dose-response relationship between training loads and changes in fitness levels. Such insights may ultimately help drive the program design process for athletes so as to optimize their physiological adaptations and maximize their readiness.
PURPOSE: Examine the associations between player-tracking data and changes in vertical jump parameters over the course of off-season training in Division I female basketball players.
METHODS: Ten female collegiate basketball players were recruited at the beginning of off-season training. They each performed countermovement jump (CMJ) tests on two force plates before and after three months of off-season training. Each testing session involved CMJ's with three loads (0, 20, 40 kg). The ground reaction force data were used to calculate the average concentric force and velocity of each CMJ. The data from the three load conditions were used to establish a force-velocity profile and estimate maximal force at zero velocity (F_0 [m/s]) and maximal velocity at zero force (V_0 [N/kg]). Training loads were monitored with a player tracking system during each practice of the off-season. Each players' Player Load (PL) and Player Load per Minute (PL/Min) were recorded for each practice and averaged over the entire off-season period. Simple linear regression models were used to determine the associations between average off-season player-tracking data and changes in force-velocity parameters.
RESULTS: The changes in F_0 and V_0 across the off-season were -.65$\pm$1.24 and 3.29$\pm$5.04, respectively. The average off-season PL and PL/Min were 442$\pm$47 and 5.00$\pm$0.54, respectively. Off-season PL did not correlate to changes in F_0 (r = 0.03; p = 0.93) or V_0 (r = 0.02; p = 0.95). Off-season PL/Min was also not correlated to changes in F_0 (r = 0.01; p = 0.97) or V_0 (r = 0.06; p = 0.86).

CONCLUSION: Neither average off-season PL or PL/Min were able to predict changes in CMJ force-velocity parameters. The average volume and intensity of off-season practice sessions did therefore not affect the jumping ability of female Division I basketball players.

3229   **Board #98**   June 2 8:00 AM - 9:30 AM

The Relationship Between Lower Extremity Strength and Overhead Squat

Nene Kitabatake, Kelvin Chiu, Karlee Burns, Will Wu, Mimi Nakajima. *Center for Sports Training and Research, California State University Long Beach, Long Beach, CA.*

(No relevant relationships reported)

Impaired lower extremity muscle strength can put athletes at risk of injuries. Assessing the relationship between muscle strength and knee instabilities during overhead squat (OHS) can help prevent injuries of collegiate female athletes. **Purpose:** Examine the relationship between lower extremity muscle strength and the depth and knee wobbling during overhead squat (OHS). **Methods:** Eight in-season Division 1 collegiate women's tennis athletes and 10 in-season Division 1 collegiate women's basketball athletes (age: 18.94 ± 1.35 yrs., height: 1.75 ± 0.08 m, weight: 71.61 ± 14.05 kg) participated. Participants' knee flexor, extensor, and hip abductor muscle strength were measured with a hand held dynamometer and the average of three trials was normalized by body weight (%BW). Participants then performed three consecutive OHS as low as possible and were video recorded for post processing from the frontal and sagittal planes. Following the assessment, participants were grouped into Above Parallel (AP) or Below Parallel (BP) depth and knee wobbles or no wobbles during OHS. **Results:** The mean differences of knee flexor, extensor, and hip abductor strength were compared for BP and AP groups. Three participants were grouped into BP and 15 were grouped into AP. An independent t-test showed significant differences of left hip abductor strength of AP (mean=17.82 ± 4.05 %BW), compared to BP (mean=21.67 ± 1.41 %BW); t(18)= -2.900, *p*= 0.016. No significant differences were found between muscle strength and knee wobbling. **Conclusion:** Overall, no relationship between knee wobbling and the lower extremity strength was found. However, there was a statistically significant relationship in OHS depth and hip abductor strength on the left side. Previous studies have demonstrated decreased hip abductor strength may cause patellofemoral pain syndrome (PFP) and knee valgus. Future studies should look at increasing hip abductor strength and its effects on PFP and knee valgus during functional movements.

Hypersomnia is Negatively Related to Maximal Strength Performance

Dan J. Belcher[1], Michael H. Haischer[1], Daniel M. Cooke[1], Joseph P. Carzoli[1], Amber M. Shipherd[2], Robert Varieur[1], Trevor K. Johnson[1], Edward P. Davis[1], Robert F. Zoeller[1], Michael Whitehurst, FACSM[1], Michael C. Zourdos[1]. *[1]Florida Atlantic University, Boca Raton, FL. [2]Texas A&M University-Kingsville, Kingsville, TX.*

(No relevant relationships reported)

Previously, ratings of performance self-efficacy (PSE) have been positively related to athletic performance. However, it has been proposed that sleeping dysfunction may disrupt PSE predictions. **PURPOSE**: Therefore, the purpose of this investigation was to examine the relationship between insomnia and hypersomnia on self-predicted acute one-repetition maximum (1RM) back squat performance. **METHODS**: Fifty-eight resistance-trained males (n=41) and females (n=17) (age: 23±3 yrs; body mass: 80.64±16.49 kg) completed the Oviedo Sleep Questionnaire (OSQ) prior to performing a 1RM back squat. Additionally, participants completed a PSE questionnaire regarding what they believed they were 100%, 75%, and 50% confident they could squat for a 1RM. Then following a brief dynamic warm-up, subjects completed a validated 1RM back squat protocol. The difference of each PSE value was then taken from the 1RM and converted to percentage (1RM-PSE) to assess differences between predicted and actual 1RM outcomes. Next, the 1RM-PSE value was converted to a percentage to determine the percentage difference between actual 1RM and predicted 1RM at each level of confidence. Pearson's product moment correlations were used between the insomnia and hypersomnia subscales of the OSQ and the percentage 1RM-PSE difference at each confidence level. **RESULTS**: Participants squatted a greater amount than predicted at 100% (14.21 ± 22.86%) and 75% (4.71 ± 15.28 %) levels of confidence, and less than predicted at the 50% confidence level (-2.04 ± 12.16 %). Hypersomnia was inversely and significantly related to the 1RM-PSE percentage difference at the 50% confidence level (50%: r=-0.26, p<0.05) and approached significance at the 75% confidence level (r=-0.23, p=0.08). However, hypersomnia was not significantly related to the 1RM-PSE percentage at 100% confidence (r=-0.18, p=0.18). The insomnia subscale was not significantly related to performance at any level of prediction confidence (100%: r= -0.04, p=0.79; 75%: r=0.07, p=-0.63; 50%: r= -0.04, p=0.78). **CONCLUSIONS**: These results indicate that hypersomnia (i.e.

acute excessive sleepiness) is associated with worse than predicted maximal strength performance in the squat at lower PSE confidence level. Therefore, acute sleep patterns should be considered as a readiness assessment.

Acute Anxiety is Not Significantly Related to Repetitions Performed in the Back Squat

Hector G. Paez[1], Michael H. Haischer[1], Daniel M. Cooke[1], Joseph P. Carzoli[1], Amber M. Shipherd[2], Trevor K. Johnson[1], Edward P. Davis[1], Robert Varieur[1], Robert F. Zoeller[1], Michael Whitehurst, FACSM[1], Michael C. Zourdos[1]. *[1]Florida Atlantic University, Boca Raton, FL. [2]Texas A&M University-Kingsville, Kingsville, TX.*

(No relevant relationships reported)

Flexible resistance training programs allow for athletes to autoregulate daily training variables based upon readiness prior to the training session. Although factors such as physical recovery, anxiety, and sleep can affect acute performance there is no consensus regarding the best training evaluation to assess readiness to train. In fact, somatic and cognitive anxiety have been both positively and negatively related to athletic performance, thus the findings for these factors as readiness indicators are equivocal. The Revised Competitive State Anxiety Inventory-2 (CSAI-2) is a common scale which allows for the acute assessment of both anxiety traits.**PURPOSE**: Therefore, the purpose of this investigation was to examine the relationship between somatic and cognitive anxiety using the CSAI-2 scale on maximal repetitions performed at 70% of one-repetition maximum (1RM) in back squat. **METHODS**: Fifty-eight resistance-trained males and females (age: 23±3yrs; body mass: 80.64±16.49 kg) completed the CSAI-2 questionnaire prior to performing a 5-minute dynamic warm-up and a 1RM back squat. Following 1RM testing, subjects had a standardized rest period of 10 minutes prior to completing two single-repetition sets on the squat at 30%, 40%, 50%, 60%, 70%, 80% and 90% of the established 1RM for which the data is included elsewhere. After the submaximal single repetition sets, subjects had a 10-minute rest period before completing one set on the back squat to volitional failure at 70% of the established 1RM. Pearson's product moment correlations were then utilized between the somatic and cognitive anxiety subscales of the CSAI-2 to determine if any relationship existed with the number of repetitions completed at 70% of 1RM. **RESULTS**: Somatic anxiety (r=-0.20, p=0.13), cognitive anxiety (r=0.19, p=0.17) and self-confidence (r=0.05, p=0.72) subscales of the CSAI-2 were not significantly correlated with back squat performance during maximal repetitions to failure at 70% of 1RM. **CONCLUSIONS**: None of the CSAI-2 subscales were related with repetitions performed to volitional failure in the squat. However, we caution that this analysis did not examine maximal strength performance, and should only be applied to repetitions performed to failure at submaximal intensities.

Grit is Not Significantly Related to Repetitions Performed in the Back Squat

Robert J. Pratt[1], Michael H. Haischer[1], Daniel M. Cooke[1], Joseph P. Carzoli[1], Amber M. Shipherd[2], Trevor K. Johnson[1], Edward P. Davis[1], Robert Varieur[1], Robert F. Zoeller[1], Michael Whitehurst, FACSM[1], Michael C. Zourdos[1]. *[1]Florida Atlantic University, Boca Raton, FL. [2]Texas A&M University-Kingsville, Kingsville, FL.*

(No relevant relationships reported)

Several psychological factors have been linked to acute strength performance through a variety of psychometric analyses. Recent research suggests that the "grittier" a person is, the greater their perseverance and passion for long-term goals. Although grit has shown promise in predicting long-term performance, the association between grit and acute strength performance is yet to be determined. **PURPOSE**: Therefore, the purpose of this investigation was to examine the relationship between grit as determined by the Short Grit Scale (Grit-S) and total repetitions performed to volitional failure at 70% of one-repetition maximum in the back squat. **METHODS**: Fifty-eight resistance-trained males and females (age: 23±3yrs; body mass: 80.64±16.49 kg) completed Grit-S prior to performing a one-rep max back squat (1RM). Following a 5-minute dynamic warm-up, subjects completed a validated 1RM back squat protocol. Following 1RM testing, subjects had a standardized rest period of 10 minutes prior to completing two single-repetition sets on the squat at 30%, 40%, 50%, 60%, 70%, 80% and 90% of the established 1RM for which the data is included elsewhere. After the submaximal single repetition sets, subjects had a 10-minute rest period before completing one set on the back squat to volitional failure at 70% of the established 1RM. A Pearson's product moment correlation was utilized to determine any relationships between Grit-S total repetitions performed at 70% of 1RM. **RESULTS**: There was a wide range of repetitions performed across all subjects (6-28) with an average of 14±4 repetitions. However, grit as determined by the Grit-S was not significantly related to total repetitions performed at 70% of 1RM in the back squat (r=-0.11, p=0.42). **CONCLUSIONS**: These results indicate that higher levels of grit are not associated

SATURDAY, JUNE 2, 2018

with repetitions performed to failure and submaximal back squat intensities. However, we suggest that the Grit-S should be used to assess long-term commitment to athletic training as well as a possible indicator of chronically improved performance.

3233   Board #102   June 2 8:00 AM - 9:30 AM

Relationship Between Fitness Testing and Performance Statistics in Baseball: A Longitudinal Study

Thejasvi Reddy Anantasagar[1], Vishak Vinod[2], Richard A. Karasch[1], James G. Disch[1], Zacharias Papadakis[1]. [1]Rice University, Houston, TX. [2]University of Houston, Houston, TX. (Sponsor: Peter W. Grandjean, FACSM)

(No relevant relationships reported)

Fitness testing (FT) is a contributing factor for success in most sports. Little evidence exists related to baseball FT and performance statistics (PS). **PURPOSE:** To examine relationships between FT and selected PS in NCAA Division I baseball team. **METHODS:** We followed the same players for a period of 5 years and we recorded their FT and PS, N = 414 (age 19.8 ± 1.3 yr; weight 89.9 ± 8.3 kg). Grip strength (GS), vertical jump height (VJ), and squat 1RM (SQ) were examined with regards to batting average % (b/avg%), slugging % (slg%), on-base % (ob%), earned run average (era), batting average against % (b/avg-a%), and strike-out per innings pitched for 9 innings (so/ip)*9. FT and PS were normalized to z-scores. Missing data were estimated from least squares prediction from non-missing variables. Multiple forward stepwise regression was used to evaluate the relative impact of FT on PS (JMP® Pro 13). **RESULTS:** GS is significantly correlated with b/avg% (r=0.26, p<0.0001), slg% (r=0.34, p<0.0001), ob% (r=0.23, p<0.001), era (r=0.39, p<0.0001), and so/ip*9 (r=0.1, p=0.03). VJ is significantly correlated with slg% (r=0.17, p=0.0007), era (r=0.25, p<0.0001), b/avg-a% (r=0.14, p=0.005), and so/ip*9 (r=0.18, p=0.0002). SQ is significantly correlated with b/avg% (r=0.30, p<0.0001), slg% (r=0.37, p<0.0001), era (r=-0.10, p=0.04), b/avg-a% (r=-0.14, p=0.005), and so/ip*9 (r=0.26, p<0.0001). Era was selected as the independent variable with the highest goodness of fit significantly correlating with GS (p<0.0001), VJ (p<.0001), and SQ (p<0.0001) with adjusted R^2=0.23. **CONCLUSIONS:** The results indicate that FT correlates with PS. GS, VJ, and SQ appeared to provide the greatest predictive power of era PS. FT accounted for 23% of the variance in era PS. Besides GS, VJ, and SQ, a prudent FT approach for performance coaches may be to also focus on improving other FT variables, such as bench press, standing long jump, 10-m sprint, back strength, and flexibility. This approach may translate to improved PS other than era PS.

3234   Board #103   June 2 8:00 AM - 9:30 AM

The Short Grit Scale Does Not Relate to Acute One-Repetition Maximum Back Squat Performance

Trevor K. Johnson[1], Michael H. Haischer[1], Daniel M. Cooke[1], Joseph P. Carzoli[1], Amber M. Shipherd[2], Edward P. Davis[1], Robert Varieur[1], Robert F. Zoeller[1], Michael Whitehurst, FACSM[1], Michael C. Zourdos[1]. [1]Florida Atlantic University, Boca Raton, FL. [2]Texas A&M University-Kingsville, Kingsville, TX.

(No relevant relationships reported)

An individual's level of "grit" is determined by their perseverance and passion for long-term goals. Existing data have demonstrated that grit has predicted success above what could be explained by talent alone. However, these existing data are based upon subjective questionnaires, including a recent meta-analysis in which grit was measured in relation to academic performance. To our current knowledge there is no research that evaluates the relationship between grit and acute athletic performance. **PURPOSE**: Therefore, the purpose of this investigation was to examine the relationship between grit as determined by the Short Grit Scale (Grit-S) and acute one-repetition maximum (1RM) back squat performance. **METHODS:** Fifty-eight resistance-trained males and females (age: 23±3yrs; body mass: 80.64±16.49 kg) completed the Grit-S questionnaire prior to performing a 1RM back squat. Additionally, participants completed a perceived self-efficacy (PSE) questionnaire in which participants stated what they believed they were 100%, 75%, and 50% confident they could squat for a 1RM. Next, following a 5-minute dynamic warm-up subjects completed a validated 1RM back squat protocol. To provide the dependent variable the difference of each PSE value was taken from the 1RM (1RM-PSE). Pearson's product moment correlations were then utilized between the Grit-S and 1RM-PSE difference at each reported percentage of confidence. **RESULTS**: Participants squatted more than predicted at the 100% (13.25±18.00 kg) and 75% confidence (3.5±15.75 kg) and less than predicted at 50% confidence (-5.00±15.25 kg). Grit-S was not significantly correlated with 1RM-PSE Difference at all percentages; 100% (r=0.17, p=0.21), 75% (r=0.20, p=0.14), 50% (r=0.11, p=0.40). **CONCLUSIONS**: These results indicate that the character trait, grit, as measured by the Grit-S is not a factor which explains acute maximal strength performance. However, since grit is defined as someone's perseverance and passion for long-term goals we suggest that grit be investigated as a possible factor influencing chronic athletic performance and improvement over time.

3235   Board #104   June 2 8:00 AM - 9:30 AM

Effects of Weighted vs Light-Rope Jumping on Upper Extremity Strength and Countermovement Jump Performance

Carlos A. Estrada, Tyler W.D. Muddle, Cameron S. Mackey, Masoud Moghaddam, Bert H. Jacobson, FACSM. *Oklahoma State University, Stillwater, OK.* (Sponsor: Bert Jacobson, FACSM)

(No relevant relationships reported)

Purpose: To compare the effects of weighted versus light-rope jumping on maximal upper extremity strength and jump performance. **Methods**: Twenty-two recreationally active females (Age: 20.27 ± 1.03yrs; height: 165.05 ± 7.17cm; mass: 68.97 ± 16.37kg) participated in a four-week rope-jumping training intervention. Assessment measures were obtained pre-and post-training intervention. Maximal isometric strength of the elbow flexors (EF), elbow extensors (EE), and grip strength (GS) were assessed via dynamometry. Additionally, countermovement jump (CMJ) height, peak power (PP), and peak velocity (PV) values were assessed using a jump mat and linear position transducer. Following pretesting, participants were randomly assigned to either a weighted rope (WR: .91kg; n = 11) or light rope (LR: .11kg; n = 11) group. The training protocol consisted of participants performing two, 4-minute sets of alternating 30s of jumping (cadence of 120/min) with 30s of rest; a third set was added to the training protocol during weeks three and four. Repeated-measures analyses of variance were performed on all pre- and post-testing measures. **Results**: No time x group interaction was revealed ($p > 0.05$), however, a main effect of time was observed for both GS and EF (F(1, 20) = 6.25, $p = 0.021$ & F(1, 20) = 5.78, $p = 0.026$, respectively), revealing increases in both groups for EF (WR: 6.3%; LR: 7.5%) and GS (WR: 8.7%; LR: 3.2%). CMJ height analysis revealed no interaction ($p > 0.05$), however, a main effect of time (F(1, 19) = 5.611, $p = 0.029$) was observed. PP and PV analyses revealed no significant interactions ($p > 0.05$), however, a main effect of time was observed for both PP and PV (F(1, 19) = 9.54, $p = 0.006$ & F(1, 19) = 7.33, $p = 0.014$, respectively). Collectively, CMJ height, PP, and PV values increased in the WR group by 5.5%, 6.5%, and 6.6%, and in the LR group by 1.1%, 1.9%, and 1.25%, respectively. **Conclusion**: Although no differences were observed between groups in strength nor jump performance, our data suggest that consistent jump rope training, regardless of rope weight, has a significant influence on upper extremity strength and jump performance.

Performance Factors Related to Throwing Distance in Collegiate Track Athletes

Yoshihiko Scott, Kainalu Nitta, Tyler Cram, Michael Bohne, Andrew Creer. *Utah Valley University, Orem, UT.*

(No relevant relationships reported)

Purpose: The purpose of this study was to identify potential correlations between upper and lower body power, balance, flexibility, and body composition in relation to actual throwing performance in collegiate throwers. **Methods**: 12 collegiate throwers (8 male, 4 female; minimum of 4 years of experience) performed a series of functional tests and a competition level throw. Participants performed a brief warm up prior to each test. Upper body power was determined using a seated medicine ball throw (9kg male, 6kg female) performed laying on a bench at a 45° incline. Lower body power and reaction time were measured using a vertical jump mat (Probotics Inc, Hunstville, AL) which provided jump height, ground reaction time, and an overall power factor (OPF). Balance was assessed during single leg trials for each leg on a Biodex balance system (Biodex Medical Systems Inc., Shirley, NY). Flexibility was assessed by sit and reach. Body composition was measured by means of air displacement plethysmography (Bod Pod; Cosmed USA Inc. Concord, CA). Functional testing results were compared to actual competition throws, which took place at a sanctioned meet within 3 days of testing. Comparisons between functional tests and competition throws were made using Pearson's R (linear) and Spearman's Rho (nonlinear) tests to identify correlations. **Results**: Nonlinear correlations were found between throwing distance and body fat percentage (rho=-0.699; p=0.011), and OPF (rho=0.609; p=0.047). Linear correlations were found between throwing distance and overall lead leg stability (r=0.701; p=0.011), and lead leg medial/lateral stability (r=0.688; p=0.013). **Conclusions**: These data suggest that body fat percentage, lower body power, and lead leg stability are each correlated with throwing distance. Improvements in these areas could lead to improvements in overall throwing distances in collegiate throwers.

Anthropometric and Performance Statistics Comparisons in Baseball Pitchers: A Longitudinal Study

Newsha Nikzad[1], Richard A. Karasch[1], Thejasvi Anantasagar[1], Vishak Vinod[2], James G. Disch[1], Zacharias Papadakis[1]. [1]Rice University, Houston, TX. [2]University of Houston, Houston, TX. (Sponsor: Peter W. Grandjean, FACSM)
(No relevant relationships reported)

Athletic ability, performance, and motor skills depend greatly on human proportionality. Practicing sports at a high level is associated with a person's ability to meet the biomechanical demands of a particular sport or playing position. The ideal somatotype of athletes in different sports and within the same sport has been described. However, there is limited evidence regarding the association between the anthropometric characteristics, such as body weight (BW), body height (BH), and body fat % (BF%) of collegiate baseball pitchers and baseball performance statistics (PS). **PURPOSE:** To compare BW, BH, BF% and selected baseball-specific PS, such as earned run average (era), batting average (b/avg-a%), and strike-out per innings pitched for 9 innings (so/ip)*9 in NCAA Division I pitchers; to examine the relationship between BW, BH, BF% and baseball-specific PS. **METHODS:** During a 5-year period, 210 collegiate pitchers (age 19.7 ± 1.2 yr; weight 92 ± 8.2 kg) were assessed for body weight (BW), body height (BH), and body fat % (BF%). The following pitchers' baseball statistics were collected: era, b/avg-a%, and (so/ip)*9. BW, BH, BF%, and PS were normalized to z-scores. Missing data were estimated from least squares prediction from non-missing variables. Forward multiple stepwise regression was used to evaluate the relative impact of BW, BH, and BF% on PS (JMP® Pro 13). **RESULTS:** BH is significantly correlated both with b/avg-a% (r=-0.18, p=0.0104) and era (r=0.22, p=0.0010). BW is significantly correlated with (so/ip)*9 (r=0.22, p=0.0016). BF% is significantly correlated with both era (r=-0.26, p=0.0001) and (so/ip)*9 (r=-0.14, p=0.0472). Strike-out per innings pitched for 9 innings was selected as the independent variable with the highest goodness of fit significantly correlating with BW (p=0.0004), BH (p=0.0004), and BF% (p=0.0022) with adjusted R^2=0.12. **CONCLUSIONS**: The results indicate that BW, BH, and BF% of pitchers correlate with b/avg-a%, era, and (so/ip)*9. BW, BH, and BF% appeared to provide the greatest predictive power of (so/ip)*9. The selected anthropometric variables accounted for 12% of the variance in (so/ip)*9. Runs are usually scored by hits. Coaches and trainers want pitchers to prevent runs. Therefore, they may need to account for other factors besides BW, BH, and BF%.

Effect Of Warm-up Intervention On Physical Performance: Meta-analysis

Seungho Ryu[1], Heontae Kim[2], Minsoo Kang, FACSM[1]. [1]The University of Mississippi, University, MS. [2]Middle Tennessee State University, Murfreesboro, TN. (Sponsor: Minsoo Kang, FACSM)
(No relevant relationships reported)

Warm-ups have been often used prior to exercise and sports. Numerous warm-up intervention studies have been conducted to maximize physical performance, yet results remain controversial. **PURPOSE:** The purpose of this study was, using meta-analysis techniques, to examine the effect of warm-up intervention on physical performance. **METHODS**: Relevant studies were identified by conducting electronic databases such as Medline, Cochran Library, and SPORTDiscus by a systematic literature search (key terms: warm-up and physical performance). Outcome measurement of physical performance included sprint, jump, flexibility, agility, power, and sports related skills (ball dribbling and penalty kick). Standardized mean difference effect size (ES) was calculated based on the difference in physical performance between pre- and post-intervention or post values of treatment and control group, respectively. A random effects model was used to provide an overall ES and 95% confidence interval (CI). Moderator analyses were conducted to evaluate the effects of study gender, warm-up type (static vs. dynamic), and performance type (sprint vs. jump vs. flexibility vs. others) on overall ES. Heterogeneity was examined using Cochran's Q statistic. All analyses were conducted using Comprehensive Meta Analysis (Version 3). **RESULTS**: Out of 1379 potentially relevant articles, 54 studies were selected based on initial screening of titles and abstracts. A total of 12 studies met the inclusion criteria and 71 ESs were calculated. The overall mean ES was not significant (ES = .035; 95% CI = -.058, .128). Moderator analyses showed that studies with flexibility (.196; .074, .318) had a greater ES than sprint (-.127; -.328, .073), jump (.020; -.100, .140), and others (.089; -.268, .446), $Q_{between}$ (Qb) = 8.491, df = 3, p = .037. However, other moderator variables had no effect on the mean ES: warm-up type, Qb = 1.800, df = 2, p = .407; gender, Qb = 0.243, df = 2, p = .886. **CONCLUSION**: In this meta-analysis, the evidence is insufficient to conclude that the warm-up interventions are effective in improving physical performance. However, warm-up might have a small effect on improving flexibility.

Positional Impact on Physiological and Performance Variables in Women's Collegiate .22 Bore Rifle Shooting

Sarah Henry, Peter Chrysosferidis, Nicholas Murray, G. A. Ryan. *Georgia Southern University, Statesboro, GA.*
(No relevant relationships reported)

Competitive rifle shooting is rapidly becoming a staple sport in American collegiate athletics. Over 300 universities in the United States now have shooting programs. Accurate shooting requires immense physiological and biomechanical control. **PURPOSE:** The purpose of this study was to determine physiological (heart rate [HR] and respiratory rate [RR]) and performance differences in three shooting positions (Stand, Kneel, and Prone) during competitive .22 caliber bore rifle shooting. **METHODS:** 9 Division I collegiate women's rifle shooters participated in the study. HR and RR data were collected for each participant via a bio-harness. Each participant completed 10 sighting shots and 10 performance shots recorded for accuracy, using an NCAA approved computer scoring system. Each participant shot in the three positions following NCAA competition rotation. A one-way ANOVA was run to determine the impact of positioning on all variables of interest, with post-hoc LSD analysis on all significant omnibus results. **RESULTS:** A significant difference was noted for Total Score ($F(2,25) = 6.258$, p = 0.007). Post-hoc analyses revealed that scores were significantly worse in the Stand position (80.0 ± 9.6) compared to Prone (92.5 ± 5.1, p = 0.002). Kneel score (86.8 ± 6.6, p = 0.066) compared to Stand approached, but was not statistically different. Significance was approached with RR (p = 0.059), with RR being highest in Prone (6.4 ± 2.1 breaths), compared to Stand (4.4 ± 2.1 breaths) and Kneel (3.9 ± 1.3 breaths). No significant differences were noted for HR (p =0.862). **CONCLUSION:** The data suggest that the Prone position yielded the highest scores, and a potentially elevated RR. This suggests that the ground-assisted positioning of the rifle, and slightly elevated RR, aid in scoring accuracy in collegiate women's .22 caliber rifle shooters. Conversely, lowest scores were recorded in the Stand position. This could be due to the weight (~17lb) of the rifle needing to be held steady in this position.

Validation Of Triathlon Time Prediction Methods For Amateur Triathletes

Todd Buckingham[1], Rebecca W. Moore[2], David Ferguson[1], Nicholas Myers[1], Karin A. Pfeiffer, FACSM[1]. [1]Michigan State University, East Lansing, MI. [2]Eastern Michigan University, Ypsilanti, MI.
(No relevant relationships reported)

Individuals new to triathlon may have difficulty accurately predicting their finish time. Equations (Schabort et al., Hue et al.) have been developed that predict Olympic distance triathlon finish time. However, triathletes were elite level with a sample size of 10 or fewer, making it uncertain if these findings are relevant to a larger sample of amateur triathletes. An online calculator (QT2) is also available to predict triathlon times, but it has not been validated. **PURPOSE**: To assess the criterion and convergent validity of two scientific equations and the QT2 in predicting actual finish time of an Olympic distance triathlon for amateur triathletes. **METHODS**: Participants were collegiate, amateur triathletes who completed an Olympic distance triathlon during 2017. Participants performed six exercise tests, as close to their race as possible, either before or after, and all tests were performed on separate days. Body composition was assessed via BodPod. Three of the exercise tests (peak treadmill speed, 4 W/kg cycle, 30-minute bike/20-minute run) were used in the scientific equations. For these, participants visited the laboratory at Michigan State University or Eastern Michigan University on three separate occasions. Blood lactate was measured for each test. The remaining three exercise tests, which participants completed on their own (400y swim, 20-minute cycle, 5k run), were used in the QT2. Pearson correlations evaluated relationships for criterion and convergent validity. Eight amateurs could not complete the 4 W/kg cycle, so analyses were also run with their data removed. **RESULTS**: Twenty-seven triathletes (20.6 ± 2.0 years, 37.0% female, actual finish time $2:48:00 \pm 0:34:32$) have completed testing. The QT2 (r=0.865, p<0.001), Hue (r=0.883, p<0.001), and Schabort (r=0.392, p<0.05) were associated with actual finish time. The QT2 and Hue (r=0.859, p<0.001) and Schabort and Hue (r=0.394, p<0.05), were associated with each other. When athletes who modified the 4 W/kg cycle were removed from the analyses, relationships with Schabort disappeared. **CONCLUSIONS**: The QT2 and Hue equation were closely associated with actual finish time. The QT2 involves easily accessible tests, unlike both scientific equations, which require blood lactate testing. Because of this, the QT2 may be preferred by amateurs.

The Effects of Simulated Altitude Masks on Aerobic Endurance in Trained Individuals

Melissa Renee Cook. *Indiana Wesleyan University, Marion, IN.*
(No relevant relationships reported)

Oxygen-dependent exercise at altitude has demonstrated ability to increase maximal oxygen uptake over a time. Traditional means of altitude training can be time-consuming and expensive, so alternative methods that simulate altitude exposure have been developed. These masks maintain that they induce the same cardiorespiratory fitness changes that an athlete training at altitude would experience. They also claim that these improvements occur in a shorter training periods than typical altitude training protocols. However, there is little research to support these claims. **PURPOSE:** The purpose of this study is to measure the potential effects of training at a simulated altitude on aerobic endurance using a two-week YMCA cycle ergometer protocol. **METHODS:** Based on subjects' VO_2max scores, 17 subjects were put into one of three groups, a control group (CG), a group training without the mask (No-mask), and a group training with the mask (mask). Each training session had the participants cycle for twelve minutes, at 50-60% of their heart rate reserve (HRR), followed by a 3-minute cool-down. Eight training sessions were completed within two weeks. **RESULTS:** Using a 3X2 mixed ANOVA, for within subjects, there was not a significant increase in VO_2max ($F(1,2,14)=.873$, $P>.05$). Means ± SD for CG were pre 44.72±9.69 and post 45.07±8.96ml/kg/min. Means ± SD for no-mask group were pre 42.70±8.83 and post 44.10±11.47ml/kg/min. Lastly, the means ± SD for mask group means were pre 45.50±8.72 and post 47.91±8.96ml/kg/min. There were no significant differences in VO_2max between the control and experimental groups ($F(1,2,14)=.170$, $P>.05$) either. Although the between groups data was not statistically significant, there was a greater increase in the mask group's aerobic endurance compared to the two other groups. **CONCLUSION:** When looking at the increase in VO_2max in response to a leg ergometer protocol, all three groups demonstrated an increase in VO_2max at the completion. Those who trained with simulated altitude masks showed the greatest improvement from pre- to post-testing, which could be a result of the mask use, in addition to the participant's outside training. The improvement shown in the other two groups may be a result of the participants' continued training outside of the study, as well as other factors.

Dynamic Strength Following Focal Knee Joint Cooling

Joo-Sung Kim. *University of Miami, Coral Gables, FL.*
(Sponsor: Perry, Arlette C, FACSM)
(No relevant relationships reported)

Focal knee joint cooling (FKJC) has been found to increase quadriceps strength during isometric contraction. It is unknown, however, if a similar response will occur with dynamic modes of muscle contraction such as concentric and eccentric. **PURPOSE:** To determine the effects of FKJC on isometric, concentric and eccentric modes of muscle contraction in the quadriceps muscle. **METHODS:** Twenty-one subjects (age=22.7±3.1year, height=170.4±10.8cm, weight=74.2±16.4kg) without lower extremity injury participated. All subjects received 20 minutes of FKJC for which two 1.5L plastic bags, filled with crushed ice, were applied to the anterior and posterior surface of the knee joint. The same bags filled with candy corn were used in the same manner for the sham treatment. FKJC and sham treatments were randomly administered to subjects on different days. An isokinetic dynamometer was used to quantify strength during isometric contraction and concentric and eccentric contraction at 60°/s and at 180°/s. For each muscle contraction mode, subjects were asked to perform 3 repetitions at their maximal effort before and immediately after treatment. Knee extension peak torque (Nm) was calculated, and the mean of the 3 trials for each mode of muscle contraction was used for statistical analysis. Separate 2 (treatment condition) by 2 (time) repeated measures ANOVAs were conducted with the alpha level set at .05. **RESULTS:** There were no significant interactions or main effects for any of the contraction modes ($p>.05$). For display of descriptive data, pre-and post-ice treatment's means and standard deviations are presented: isomeric (pre-ice:234.0±67.5, post-ice:237.5±72Nm), concentric 60°/s (pre-ice:188.5±58.1, post-ice:185.1±58.1Nm), concentric 180°/s (pre-ice:170.6±50.5, post-ice:169.2±53.5Nm), eccentric 60°/s (pre-ice:246.5±88.8, post-ice:250.1±85.0Nm), eccentric 180°/s (pre-ice:224.8±75.0, post-ice:223.8±76.2Nm). **CONCLUSION:** Twenty-minutes of FKJC did not change quadriceps strength during isometric, concentric, or eccentric muscle contraction. FKJC is not beneficial for increasing quadriceps isometric or dynamic strength in healthy individuals.

Longitudinal Correlation of Sleep Time, Strength Gains, and Performance in Collegiate Baseball Players: A Pilot Study

Delmas Bolin, FACSM[1], James Buriak[2], John Creasy[2], Gabrielle Deucher[2], Emily Whitaker[2], Adam Childers[2]. *[1]Performance Medicine of Southwestern Virginia, Roanoke, VA. [2]Roanoke College, Salem, VA.*
(No relevant relationships reported)

Sleep time influences lean body mass in dieting adults; sleep has not been demonstrated to influence anabolic processes in collegiate athletes. Longer sleep time is correlated with improved performance in sports.
Purpose: We followed 14 baseball players to describe sleep patterns and investigate their relationship to strength gains from weight training and performance parameters over a semester.
Methods: The study was approved by Roanoke College IRB. 14 baseball players were chosen at random and agreed to participate. Body composition was determined pre and post study by bioimpedence. Sleep/wake time were recorded using Actigraph monitor. Participants followed standard preseason conditioning & weight lifting regimen; 3 lift maximum pre and post study were recorded for biceps curl, dip, chest press, shoulder press, pull up and squat. Pitchers accuracy of fastball and skill pitches (curve, etc) were recorded during games.
Results: 13 of 14 athletes completed the study. 1 withdrew due to injury. The players sleep profile showed a significant difference between the shortest (311+/- 48 min/night) and longest sleepers (430+/- 54 min/night) (p<0.05). For statistical evaluation, "short sleepers" (<6.0 hours, n=8) and "long sleepers" (>6 hours, n=5) categories were used. Body composition: long sleepers tended to gain less body fat (0.22 +/- 0.64%) compared to short sleepers (0.63 +/- 1.65%) but was not significant (p=0.61) Long sleepers had strength gains in all 6 weight categories compared to short sleepers but changes were not significant (p=0.6). Pitching accuracy (strikes/total pitches) for fast ball correlate with night-before-performance sleep time, but were not significant.
Conclusion: This study demonstrates remarkable variation of sleep time in baseball athletes over a semester; the shortest sleepers had about 180 fewer hours of sleep than longest sleepers. Pilot data on weight training and performance demonstrates interesting trends relative to sleep time, but the study is not powerful enough to generate statistically significance. Our body composition results agree with previously published data and suggest further study is warranted.

Jumping To Conclusions: The Recovery-Monitoring Service 'Jump Test' Is Sensitive To Neuromuscular Fatigue in Recreational Runners

Luke J. Montzingo[1], Kyler Eastman[1], Kris Homsi[2], Jeff Knight[1]. *[1]Under Armour, Connected Fitness, Austin, TX. [2]Under Armour, Athlete Performance and Innovation, Portland, OR.*
Reported Relationships: L.J. Montzingo: *Consulting Fee; Under Armour Connected Fitness.*

Numerous studies over the last decade have shown a relationship between countermovement vertical-jump (VJ) performance and training load in both competitive team-sport athletes as well as in elite runners. As such, VJ performance serves as a marker of neuromuscular fatigue. However, less clear is the degree to which this relationship persists in non-elite, recreational 'run' athletes. 'Jump Test' is a footwear-integrated self-testing utility that measures and analyses repeated-VJ performance. **PURPOSE**: To determine how repeated-VJ performance, as measured before each training bout by average flight time and monitored via 'Jump Test', varies with training load in recreational 'run' athletes over a six-week period. **METHOD**: Eleven moderately trained (1-6 runs/week, 10-60 miles/week, >3 months) subjects (2F, 9M; 33.6 +/- 4.5 years) were enrolled voluntarily. Subjects followed a six-week training program devised to impose significant training loads that could be deemed counter-productive to performance (i.e. induce over-reaching if not over-training). Training was divided into three 2-week phases: baseline training (BL), overload training (OL), and active recovery (AR). Each weekday subjects performed the 'Jump Test' and rated their perceived level of muscle soreness. Training data was collected and analyzed via the mobile application *MapMyRun*. Chronic and acute training loads were computed. Training phase comparisons were made using paired T-tests. **RESULTS**: VJ performance decreased progressively throughout the first week of OL (z-score, -0.2 +/-1.0, OL vs 0.3 +/-0.8, BL; p < 0.01). Furthermore, reduced jump scores correlated with an increase in chronic training load (5.8 +/-3.8, OL vs. 3.1 +/-

2.5, BL r = -0.45, p < 0.01) and an overall increase in subjects' self-reported muscle soreness (2.7 +/- 0.9, OL vs. 3.4 +/-1.0, BL; r = 0.3, p < 0.01) during that week. **CONCLUSION**: Pre-workout, repeated-VJ performance was measured with a shoe-borne, jump-testing utility in recreational athletes over six weeks of variable training load. It was found VJ performance fluctuates with training load and perceived muscle soreness. The close relationship demonstrated between jump scores and self-reported measures suggests 'Jump Test' is a practical tool for monitoring neuromuscular fatigue and informing training load.

Evaluating The Potential Impact Of Fatigue On Ultimate Frisbee Players During Tournament Play

Jared Feister, Robert T. Sanders, Chris Carver, Hannah E. Nelson, James Kelly, Andy Bosak, James Schoffstall, FACSM. *Liberty University, Lynchburg, VA.* (Sponsor: Dr. James Schoffstall, FACSM)

(No relevant relationships reported)

Previous research has evaluated the quality of recovery from bouts of athletic events. Various measures have been used to assess recovery, yet most methods were somewhat problematic for rapid data collection. When costs are a limitation, it may be best to seek less expensive alternative methods of evaluating recovery. **PURPOSE:** To evaluate potential fatigue of collegiate ultimate frisbee athletes over two days of tournament play (TP) utilizing the perceived recovery status scale (PRSS) and ratings of perceived exertion (RPE). **METHODS:** Nineteen college-aged males participated in the study. Occurring over two days of TP, PRSS and RPE were recorded during 5 frisbee matches with each match separated by 30min. Two minutes prior to the first and second half, PRSS was recorded for each athlete and 2 minutes after each half, RPE was recorded. **RESULTS:** Significant differences occurred in PRSS with a decrease in values from the 2nd to the 5th matches (p = 0.006) and within the 2nd half of comparable matches (p = 0.031). No RPE recordings were significant. **CONCLUSION:** The results suggest that much of the variance in fatigue and fatigue-related measures occur between the 2nd and 5th matches of TP. The cumulative effects of fatigue during TP may have been a result of several potentially uncontrollable factors. Note, decreased perceived recovery could be related to the increased stress levels that occurred because of the amplified significance of the final match. Future research may evaluate other quantifiable recovery data (i.e. HRV and GPS) during tournament play.

3246   Board #115   June 2 8:00 AM - 9:30 AM

An Assessment of a 15 vs. 30 Second Recovery Period on Vertical Jump Performance

Hannah E. Nelson, Andy Bosak, Russell K. Lowell, Branden M. Ziebell, Robert T. Sanders, Jared Feister, Madeline M. Phillips. *Liberty University, Lynchburg, VA.* (Sponsor: Dr. James Schoffstall, FACSM)

(No relevant relationships reported)

The vertical jump (VJ) test is often used to assess an individual's lower body peak power. The standard recovery time between subsequent jumps is typically 30 seconds (secs) with a completion of 3-6 jumps. Prior studies have reported no significant difference between 30 vs. 60 secs recovery on VJ performance. However, it may be possible that a shorter passive recovery (PR) period may allow for maintenance or improvements in jumping performance versus the standard recovery time and therefore, potentially contribute to a more time efficient testing session. In contrast to this, if an individual is not completely recovered before their next jump, it is possible that their performance may be diminished compared to earlier jumps. To the best of the researchers' knowledge, the impact of a shorter PR period, such as 15 vs. 30 secs PR, on VJ performance has not been assessed. **PURPOSE:** To investigate potential differences between a 15 vs. 30 secs PR period on VJ performance in no less than averagely fit college-age males. **METHODS**: After measuring descriptive data (Ht., Wt., BF%, age), 31 averagely fit college-age males completed an 8 minute (min) dynamic warm-up on a cycle ergometer. Subjects were given a 4 min PR during which their reach height was measured. Following the PR, four familiarization jumps were completed using a VJ measurement device. After another 4 min PR, the subjects completed 2 series of jumps, with 6 trials each, in a counterbalanced order with either 15 (FIF) or 30 (THI) secs of recovery between each jump. The FIF and THI jump series were separated by 6 min of PR. Excluding the first jump, the highest jump for FIF and THI were compared using Paired-Samples t-Tests with significant differences occurring at p ≤ 0.05. **RESULTS:** Significant differences (p = 0.016) occurred between FIF (69.64 ± 8.61 cm) and THI (70.35 ± 8.99 cm). **CONCLUSION**: The current results suggest that 30 secs of PR between jumps is optimal recovery for performance during the VJ test, while 15 secs of PR may hinder peak VJ performance in averagely fit college-age males. Although THI was less than a centimeter above FIF, a sufficient number of subjects had improved performance during THI. Future research may assess the impact of 15 vs. 30 secs PR on VJ performance using highly fit collegiate athletes that use vertical jump as a sport specific movement.

The Effect Of Varying Self-myofascial Release Duration On Subsequent Athletic Performance

Jake Phillips, David Diggin, Deborah L. King, Gary A. Sforzo, FACSM. *Ithaca College, Ithaca, NY.* (Sponsor: Gary Sforzo, FACSM)

(No relevant relationships reported)

Self-myofascial release (SMR) treatments appear to enhance joint range of motion (RoM) and restore movement function but the effects of different SMR durations on athletic performance have yet to be examined. **PURPOSE**: To investigate the effects of different SMR treatment durations (1 minute and 5 minutes) on joint RoM, power, and agility. **METHODS**: Twenty-four volunteers participated with ankle and knee joint RoM assessed using modified weight-bearing (WBL) and kneeling lunge (KL) tests. Vertical jump (VJ) performance and pro-agility (PA) sprint performance were also examined. All tests were conducted before and immediately after one-minute (SMR_1) and five-minutes (SMR_5) of SMR and immediately following a control (CONTR) condition. SMR was done on the quadriceps and triceps surae muscle groups using a standardized protocol and foam roller. Differences in dependent variables (VJ height, PA run time, WBL distance, KL angle) between treatment groups (SMR_1, SMR_5, CONTR) at two time-points (pre- and post-treatment) were analyzed using a 3 x 2-way repeated measures analysis of variance (ANOVA). Alpha = 0.05. Effect sizes (ES) were calculated to clarify the magnitude of the effect of differences between means from pre- to post-treatment for each treatment condition. **RESULTS**: KL angle increased following SMR_5 (16.4 %; ES = 0.85) when compared with SMR_1 (12.5 %; ES = 0.58). WBL distance showed little change following SMR treatments and the CONTR condition exhibited little effect on RoM tests. VJ height decreased following SMR_5 (5.1 %; ES = 0.26) but changed little following SMR_1 (0.7 %; ES = 0.03) and CONTR (1.9 %; ES = 0.10) conditions. PA run time improved slightly following SMR_1 (1.1 %) but deteriorated following CONTR (1.2 %) and SMR_5 (0.5 %). Effect size calculations for changes in PA, however, were trivial across all conditions (0.06 – 0.15). **CONCLUSION**: Extended periods of SMR may be recommended should improvements in joint RoM be required. If power output is a critical requirement of subsequent tasks, prolonged SMR treatment (i.e., 5-min) should be avoided.

Fascia Stretch Training-7 Induces Similar Metabolic Response, But Lower Mechanical Stress

Filipe Dinato de Lima[1], Ubiratan Contreira Padilha[1], Amilton Vieira[1], Marco A. Dourado[1], Lee E. Brown, FACSM[2], Martim Bottaro[1]. [1]*University of Brasília, Brasília, Brazil.* [2]*California State University, Fullerton, CA.* (Sponsor: Lee E. Brown, FACSM)

(No relevant relationships reported)

The strength training is the most efficient modality to improve muscle volume and strength in health and disease. Recently, a new method of training including static stretching named Fascia Stretch Training (FST-7) has emerged. It is argued that the FST-7 could induce greater muscle swelling, known as an important hypertrophic stimulus. However, the acute responses to FST-7 have not been established. **PURPOSE**: To compare mechanic and metabolic responses from FST-7 with traditional strength training protocols. **METHODS**: Twelve resistance-trained men (age: 29.0 ± 6.1 years; weight: 84.4 ± 10.3kg; height: 1.78 ± 0.06m) participated of the study. The volunteers attended to the laboratory in four non-consecutive days. The first session was used to familiarization with the testing procedures. On the following sessions, volunteers performed randomly one of the three training protocols: 1) FST-7: seven sets of 10 isokinetic knee extension with a 40-sec rest-interval and 20-sec of quadriceps static stretching; 2) Control (CON): seven sets of 10 isokinetic knee extension with a passive 40-sec rest-interval; and 3) Traditional (TRA): seven sets of 10 isokinetic knee extension with a passive 120-sec rest-interval. Total work (TW) of each protocol was recorded. Muscle swelling (MS) and blood lactate (BL) was measured before and after each exercise protocol. Repeated measures multifactorial ANOVA was used to analyze data. **RESULTS**: On TW, there was a significant main effect for protocol (F = 23.843; p < 0.001). FST showed a lower TW (11823.01 ± 1735.06J) than CON (13976.08 ± 2378.07J) and TRA (15510.77 ± 2250.56J). On MS, there was no significant protocol and time interaction (F = 0.380; p = 0.69). All protocols showed a similar increase in MS after training session (p < 0.001). On BL, there was no significant protocol and time interaction (F = 2.166; p = 0.14). All protocols showed a similar increase in BL after training session (p < 0.001). **CONCLUSIONS**: FST, CON and TRA induce a similar increased in metabolic responses. However, FST produce lower mechanic stress than CON and TRA. These results suggest that FST may not be a superior stimulus than previous traditional strength protocols to induce muscle hypertrophy.

Abstracts were prepared by the authors and printed as submitted.

Could Knee Extension And Leg Press Exercises Induce Different Time Course Of Muscle Recovery?

Marco A. Dourado[1], Filipe Dinato de Lima[1], Amilton Vieira[1], Lee E. Brown, FACSM[2], Martim Bottaro[1]. [1]University of Brasília, Brasília, Brazil. [2]California State University, Fullerton, CA. (Sponsor: Lee E. Brown, FACSM)

(No relevant relationships reported)

Single- (SJ) and multiple-joint (MJ) resistance exercises are recommended for strength and hypertrophic gains. However, the levels of mechanical strain and hence muscle damage may be distinct between MJ and SJ resistance exercises. Studies comparing symptoms of muscle damage following MJ and SJ exercises are lacking. **PURPOSE**: This study investigated the time course of symptoms of muscle recovery after two knee extension exercises in resistance-untrained men.
METHODS: Seven men (25 ± 4 yrs) were randomly assigned to perform a unilateral MJ multi-joint resistance exercise (i.e. leg press, LP) and a unilateral single-joint resistance exercise (i.e. seated knee extension, KE) with the contralateral limb. Participants performed 8 sets of 10 repetition maximum of both exercises with 2 min rest between sets. Muscle edema (ME), peak torque (PT), 1-legged countermovement (CMJ), and muscle soreness (MS) were measured pre, post, 24, 48, 72 and 96h following exercise.
RESULTS: ME of the rectus femoris returned to baseline at 48h after LP exercise, and at 24h after the KE exercise. ME of the vastus lateralis recovered at 24h after both exercises. PT recovered at 24h, and there was no difference between both exercises ($p>0.05$). CMJ returned to the baseline values 72h after the LP exercise, and 24h after the KE exercise. Muscle soreness of the rectus femoris was greater at 48h after KE when compared to LP exercise. There was no difference between exercises in the magnitude of MS response in vastus lateralis ($p>0.05$).
CONCLUSIONS: Resistance-untrained men experience different muscle recovery following LP and KE exercises. The MJ condition was more stressful for knee extensors muscles than SJ, taking more time to recover from muscle damage.

Assessment of Countermovement Jump Performance Recovery in Professional Soccer Players Using an Inertial Sensor

Malachy P. McHugh, FACSM[1], Tom Clifford[2], Will Abbott[3], Susan Y. Kwiecien[1], Ian J. Kremenic[1], Joseph J. Devita[1], Glyn Howatson, FACSM[4]. [1]Nicholas Institute of Sports Medicine and Athletic Trauma, Lenox Hill Hospital, New York, NY. [2]Newcastle University, Newcastle, United Kingdom. [3]Brighton and Hove Albion F.C., Lancing, United Kingdom. [4]Northumbria University, Newcastle, United Kingdom.

(No relevant relationships reported)

Purpose
We recently demonstrated accelerated recovery of strength and more rapid resolution of pain in professional soccer players wearing phase change material (PCM) cooling garments post game. During that study, recovery of countermovement jump (CMJ) mechanics was assessed using a wireless inertial sensor (BTS G-Sensor 2, Brooklyn, NY). The purpose of this study was to compare recovery of CMJ mechanics between PCM and control and thereby determine if this sensor is useful for assessing recovery.
Methods
In a randomized, crossover design, 11 elite professional soccer players wore either PCM shorts cooled to 15°C (PCMcold) or ambient temperature (PCMamb; control) for 3 h after a game. CMJ performance was assessed pre game and at 12, 36 and 60 h post game. The following metrics were assessed: flight height (calculated from time in air), jump height (flight height + difference between standing height and takeoff height), low force (unweighting during initiation of countermovement), countermovement (distance dropped during countermovement), force at end of countermovement, rate of force development, eccentric power, peak propulsive force, maximum power, and peak landing force. Data are expressed as % of baseline and analyzed with Treatment (PCMcold vs. PCMamb) by Time (Baseline, 12, 36, 60 h post game) repeated measures ANOVA.
Results
Over the 3-day post-game period PCMcold resulted in better CMJ flight height (PCMcold 104% of baseline, PCMamb 90%; P=0.007) and jump height (PCMcold 110%, PCMamb 95%; P=0.035). Other kinetic and kinematic measures were not different between PCMcold and PCMamb. Overall, low force was progressively higher on the days after the game (P=0.018, 55% higher at 60 h) indicating that players did not unweight themselves as much during the initiation of the countermovement. Additionally, peak landing force was progressively lower on the days after the game (P=0.012, 89% of baseline at 60 h). These effects on low force and landing force did not impair recovery of jump heights as jump heights had fully recovered by 60 h.
Conclusions

The better CMJ performance when players wore PCM cooling shorts post game is evidence of accelerated recovery. This inertial sensor provides a portable and practical means of assessing recovery in elite soccer players.

Effect Of Cold Water Immersion On Skin Temperature: A Thermography Study

Braulio Sánchez-Ureña[1], Daniel Rojas-Valverde[1], Randall Gutiérrez-Vargas[1], Juan Carlos Gutiérrez-Vargas[1], Christopher T. Minson, FACSM[2]. [1]National University of Costa Rica, Heredia, Costa Rica. [2]University of Oregon, Oregon, OR. (Sponsor: Christopher Todd Minson, FACSM)

(No relevant relationships reported)

Cold water immersion (CWI) is a recovery method in sports, acting through a reduction in body temperature and improved muscular function by limiting post-exercise inflammation. Infrared Thermography (IRT) is a non-invasive technique to measure skin temperature, and has been used in the diagnosis of hyperthermic muscles, such as occurs with delayed onset muscular soreness. To our knowledge, there are no studies using IRT to analyze the skin temperature in the recovery process following fatiguing exercise. **PURPOSE**: To compare the effect of two CWI protocols as a recovery treatment on skin temperature. **METHODS**: 40 healthy male subjects (age 21.8 ± 2.76 yrs, body mass 73.15 ± 8.15 kg, height 176.6 ± 5.3 cm, and body fat $13.5 \pm 3.4\%$). Subjects went through a fatiguing protocol: 8 sets/30 secs countermovement jumps with 90 second pauses between series. Subjects were randomized in three conditions: control group (CG) (passive recovery, 12 min sitting in a 23 °C room); continuous CWI (CnCWI) (12 min in water at 12 ± 0.4 °C); and intermittent CWI (InCWI) (2 min CWI at 12 ± 0.4 °C, 1 min in a controlled environment at 23°C, until the 12 min of CWI were completed). Maximal lower limb skin temperature (MST) was measured at pre, post24 and post48 hours via IRT camera (FLIR T450). Repeated measures ANOVA were used. Significance was set at p< 0.05.
RESULTS: No between group interaction effects were found in the dominant limb in the frontal plane (F(4,74)= 0.89, p= 0.47): post24 (CG: 33.5±1.1°C vs. CnCWI: 33.4±1.4°C, InCWI: 33.7±0.8°C); post48 (CG: 34.2±0.9°C vs. CnCWI: 33.9±0.8°C, InCWI: 33.6±0.8°C), or in the posterior plane (F(4,74)= 0.54, p= 0.70): post24 (CG: 33.3±1.2°C vs. CnCWI: 33.3±0.7°C, InCWI: 33.5±0.9°C); post48 (CG: 33.2±0.8 vs. CnCWI: 33.8±1.9°C, InCWI: 33.5±1°C). Similarly, no between group interactions were observed in the non-dominant limb in the anterior plane (F(4,74)= 0.68, p= 0.64): post24 (CG: 33.4±1.0°C vs. CnCWI: 34±2.1°C, InCWI: 33.6±0.9°C); post48: (CG: 34.1±0.9°C vs. CnCWI: 33.9±1 °C, InCWI: 34.0±1°C), or for the posterior plane (F(4,74)=0.70, p=0.59), post-24 (CG: 33.1±0.9°C vs. CnCWI: 33.2±0.7°C, InCWI: 33.5±1°C); post48 (CG: 33.1±0.9°C vs. CnCWI: 33.3±0.7°C, InCWI: 33.6±1.1°C).
CONCLUSIONS: Neither CWI protocol reduced mean or maximal lower limb skin temperature at 24 nor 48 hours post fatiguing protocol.

Reproducibility of the RMSSD Index of Heart Rate Variability in Recovery After Exercise

Lucieli T. Cambri, Jaqueline A. Araújo, César S.A. Mello, Geovane J. Tolazzi, Fabiula I. Novelli, Gisela Arsa. *Federal University of Mato Grosso, Cuiabá, Brazil.*

(No relevant relationships reported)

Heart rate variability (HRV) is an important parameter that allows evaluate parasympathetic reactivation after physical exercise. However, because its a cardiac phenomenon evaluated in non-stationary conditions, it is fundamental to evaluate its reproducibility in post exercise recovery. **PURPOSE**: To analyze whether the RMSSD index of HRV shows reproducibility in both passive and active after maximal exercise recovery. **METODOLOGY**: Eleven young healthy (22.1 ± 3.2 years, 23.5 ± 2.3 kg/m²) and untrained men (36.1 ± 5.2 mL/kg/min) were evaluated. HRV was evaluated by LnRMSSD (heart rate monitors - transformed into a natural logarithm), which reflects the parasympathetic activity, after maximal progressive exercise (cycle ergometer) every 30s throughout the 10 min of test and retest of passive recovery (seated position) and active (5 min at 15W e then at 5 min passively) after exercise. The Shapiro Wilk test was used to test the normality of data, test T-Student's and Wilcoxon were used to compare each recovery of test and retest (p<0,05). Intraclass correlation coefficient (ICC) was used to evaluate the relative reproducibility and standard error of measurement (SEM) and coefficient of variation (CV) to the absolute reproducibility. **RESULTS**: There was difference between test and retest for LnRMSSD only at 120s (p: 0.00) in passive recovery and at 420s (p: 0.04) in active. Reproducibility was observed to both recovery types - in passive recovery: very high at 90, 270, 480 and 570s (ICC: 0.90 - 0.95) and high at 60, 120 to 240, 300 to 450, 510, 540, 600s (ICC: 0.72 - 0.89); at active recovery: high at 30, 150, 240, 270, 330 to 420, 480, 510 and 540s (ICC: 0.70 - 0.87) and moderate at 60, 120, 180, 210, 300, 450, 570 and 600s (ICC: 0.50-0.69). During passive recovery CV varied between 12.83 - 39.73% and SEM between 0.33 - 1.14 ms and during active recovery varied between 16.58 - 39.51% and 0.43 - 1.05 ms. **CONCLUSION**: The RMSSD index is reproducible in

both passive and active recovery after maximal exercise in young men. Therefore, it can be used as a reliable index to evaluate cardiac parasympathetic reestablishment after maximal exercise. Supported by CNPq (process 443361/2014-2) and CAPES.

Perceived Recovery Status is Associated with Back Squat One-Repetition Maximum Self-Efficacy

Michael H. Haischer[1], Daniel M. Cooke[1], Joseph P. Carzoli[1], Amber M. Shipherd[2], Trevor K. Johnson[1], Edward P. Davis[1], Dan J. Belcher[1], Robert F. Zoeller[1], Michael Whitehurst, FACSM[1], Michael C. Zourdos[1]. *[1]Florida Atlantic University, Boca Raton, FL. [2]Texas A&M University-Kingsville, Kingsville, TX.*
(No relevant relationships reported)

Self-efficacy (SE) is defined as an individual's belief in their ability to successfully complete a task. According to SE theory, physiological and affective states can exert influence on efficacy beliefs, thereby affecting performance outcomes. Additionally, fluctuation in daily readiness can also impact performance outcomes due to factors such as stress, sleep problems, or poor physiological recovery from previous bouts of training. To evaluate daily readiness through the assessment of these performance factors, a variety of scales and questionnaires exist. One such assessment, the Perceived Recovery Status (PRS) scale, asks individuals to indicate how well recovered they feel on a 0-10 Likert scale. However, despite widespread usage of the PRS scale, no study has examined if pre-training recovery is indeed related to increased SE. **PURPOSE**: To investigate the relationship between recovery as indicated by the PRS scale and SE in resistance trained individuals prior to a one-repetition maximum (1RM) back squat test. **METHODS**: Fifty-eight resistance-trained males (n=41) and females (n=17) (age: 23±3 yrs, body mass: 80.64±16.49 kg) completed the PRS scale and a modified version of the Self-Efficacy Questionnaire for Athletes (mSEQ-A), prior to a 1RM back squat test. The mSEQ-A required participants to rate, on a 0-100 Likert scale, how confident they were that they could beat their previous back squat personal record by any load. Next, following a 5-minute dynamic warm-up, subjects completed a validated 1RM back squat protocol. A Pearson's product moment correlation was used to determine any relationships between PRS ratings and SE beliefs. **RESULTS**: Mean PRS rating was 7.7±1.5, while mean mSEQ-A rating was 52.4±35.7. Regression analysis revealed that the PRS scale was significantly related to SE as determined by the mSEQ-A (r=0.39, p<0.05). **CONCLUSIONS**: The PRS scale was significantly related to SE. These findings reflect the fact that individuals who perceived themselves to be more well-recovered, also perceived themselves to be more likely to succeed in a 1RM test.

Electromagnetic Field Application Effects on Recovery and Power after Sport-Specific Exercise Intervention: Feasibility Study

Nauris Tamulevicius[1], Tanuj Wadhi[1], Emily A. Daniels[1], Guillermo R. Oviedo[2], Stephen Baeder[1]. *[1]The University of Tampa, Tampa, FL. [2]University Ramon Llull, Barcelona, Spain.*
(No relevant relationships reported)

Electromagnetic field application (EFA) has demonstrated increased vasomotor function of vessels throughout the body and thus on microcirculatory blood flow regulation in the clinical population. It is unknown if EFA can positively influence recovery and improve physical conditioning in tennis players. **PURPOSE**: To determine if EFA optimizes recovery and improves anaerobic/power parameters in female college tennis players. **METHODS:** Subjects for this study consisted of female NCAA Division II tennis players (n=7, age 19.7±1.3 y.o., weight 65.7± 9.7 kg, height 168.1 ±2.04 cm). EFA was used 22 times across a 4 week period after sport-specific training or after matches. EFA protocol included 8 minutes of laying on the BEMER EFA, which transmitted weak electromagnetic field of flux density 35-50 µTesla (highest level). Subjects were also required to express their Rate of Perceived Fatigue (RPF scale 0-10) before and after every application. Standardized 30 s Wingate tests were performed before the 1st week of the application, 1 week after, 3 weeks after, and 4 weeks after EFA recovery protocol. Heart rate (HR), O_2 saturation and blood lactate (BL) were analyzed pre, post, post-1 min, post-3 min, post-5 min, and post-10 min after the Wingate tests. **RESULTS:** Absolute Peak Power (APP) increased after 22 EFA applications from 428.7±118.5 W to 491.5±113.4 W (p=0.063) and Relative Peak Power (RPP) increased from 6.5±1.2 W/kg to 7.5±0.9 W/kg (p=0.063). BL levels decreased post-1minute from 11.2±1.15 mmol/L to 9.8±1.5 mmol/L (p=0.063). ΔRPF before and after application decreased significantly from 2.57±0.79 to 1.43±0.79 (p=0.034). Although APP, RPP, and BL post-1minute improved, it was not significant (p=0.063) possibly because of the relatively small sample size. Changes in other anaerobic/power parameters were not as notably expressed. **CONCLUSION:** Improved microcirculatory blood flow could suggest that APP and RPP increased over the span of a 4-week period in female tennis players. Significant decrease in RPF

---

suggests that EFA might be an effective tool to use for recovery after sport-specific training and/or matches for tennis players. Considering the observed changes in 4 weeks, supplementary studies using a larger sample size should be explored.

Effects of Recovery Type on Blood Lactate and Performance Following Repeated Wingate Tests in Females

Madison L. Kirkpatrick, Boe M. Burrus. *Humboldt State University, Arcata, CA.* (Sponsor: Vincent J Paolone, FACSM)
(No relevant relationships reported)

The optimal type of recovery to maximize performance and regain homeostasis after maximal exercise in sport has mixed results. There is a lack of research on the effect of a longer duration active recovery protocol on blood lactate and performance in repeated Wingate tests. Also, minimal research exists with females in this area. **PURPOSE:** To determine if an active recovery of a prolonged duration at a moderate intensity is more beneficial for subsequent anaerobic performance than passive recovery by analyzing blood lactate and anaerobic performance variables across Wingate tests. **METHODS:** Subjects completed an incremental test to determine their peak power output, and 50% of peak power was used as the active recovery intensity. A 15 minute recovery time frame was used. Blood lactate measurements were collected after the first Wingate, at five-minute increments of the recovery protocol, and after the second Wingate. RPE was also collected after each Wingate test. **RESULTS:** A significant interaction was found between recovery and time for blood lactate ($F = 6.935$; p = 0.000). Blood lactate levels were significantly lower for the active recovery trial at all time points of recovery, but no significant difference in performance was observed for any of the variables measured between the passive and active trials. **CONCLUSION:** Based on previous research, the lower lactate values and performance might not be as connected as previously thought. However, the lower lactate levels can still be beneficial to recovery after intense exercise and repeated attempts, but there may be no effect of blood lactate clearance on performance. It is possible that a buildup of H^+ ions decreases muscle cell contractility enough for both recovery types that differences in performance between the two conditions are miniscule and therefore may be negligible when using the current parameters.

Respiratory Impedance Enhances Recovery and Performance During Repeated Bouts of High-Intensity Exercise

Peggy A. Plato, Isabel L. Romero, Olivia M. Nierhake, Andrew W. Tsao. *San Jose State University, San Jose, CA.* (Sponsor: Craig Cisar, FACSM)
(No relevant relationships reported)

Impedance threshold devices (ITD) were initially developed to maintain blood pressure during battlefield trauma. By creating a greater negative intrathoracic pressure, venous return is enhanced (Ryan et al., 2008). Convertino et al. (2005) found that spontaneous breathing through an ITD increased stroke volume and cardiac output during the initial 10 s of standing from a squat position and was an effective countermeasure against hypotension initiated by the squat-to-stand test. **PURPOSE:** This study evaluated the efficacy of using an ITD during recovery following three consecutive 30 s, high-intensity exercise bouts on a bicycle ergometer. **METHODS:** Fifteen participants (11 men, 4 women, 24 ± 1 years-of-age, $M \pm SEM$) completed two exercise conditions separated by at least 7 days: control (no ITD) and breathing through an ITD during recovery (ResQGARD®, Advanced Circulatory Systems, Eden Prairie, MN). Each exercise bout was performed with a resistance set at 60 g/kg body weight followed by a 4 min recovery between bouts. **RESULTS:** Ratings of perceived exertion ranged between 7.9 and 9.5 on the Borg category-ratio scale during the three exercise bouts with ratings slightly lower during the ITD condition ($F(1, 54) = 4.774$, $p < .05$). There was a significant interaction effect for ratings of perceived recovery ($F(3, 40) = 2.980$, $p < .05$) with participants indicating they felt better recovered after bout 3 when using the ITD. There was also a significant interaction effect for mean power ($F(2, 28) = 3.842$, $p < .05$) with power better maintained during bout 3 when using the ITD (416 ± 32 W vs. 400 ± 34 W for the control condition). In contrast, there were no significant effects of the ITD on peak power or blood lactate compared to the control condition. **CONCLUSION:** Using an ITD between repeated bouts of high-intensity exercise may help individuals feel better recovered and, thus, able to maintain higher mean power during subsequent exercise bouts.

The Effect Of Self-myofascial Release As A Warm-up On Muscular Strength And Power

Theodore M. DeConne, II, Marc Robertson, William Lunn. *Southern Connecticut State University, New Haven, CT.*
(No relevant relationships reported)

Individuals are often instructed to use a foam roller as a warm-up (WU), despite a lack of evidence supporting performance enhancement claims attributed to foam rolling self-myofascial release (FR-SMR). Studies have investigated whether foam rolling can be used to enhance performance; however, more research is required.
PURPOSE: To determine whether variations of an acute bout of FR-SMR WU will affect maximal muscular strength and power performance differently than a placebo SMR WU.
METHODS: Adult men (N=3) and women (N=3) [N=6, age=23.5 ± 3.39 years, height=66.08 ± 4.77 cm, and average mass=67.46 ± 17.57 kg] were recruited for the study. This study was an intra-participant design consisting of one condition comparing the impact of three different WU conditions on two performance tests. Each participant randomly performed one of the three WU conditions each day: 1) FR-SMR plus dynamic WU (FR-D), 2) FR-SMR only (FR), and 3) FR "shadowing" plus dynamic WU (noFR-D). The "shadowing" condition involved the foam rolling movements without the actual roller. Routines were separated by a week, for a total of three weeks. The performance tests were completed after each WU in the following order: a counter-movement squat jump (CMSJ) on a force platform and 10 repetitions maximum (10RM) bench press. The CMSJ was used to measure relative maximal power and the 10RM bench press was used to assess relative maximal strength. A one-way multivariate ANOVA was used to test significance in performance between WU conditions (p < 0.05).
RESULTS: There were no significant differences in maximal strength or power between FR-D, FR, and noFR-D (relative maximum power: FR-D=54.93 ± 3.92 W/kg, noFR-D=56.03 ± 5.95 W/kg, FR=56.59 ± 4.08 W/kg; relative maximum strength: FR-D=0.83 ± 0.34 kg/kg, noFR-D=0.82 ± 0.33 kg/kg, FR=0.88 ± 0.36 kg/kg) (*p*=0.980).
CONCLUSIONS: Integration of FR SMR into a WU offers no additional benefits to produce maximal strength or power. While FR did not enhance maximal strength and power, FR did not appear to be detrimental to the production of maximal strength and power.

The Effects of a Proprietary Resistance Garment Technology on Exercise and Recovery Energy Expenditure

John Paul M. Arreglado, Samantha Silva, Edward Jo. *Cal Poly Pomona, Pomona, CA.*
(No relevant relationships reported)

Previous research demonstrates the benefits of compression exercise garments as it relates to performance and recovery. For instance, compression garments have attenuated delayed onset of muscle soreness and increased the rate by which muscular contractile kinematics were restored. However, the overall body of research related to the use of compression garments have failed to evaluate its full complement of potential applications in sport and exercise. Physiclo with their Pro Resistance Technology has innovated a new line of compression garments that may apply added resistance to physical movements ranging from every day activities to high intensity athletic training. In turn, the purported benefits include facilitated performance and body composition adaptations due the added metabolic demand and musculoskeletal stress. There is limited empirical information regarding the effects of such class of compression garments on energy expenditure across various exercise modes. PURPOSE: The purpose of this investigation is to examine the effects of Physiclo compression garments on exercise and recovery energy expenditure in NCAA collegiate athletes. METHODS: In a randomized, cross-over design study, 16 healthy male (n=8) and female (n=8) subjects underwent a series of exercises wearing either the experimental (Physiclo) compression garment (EXP) or general exercise attire (CON) while simultaneously undergoing indirect calorimetry and heart rate measurements. RESULTS: When examining the data in aggregate the EXP increased oxygen consumption and energy expenditure by 15%, ventilation rate by 22%, and heart rate by 18% during an entire bout of exercise in comparison to non-specialized sports garments (p<0.05). The improvement in oxygen consumption, energy expenditure, ventilation and heart rate was statistically equivalent between sexes and among each exercise task. Post-workout recovery measures for oxygen consumption, energy expenditure, ventilation, and heart rate did not differ between EXP and CTL conditions. CONCLUSIONS: We conclude that the use of the Physiclo compression garment may enhance the metabolic demand of an exercise bout which provides some insight into their benefits relating to performance and physiological adaptations to training.

Sleeping Patterns of NCAA D1 Collegiate Athletes: A Sex Comparison

Courteney L. Benjamin[1], William M. Adams[2], Ryan M. Curtis[1], Yasuki Sekiguchi[1], Gabrielle E.w. Giersch[1], Anne M. Muholland[1], Douglas J. Casa, FACSM[1]. [1]*University of Connecticut, Storrs, CT.* [2]*University of Connecticut, Storrs, CT and University of North Carolina, Greensboro, NC.*
(No relevant relationships reported)

PURPOSE: To compare male and female sleep surrounding competition in NCAA Division 1 athletes. **METHODS**: 22 collegiate male soccer athletes (mean±SD; age, 20±0 y; height, 181.2±6.5 cm; mass, 79.4±6.9 kg) and 11 collegiate female cross-country runners (mean±SD; age 19±1 y; height 168.4 ± 7.7 cm; mass 58.8 ± 9.6 kg) participated in this study, in which their sleeping behaviors were captured using a wrist-worn actigraphy device throughout the entire competitive season. Metrics captured included: Heart rate Variability (HRV), Hours of Sleep (SleepHours), Sleep Need (SN), Sleep Efficiency (SE), Sleep Disturbances (SD), Wake Time (WT), Light Sleep Time (LS), Slow Wave Sleep Time (SWS), Rapid Eye Movement Sleep Time (REM), and Time in Bed (TiB). A linear mixed effect model assessed the differences between male and female athletes during one night prior to competition (COMPpre) and the night following competition (COMP). The total number of observations and the number of athletes were recorded (COMPpre: 300 observations, 33 athletes; COMP: 267 observations, 30 athletes). The results are reported as mean difference (MD) with 95% confidence intervals (95%CI). **RESULTS**: The female athletes experienced significantly less SN on COMPpre than males (MD [95%CI], - 0.53h [-1.00, -0.05], p=0.03). No other sleep variables were significantly different on COMPpre.
In regards to COMP, the female athletes obtained more SleepHours, LS, REM, and TiB than males (SleepHours, 1.13 h [0.11, 2.15], p=0.03; LS, 0.98h [0.29, 1.66], p=0.01; REM, 0.63h [0.32,0.94], p<0.001; TiB, 1.24h [0.25, 2.23], p=0.02). However, females experienced more SD than their male counterparts (SD, 3.77 [1.17, 6.37], p=0.01). The female athletes also experienced less SWS than males on COMP (SWS, -0.41h [-0.76, -0.06], p=0.02). **CONCLUSION:** The findings of this study illustrated that the female athletes were more rested prior to competition, which could be related to the men's team having midweek games and less sleep continuity. Future investigation is warranted to determine the potential causes of the differences on COMP. Increased sleep duration and quality could positively affect performance on the field and in the classroom, which is important for the collegiate cohort. Future studies should standardize the sleep quality metrics relative to SleepHours.

G-40   Free Communication/Poster - Muscle Architectural Adaptations - Hypertrophy and Atrophy

Effects Of Glutamine Supplementation On Overload-induced Muscle Growth And Function In Mice

Kimberly Huey, FACSM, Kyle Godwin. *Drake University, Des Moines, IA.*
(No relevant relationships reported)

Muscle hypertrophy induced by functional overload (FO) provides an *in vivo* model to study muscle growth. Glutamine has been shown to improve muscle function, maintain contractile protein levels, and reduce inflammation; however, its effects during muscle growth is unclear. **PURPOSE:** These experiments tested the hypothesis that glutamine supplementation positively impacts the skeletal muscle response to a growth stimulus as evidenced by greater hypertrophy, increased growth factor levels, and improved contractile function compared to placebo. **METHODS:** Mice underwent FO of the plantaris or sham surgery. *In vivo* plantaris force and fatigue resistance (% of maximal force after 10 contractions) were measured 14 days after FO or sham in mice receiving daily glutamine (1 g/kg body mass) or placebo (n= 7-9/group). Insulin-like growth factor 1 (IGF-1) was measured in the plantaris by ELISA after 14 days of FO or sham. Data were analyzed with 2-way ANOVAs. **RESULTS**: FO increased plantaris mass independent of treatment; however, glutamine tended to enhance muscle hypertrophy compared to placebo (Placebo: 15 ± 0.6 vs. 28 ± 2 mg and Glutamine: 16 ± 0.5 vs. 34 ± 3 mg, for sham and FO, respectively, p<0.05). Maximal isometric force relative to body mass was unchanged with FO, independent of glutamine. Fatigue resistance was increased with FO compared to sham, independent of glutamine (Placebo: 39 ± 4 vs. 50 ± 5% and Glutamine: 33 ± 2 vs. 56 ± 2%, for sham and FO, respectively, p<0.05). Muscle levels of IGF-1 were significantly increased with FO, independent of glutamine

(Placebo: 55 ± 7 vs. 848 ± 131 pg/mg protein and Glutamine: 25 ± 10 vs. 813 ± 174 pg/mg protein, for sham and FO, respectively, $p<0.05$). **CONCLUSIONS:** Functional overload was associated with significant hypertrophy, elevated IGF-1 levels, and increased fatigue resistance, but these adaptations were not enhanced with glutamine supplementation.

Contribution Of Exercise, Physical Activity, And Protein To Functional Cross-sectional Area And Intramuscular Adipose Tissue

Kyle J. Hackney[1], Nathan D. Dicks[1], Kara A. Stone[1], Christopher J. Kotarsky[1], Allison M. Barry[1], Jill Keith[1], Steven Mitchell[2], Wonwoo Byun[3], Sherri N. Stastny[1]. *[1]North Dakota State University, Fargo, ND. [2]Sanford Health, Fargo, ND. [3]University of Utah, Salt Lake City, UT.*
(No relevant relationships reported)

Muscle cross sectional area (CSA) has historically been used as a measure for skeletal muscle size, however, functional cross sectional area (FCSA), defined as the area of muscle isolated from adipose tissue within the CSA, is more closely associated with muscular health. The visible adipose tissue beneath the muscle fascia, defined as intramuscular adipose tissue (IMAT), has also been linked to metabolic abnormalities at increased levels in clinical populations. In contrast, in some healthy populations IMAT may be used as a fuel source for physical activity (PA) and dietary intake may influence IMAT.
PURPOSE: This study examined factors that predicted FCSA and IMAT in the knee extensors (KE) of younger and older men and women. **METHODS:** Ninety-eight participants (46 male, 52 female) were classified as younger (20-35 yr) and older (50-65 yr) as well as sedentary (< 2 days per week) and active (3+ days per week) based on self-reported age and concurrent resistance and aerobic exercise training status. All participants completed anthropometry measurements, lower body muscle function testing, a 3-day dietary intake log, and wore an accelerometer for seven days. Participants then completed magnetic resonance imaging (MRI) scanning of the lower limbs. Muscle CSA was determined by manually tracing the KE and FCSA and IMAT were derived through color thresholding. Independent samples t-tests were conducted and two separate step-wise regression analyses were performed to predict FCSA and IMAT. **RESULTS:** IMAT (cm^2) was significantly higher in the sedentary (3.74 ± 1.93) vs. active (1.85 ± 0.56) as well as in older (3.14 ± 2.05) vs. younger (2.74 ± 1.25) (P < 0.05). Protein intake (g·kg·day^{-1}) was also significantly higher in active (1.63 ± 0.55) vs. sedentary (1.19 ± 0.40) (P < 0.05). Gender, age, concurrent exercise training status, and protein intake significantly predicted 70% of the variance in FCSA (P < 0.01), while concurrent exercise training status and light PA predicted 33% of the variance in IMAT (P < 0.01). **CONCLUSION:** Concurrent exercise, protein intake, and light PA are major determinants of skeletal muscle health and may require further investigation to mitigate aging and activity related loss of muscle quality. Funding: Sanford Health/NDSU Collaborative Research Seed Grant Program

Muscle Morphology is Not Altered in PGC-1α Transgenic Mice following Bupivacaine Injection

Wesley S. Haynie, Richard A. Perry, Lemuel A. Brown, David E. Lee, Jacob L. Brown, Megan E. Rose-Caldwell, Nicholas P. Greene, Tyrone A. Washington. *University of Arkansas, Fayetteville, AR.*
(No relevant relationships reported)

Peroxisome proliferator-activated receptor-γ coactivator-1α (*PGC-1α*) is a transcriptional activator shown to stimulate mitochondrial biogenesis. *PGC-1α* overexpression has been shown to reduce muscle damage and wasting in a variety of pathophysiological conditions. However, how *PGC-1α* accomplishes this is unknown. **PURPOSE:** To examine the effects of muscle specific overexpression of *PGC-1α* on muscle fiber size distribution, cross-sectional area (CSA), 4EBP-1 protein content, and *MyoD* gene expression during muscle regeneration. **METHODS:** 23 C57BL/6 (WT) and 24 Transgenic (A1) mice were used for this study, with A1 mice having muscle specific overexpression of the protein *PGC-1α*. Mice were injected with either PBS or Bupivacaine (MAR) at 12 weeks of age. Tibialis anterior (TA) muscle and tibias were excised 3 days and 28 days post injection. Tissue was immediately frozen for morphology and gene expression analysis using RT-qPCR. **RESULTS:** *PGC-1α* gene expression was 15-fold greater in A1 mice compared to WT mice (p<0.05). There was no difference in TA mass/Tibia length ratio in any mice 3 days or 28 days post-injection with bupivacaine. In WT mice 3 days post-bupivacaine injection, *MyoD* gene expression was 50% higher (p< 0.05) than the PBS control group. In A1 mice 3 days post-bupivacaine injection, *MyoD* gene expression was 75% lower than PBS control group. P-4EBP-1/4EBP-1 content was 50% higher in WT mice 3 days post-bupivacaine injection compared to the PBS control group. In A1 mice 3 days post-bupivacaine injection, P-4EBP-1/4EBP-1 was ~50% lower compared to the PBS

---

control group (p<0.05). 28 days post-bupivacaine injection there was a 18% decrease in CSA in WT mice, however there was no change in CSA of A1 mice (p<0.05). In WT mice 28 days post-bupivacaine injection, there was an increase in the proportion of small fibers (<300µm^2) and a decrease in the proportion of large fibers (>900µm^2). In A1 transgenic mice 28 days post-bupivacaine injection, there were no differences in fiber size distribution. **CONCLUSION:** Muscle specific overexpression of *PGC-1α* has been shown to protect muscle from damage. We demonstrate no change in muscle morphology in mice that overexpress *PGC-1α* in muscle. The altered microenvironment could be due to a shift away from proliferation of myoblasts towards differentiation.

Characterizing a Novel Rodent Exercise Model to Explore the Permanency of Myonuclear Accretion During Muscle Adaptation

Cory M. Dungan, Kevin A. Murach, Ivan Vechetti, Jr, John J. McCarthy, Charlotte A. Peterson. *University of Kentucky, Lexington, KY.* (Sponsor: Brian Noehren, FACSM)
(No relevant relationships reported)

Myonuclear density increases during skeletal muscle hypertrophy, and it has been postulated that newly-acquired myonuclei are permanent and constitute a "muscle memory" of previous adaptation; however, the available evidence supporting this is equivocal. **PURPOSE:** To determine if myonuclear accretion in skeletal muscle is permanent following a period of prolonged detraining after training utilizing a novel progressive weighted-wheel running (PoWeR) protocol. **METHODS:** PoWeR training involved the progressive addition of weight (2-6g) to an un-balanced running wheel over 8 weeks. Four month old female C57Bl/6J mice (n=8-10/group) performed PoWeR, while another cohort performed PoWeR followed by 12 weeks of detraining. Age-matched ambulatory controls were used for baseline comparisons. Following training and detraining, the soleus and plantaris muscles underwent immunohistochemical analyses. **RESULTS:** Wet weight of the soleus muscles, when normalized to body weight (mg/g), was greater in the PoWeR trained mice when compared to the in the controls, 0.48 ± 0.05 and 0.36 ± 0.02, repectively (P<0.05). Similarly, normalized plantaris muscle mass was increased following PoWeR training (0.51 ± 0.04) when compared to the controls (0.58 ± 0.05; P<0.05). This resulted in a 32% and 14% increase in normalized wet weight after PoWeR in the soleus and plantaris muscles, respectively (P<0.05). Fiber cross-sectional area (CSA) was 22% greater in the soleus and 15% greater in the plantaris (P<0.05), while myonuclei per fiber increased by 32% and 41% in the soleus and plantaris, respectively (P<0.05). Additionally, there was a fiber-type shift toward a more oxidative phenotype in the soleus and plantaris. After detraining, normalized muscle wet weight and muscle fiber CSA are returning towards baseline, while the fiber-type distribution shifted from slow-to-fast. Myonuclear density following detraining is currently being quantified. **CONCLUSION:** PoWeR provides a methodological advantage over exercise models currently used in mice since it is non-surgical, and elicits oxidative and hypertrophic adaptations in both slow-twitch and fast-twitch muscles. Moreover, the data gathered in this study will provide new insight into the plasticity of myonuclear number following detraining of hypertrophied muscles.

Effect Of Repeated Bouts Of Resistance Exercise On Skeletal Muscle Proteolytic Response In Rat.

Takaya Kotani[1], Junya Takegaki[1], Ryo Takagi[2], Koichi Nakazato[2], Naokata Ishii[1]. *[1]The University of Tokyo, Tokyo, Japan. [2]Nippon Sport Science University, Tokyo, Japan.*
(No relevant relationships reported)

Resistance training (RT) increases the skeletal muscle mass and strength. It has been reported that activation of the mammalian target of rapamycin (mTOR) signaling, which is important for skeletal muscle protein synthesis, is attenuated by increasing exercise bout. However, the effect on proteolytic response is unclear. **PURPOSE**: The present study aimed to investigate the changes in proteolytic responses to repeated bouts of resistance exercised. **METHODS**: Male Sprague-Dawley rats were randomly assigned into four groups: Sedentary (SED), resistance-exercised with 1bout (1B), 2bouts (2B), 3bouts (3B). RT protocol consisted of 50 repetitions of maximal isometric contraction of the right gastrocnemius muscle by direct electric stimulation under anesthesia. Muscle samples were collected 3h and 6h after the final exercise session. **RESULTS**: Phosphorylation of p70S6K increased in all trained groups (1B: 15 fold, 2B: 10 fold, 3B: 8 fold, P<0.05). And there was also significant difference between 1B and 3B. The protein ubiquitination increased in all trained groups of 1.2-fold in SED (P<0.05). And Light chain 3 (LC3), which is a marker for autophagy, increased in all trained groups of 1.5-fold in SED (P<0.05). MuRF-1 mRNA showed a significant 5.1-fold increase with training (P<0.05). However, there were no effect of repeated bouts of RT in muscle proteolytic response. **CONCLUSIONS**: The present results suggest

---

that the muscle protein proteolytic response was activated by RT. In addition, the activation of mTOR signaling attenuated with the increase in RT bouts, but the level of activation of proteolytic response did not change.

Elevating Protein Synthesis: Turn it Down a Notch

Joshua R. Huot, Susan T. Arthur. *University of North Carolina at Charlotte, Charlotte, NC.*
(No relevant relationships reported)

PURPOSE: Notch signaling is thought to be crucial in regulating skeletal muscle regeneration, however, the impact Notch signaling has on other skeletal muscle processes (e.g. protein synthesis) remains unclear. The purpose of this project was to determine the effects of Notch inhibition on protein synthesis during the myogenic program.
METHODS: C2C12 cells were treated with or without a λ-secretase inhibitor (GSI) to determine the effect of Notch inhibition on anabolic signaling and protein synthesis during myoblast proliferation and differentiation. Samples were collected and analyzed for components of Notch, anabolic signaling (PTEN/AKT/mTOR pathway), and protein synthesis (via puromycin incorporation).
RESULTS: GSI treatment reduced Notch signaling: c-myc ($P < 0.05$) and Hes1 ($P < 0.01$). GSI treatment elevated pmTOR Ser2448 ($P < 0.05$), pmTOR Ser2481 ($P < 0.05$), pTSC2 Thr1462 ($P < 0.05$), and protein synthesis ($P < 0.05$) in C2C12 myoblasts. GSI-treated C2C12 myotubes demonstrated increases in pAKT Thr308 ($P < 0.01$), pAKT Ser473 ($P < 0.05$), pTSC2 Thr1462 ($P < 0.001$), pmTOR Ser2448 ($P < 0.05$), and protein synthesis ($P < 0.01$). GSI treatment lowered PTEN expression in myotubes ($P < 0.05$).
CONCLUSIONS: These results demonstrate that Notch signaling may regulate protein synthesis via the PTEN/AKT/mTOR pathway.

Apoptosis In Recovering Human Skeletal Muscle after High Intensity Cycling In Men Receiving Ergogenic Rg1 Compound

Chia-Hua Kuo, FACSM, Jin-Fu Wu. *University of Taipei, Taipei, Taiwan.*
(No relevant relationships reported)

PURPOSE: To examine the impact of high intensity exercise on cell death in human skeletal muscle during recovery with Rg1 supplementation, which has been shown to increase endurance performance. **METHODS**: Using randomized double blind placebo controlled crossover design, twelve young men were studied on three occasions: Placebo, Rg1 (1 mg) and Rg1 (5 mg) supplementation 1 h prior to a high-intensity exercise. Biopsied samples were taken from vastus lateralis before, immediately after and 3 h after a 1-h cycling exercise at 75% VO$_{2max}$. **RESULTS**: Apoptotic and necrotic cells in vastus lateralis increased immediately after 1 h cycling (80-140% and 80-120%, $P < 0.05$), concurrent with macrophage infiltration (both CD68+ and CD163+). Increases in iNOS and myogenic factor Myf5 mRNA levels after exercise were further elevated during Rg1 supplemented trial. Rg1 (5 mg) significantly increased high intensity endurance performance and accelerates the disappearance of apoptotic and necrotic cell number occurred 3 h after exercise during recovery. **CONCLUSION**: High intensity exercise increased cell death in human skeletal muscle after high intensity aerobic exercise. The ergogenic compound Rg1 accelerates phagocytosis to remove unhealthy muscle cell in exercised skeletal muscle.

Systemic Effect On Myotube Size After Sprint Exercise Combined With Nutrients

Hakan C. Rundqvist[1], Janelle Tarum[2], Mona Esbjörnsson[1], Fawzi Kadi[2], Eva Jansson[1]. *[1]Karolinska Institutet, Stockholm, Sweden. [2]School of Health and Medical Science, Örebro University, Örebro, Sweden.*
(No relevant relationships reported)

PURPOSE: To study systemic effects of sprint exercise combined with nutrient ingestion on muscle cell hypertrophy. It was hypothesized that the size of human muscle cells increases when they are exposed to post-exercise serum in nutrient but not in placebo condition. Previously studies have shown that oral ingestion of essential amino acids (EAA) and carbohydrate results in higher activation of Akt/mTOR signalling and higher rate of muscle protein synthesis following sprint exercise in humans. Both local and systemic factors may contribute to these effects. Moreover, If the nutrient-induced effects on signalling and muscle protein synthesis result into muscle hypertrophy is not known. In this study we "isolate" the systemic effects by exposing cultured muscle cells for post sprint exercise serum from either nutrient ingestions or placebo.

METHODS: This study is based on a previous study, were healthy subjects performed three 30-s sprints with 20 minutes rest in between. Subjects ingested a flavoured drink containing EAA and maltodextrin (nutrient) or only flavoured water (placebo) during the sprint exercise session up to 15 min after the last sprint in a randomized order with one month interval. Blood samples were collected before during and up to 200 minutes after the last sprint and were analyzed for EEA, insulin lactate and glucose. Human myoblasts were isolated from vastus lateralis and differentiated into multinucleated myotubes, which were cultured in serum collected from 5 subjects from the sprint exercise study described above. Blood samples, obtained at 80 min after the last sprint, were chosen since the peak values for the accumulation of insulin and EAA occur approximately at that time point.
RESULTS: Both serum insulin (6-fold; $P<0.05$) and plasma leucine levels (2.6-fold; $P<0.01$) were higher after nutrient compared to placebo 80 min post-exercise. Plasma lactate and glucose levels did not differ between the conditions. Myotube size was 16% larger after exposure to post sprint exercise serum obtained during nutrient as compared to placebo ($P<0.05$).
CONCLUSIONS: Systemic factors may stimulate muscle hypertrophy after sprint exercise when combined with nutrient ingestion. If such a systemic effect may be counteracted by intracellular metabolic perturbations after sprint exercise is not known.

Comparing Muscle Hypertrophy and Myosin Heavy Chain Content between Relative Intensity and Repetition Maximum Resistance Training

Kevin M. Carroll, Jake R. Bernards, Michael H. Stone. *East Tennessee State University, Johnson City, TN.*
(No relevant relationships reported)

Comparison of resistance training (RT) methodologies is a critical component of determining appropriate and specific recommendations for health and human performance. Repetition maximum (RM) training typically consists of performing each exercise to momentary failure, thus providing a RM each day of training. Relative intensity based on sets and repetitions (RI$_{SR}$) conversely uses a percentage of a maximum or estimated maximum, typically not leading to failure. **PURPOSE:** To compare 10-weeks RI$_{SR}$ or RM resistance training on skeletal muscle fiber size and protein accretion in well-trained subjects. **METHODS:** Fifteen well-trained males (age = 26.9+3.9yrs, body mass = 86.2+12.1kg) participated in the study (RI$_{SR}$ group, n=7; or RM group, n=8). Muscle biopsies of the vastus lateralis were sampled 72 hours before beginning the intervention and again 72 hours after the final training. The 10-week RT program consisted of several phases: strength-endurance, maximum strength, a planned overreach, and a taper. The RM group achieved a daily maximum in each lift while the RI$_{SR}$ group used a variety of submaximal training loads not leading to muscular failure. Workloads measured by volume load were similar between groups ($p>0.05$). A 2x2 mixed design ANOVA and effect size using Hedge's g were performed for Type I cross-sectional area (CSA), Type II CSA, myosin heavy chain (MYH)1, MYH2, and MYH7. **RESULTS:** RI$_{SR}$ significantly increased Type I CSA ($p = 0.018$) and Type II CSA ($p = 0.012$). None of the MYH proteins reached statistical significance for either group ($p>0.05$). Between-group effect sizes favored the RI$_{SR}$ group for all variables: Type I CSA g=0.48, Type II CSA g=0.50, MYH1 g=0.31, MYH2 g=0.87, and MHY7 g=0.59. **CONCLUSIONS:** These results suggest RT utilizing a RI$_{SR}$ approach may provide superior intramuscular outcomes compared to RM training in higher level lifters.

Elevated Myostatin Expression Promotes Skeletal Muscle Fibrogenic Cell Expansion Following ACL Injury

Christopher S. Fry[1], Bailey D. Peck[2], Darren L. Johnson[2], Mary L. Ireland, FACSM[2], Brian Noehren, FACSM[2]. *[1]University of Texas Medical Branch, Galveston, TX. [2]University of Kentucky, Lexington, KY.* (Sponsor: Brian Noehren, FACSM)
(No relevant relationships reported)

Anterior cruciate ligament (ACL) injuries induce quadriceps muscle maladaptations that contribute to protracted weakness. We have previously shown negative morphological and cellular changes in the quadriceps following an ACL injury that promote a pro-fibrotic muscle environment. There are many unknown initiators and contributors to fibrotic pathways and understanding the mechanisms, cell types, and factors involved in the progression of fibrosis is critical for developing treatment strategies.
PURPOSE: To determine the contribution of myostatin to the development of a pro-fibrotic muscle environment following an ACL injury.
METHODS: We obtained muscle biopsies from the injured and non-injured vastus lateralis of young adults (n=14; 23±4 yr). Expression of myostatin, transforming growth factor-β and other regulatory factors were investigated. Immunohistochemical analyses were performed to assess fibrogenic cell expansion, and primary fibroblasts were isolated from muscle biopsies and subsequently treated with myostatin *in vitro*.

RESULTS: Injured limb skeletal muscle demonstrated an approximate 100% increase in myostatin gene (p < 0.005) and protein (p < 0.0005) expression, which correlated (p < 0.05) with fibroblast abundance in the injured limb. Human fibroblasts expressed the activin type IIB receptor, underscoring the regulatory ability of myostatin. Treatment with myostatin induced a 70% increase in the proliferative rate of primary human muscle-derived fibroblasts (p < 0.05).
CONCLUSIONS: These findings support an integral role for myostatin in promoting fibrogenic alterations within skeletal muscle following an ACL injury. Supported by NIH grants: K23 AR062069 and P30 AG024832 and the John Sealy Memorial Endowment Fund.

Comparisons The Strength Performance of Sarcopenia Defined by AWGS & EWGSOP Criteria Among Elderly

Yu-Tzu Liu, Li-Lan Fu. *National Taiwan Sport University, Taoyuan, Taiwan.*

(No relevant relationships reported)

PURPOSE: The aim of the present study was to identify a better criteria of sarcopenia for community-dwelling older Taiwanese.
METHODS: Sixty-two community dwelling people (48 men and 14 women) over 65 years were recruited from Taoyuan, northern Taiwan. Participants were interviewed by trained investigators using Short Portable Mental Status Questionnaire (SPMSQ) and Physical Activity Readiness Questionnaire. Body composition was measured by skinfold (SF) and Body Mass Index (BMI). Strength functional performances were obtained by sit to stand (SS), arm curl (AC), eight-inch walk (EW), grip strength (GS), knee strength (KS) using the standard procedures. Sarcopenia was defined according to the Asian Working Group for Sarcopenia (AWGS) and Report of the European Working Group on Sarcopenia in Older People (EWGSOP). One-way ANOVA test was used to compare the differences within groups.
RESULTS: Of the 62 subjects (76.79 ± 5.32 yrs), 18 were classified in sarcopenia group (ASG) and 44 were normal group (ANG) by AWGS. Ten were classified in sarcopenia group (ESG) and 53 were normal group (ENG) by EWGSOP. The strength performances were different in ASG and ANG, included in SS, AC, EW, GS left and GS right hand (p<0.05), except KS extension and flexion (p>0.05). The strength performances were also different in ESG and ENG, included in AC, EW, GS left and GS right hand, except SS, KS extension and flexion (p>0.05), as listed in Table 1.
CONCLUSIONS: Both AWGS and EWGSOP can effectively define sarcopenia in community-dwelling older Taiwanese, especial AWGS. Supported by NSC 97-2410-H-179-007-MY2.

Table 1. Strength performance different between Sarcopenia and normal elderly				
	ASG	ANG	ESG	ENG
SS (times)	10.62 ± 4.05*	13.87 ± 3.24	11.78 ± 4.28	13.76 ±3.22
AC (times)	13.31 ± 7.00 *	18.30 ± 4.96	14.71 ± 6.64*	18.29 ± 5.09
EW (second)	7.63 ± 3.23 *	6.08 ± 1.68	7.55 ± 2.87*	5.94 ± 1.61
GS left (kg)	21.52 ± 3.65 *	29.82 ± 7.00	22.82 ± 4.17*	30.24 ± 7.19

Long-term Physical Inactivity Exacerbates Hindlimb Unloading-induced Soleus Muscle Atrophy In Young Rats

Toshinori Yoshihara[1], Takamasa Tsuzuki[1], Chang Shuo-wen[1], Toshiharu Natsume[1], Ryo Kakigi[2], Noriko Ichinoseki-Sekine[3], Shuichi Machida[1], Takao Sugiura[4], Hisashi Naito[1]. *[1]Juntendo University, Inzai, Japan. [2]Juntendo University, Bunkyo-ku, Japan. [3]The Open University of Japan, Chiba, Japan. [4]Yamaguchi University, Yamaguchi, Japan.*

(No relevant relationships reported)

Physical inactivity (sedentary lifestyle) in adulthood increases a degree of aging-related skeletal muscle weakness; however, it has been unclear whether long-term physical inactivity in childhood exacerbates subsequent disuse-induced skeletal muscle atrophy.

PURPOSE: This study investigated the effects of long-term physical inactivity in childhood on subsequent hindlimb unloading-induced muscle atrophy in rat soleus muscle.
METHODS: Forty-eight 3-week-old male Wistar rats were assigned randomly into control (CON, n = 24) or physical inactivity (IN, n = 24) groups. Rats in the IN group were housed in a narrow cage with half of the usual floor space to limit the range of their movement. After 8 weeks (12-week-old), the rats (CON & IN) were exposed to hindlimb unloading. The soleus muscles were quickly removed before (0 d, n = 6/each group), 1 day (1d, n = 6/each group), 3 days (3d, n = 6/each group) and 7 days (7d, n = 6/each group) after unloading. mRNA and protein levels were determined by RT-PCR and Western blot analysis. Statistical significance was established at p<0.05.
RESULTS: Although 7-days of hindlimb unloading significantly decreased soleus muscle weight (CON; -28%, IN; -33%, p<0.001), the decrease was drastically in IN group (Inactivity × Unloading, p = 0.0009). A significant interaction between inactivity and unloading (p<0.01) was observed on the HDAC4 and NF-kB protein expressions. The HDAC4 and NF-kB expressions in the IN group increased significantly 1 day after onset of hindlimb unloading (CON; 1.4 and 1.2, IN; 5.1 and 2.7 fold change from each 0d, respectively). Moreover, their downstream targets *Myogenin* and *MuRF1* mRNA levels were upregulated by long-term physical inactivity (Inactivity, p<0.05).
CONCLUSIONS: Our data suggest that long-term physical inactivity exacerbates hindlimb unloading-induced disuse muscle atrophy in young rat soleus muscle, which may be mediated by HDAC4 and NF-kB-induced *MuRF1* mRNA upregulation. Supported by JSPS KAKENHI Grant Number 17K01765.

Blood Lipid is Associated with Skeletal Muscle PPARδ Protein Content after a 10-week Resistance Exercise Training

Vincent C.W. Chen[1], Chang Woock Lee[2], James D. Fluckey[3], Steven E. Riechman[3]. *[1]Georgian Court University, Lakewood, NJ. [2]University of Houston-Victoria, Victoria, TX. [3]Texas A&M University, College Station, TX.*

(No relevant relationships reported)

Peroxisome proliferator activated receptors (PPARs) are main regulators of blood lipid profile while PPARδ is the most abundant PPARs isoform in skeletal muscle. Although skeletal muscle is a major player in lipid metabolism, the association between muscle PPARδ and blood lipid profile is currently unknown. **PURPOSE**: The purpose of this study was to investigate the association between muscle PPARδ protein content and blood lipid in the context of resistance exercise training. **METHODS**: Fifteen untrained, healthy young men (n=8) and women (n=7) performed a 10-week progressive whole-body resistance exercise training program. Muscle samples were obtained from the vastus lateralis muscles 24 hours before the first exercise and 24 hours after the last exercise. Blood samples were collected from antecubital veins immediately before the first and the last exercises. Western Blotting was conducted to quantify the PPARδ content, and serum lipid profile was analyzed. **RESULTS**: While PPARδ protein content was not correlated with blood lipid profile before the training, it was negatively correlated with total cholesterol (R=-0.731, R-square=0.534, P=0.04) and LDL (R=-0.746, R-square=0.557, P=0.033) after the training. **CONCLUSION**: The results imply that resistance exercise training may enhance the regulation of blood lipid via PPARδ.

Coefficient of Determination of Skeletal Muscle PPARδ Protein Content to Serum Lipid Profile		
	PPARδ Protein Content (AU)	
	Before Training	After Training
Triglyceride (mg/dL)	0.023	0.086
Total Cholesterol (mg/dL)	0.027	**0.534 ***
HDL (mg/dL)	0.025	0.033
LDL (mg/dL)	0.012	**0.557 ***

Comparing The Effects Of Nexrutine And Exercise In Modulating The Pathophysiology Of Cachexia In Treatment Naïve Prostate Cancer Mouse Model

Darpan Patel, Derek Wallace, Kira Pamerleau, Paul Rivas, Nicolas Musi, A Pratap Kumar. *University of Texas Health Science Center at San Antonio, San Antonio, TX.*

(No relevant relationships reported)

Oncologists encourage nutritional and physical interventions to improve outcomes in cancer patients with cachexia; however, it is inconclusive how these interventions

---

Abstracts were prepared by the authors and printed as submitted.

affects the pathophysiology of cachexia. **PURPOSE:** To compare the effects of Nexrutine® (Nex; a natural bark extract of the Amur cork tree) and exercise in modulating the pathophysiology associated with cachexia in treatment naïve transgenic adenocarcinoma of mouse prostate (TRAMP) model. **METHODS:** Forty-five, 10-week old male TRAMP mice were randomized to control (Con), Nex (600 mg/kg pelleted into chow) or exercise (Ex; voluntary wheel running). At 4, 8, 12 and 20 weeks, gastrocnemius muscle was collected to quantify intramuscular IGF-1, myostatin, TNF-α, proteolysis-inducing factor (PIF) and ubiquitin (Ub). An ANOVA with Tukey's post hoc test was done with significance set at $p < 0.05$. **RESULTS:** Analysis of gastrocnemius mass revealed significant group differences (F=4.159, p=0.02) with both Nex and Ex groups having greater mass compared to Con ($p < 0.05$). A treatment response was observed for myostatin (F=4.762; p=0.01), PIF (F= 8.633, p=0.001) and Ub (F=19.55, p<0.001). Specifically, Ex mice had significantly lower concentrations of myostatin, PIF and Ub compared to Con ($p < 0.01$). Group comparisons at 20 weeks showed significantly lower concentrations of PIF (F= 22.85, p<0.001) with Ex (p<0.001) and Nex (p=0.03) significantly lowering PIF concentrations compared to Con. Time point comparisons for Ub revealed significant differences at weeks 4 (F=32.35, p<0.001) and week 8 (F=16.24,p=0.002), respectively, with Ex mice having significantly lower concentrations of Ub compared to Con mice (p=0.004) at both time points. **CONCLUSION:** The results of this study suggest that Nex and Ex similarly maintain muscle mass in treatment naïve TRAMP mice by reducing tumor specific cachectic protein PIF. Exercise was capable of reducing downstream Ub; however, the mechanisms by which Nex elicits a protective effect require further study.

Dietary Protein Intake and Muscular Health with Aging: Countermeasures for Sarcopenia and Dynapenia

Kara A. Stone[1], Christopher J. Kotarsky[1], Nathan D. Dicks[1], Daniel M. Streeter[1], Allison M. Barry[1], Jill Keith[2], Rachel Iverson[1], Sherri N. Stastny[1], Shannon David[1], Wonwoo Byun[3], Steven Mitchell[1], Kyle J. Hackney[1]. [1]North Dakota State University, Fargo, ND. [2]University of Wyoming, Laramie, WY. [3]University of Utah, Salt Lake City, UT.
(No relevant relationships reported)

Protein intake and aerobic and resistance exercise have been suggested as effective stimuli for muscle growth and function in the young and old. However, the magnitude of these stimuli combined is not completely understood. **PURPOSE:** To examine relationships between total protein intake and combined aerobic and anaerobic training on muscle size and strength in sedentary and active adults. **METHODS:** A total of 98 subjects were divided into the following groups: active younger females (AYF), sedentary younger females (SYF), active older females (AOF), sedentary older females (SOF), active younger males (AYM), sedentary younger males (SYM), active older males (AOM), and sedentary older males (SOM). Subjects completed an assessment of knee extensor peak torque (KEPT), a 3-day dietary intake log, and magnetic resonance imaging (MRI) scan for muscle cross-sectional area analysis of the right quadriceps (CSAq). Two stepwise regression models were used to examine the relationship of gender, protein intake, activity level, and age, with CSAq and KEPT. **RESULTS:** Mean differences are displayed in the table below. Gender, protein intake, age and physical activity were predictive for CSAq (F (1, 93) = 11.798, R^2 = 0.725, p < 0.01). Additionally, gender, age, and physical activity were predictive for KEPT (F (1, 94) = 14.309, R^2 = 0.631, p < 0.01). **CONCLUSION:** The results suggest that changes in skeletal muscle size and strength are related to differences in age, gender, total daily protein intake, and physical activity. Furthermore, concurrent exercise appears to be an intervention to potentially mitigate sarcopenia and dynapenia in older adults.

Constant And Progressive Resistance Exercise Reduces Anabolic Signaling But Inreased Myofiber Hypertrophy In Human Skeletal Muscle

Dr. Sebastian Gehlert. *Universität Hildesheim, 31143 Hildesheim, Germany.*
(No relevant relationships reported)

PURPOSE: To determine the effects of progressive (PR) and constant (CO) loading induced by resistance exercise (RE) on anabolic signaling, myofibrillar damage and selective type I and II myofiber hypertrophy when RE is prolonged and interrupted over time.
METHODS: 15 healthy male subjects (24 +- 3 years) conducted six weeks of progressive (PR) (n=8) or constant (CO) (n=7) RE on a leg extension and leg press machine. Subjects conducted in sum 14 training units with 3 training sessions per week. Each session consisted of 3 sets with 10-12 repetitions on each machine. At baseline (T0) after the 1st (T1), 3rd (T2), 7th (T3), 10th (T4), 13th (T5) and 14th (T6) RE session, skeletal muscles biopsies from vastus lateralis muscle were collected at 45min post RE. Subjects of PR increased RE load by 5% each week while in the CO group RE-load was constant. Continuous training was performed up to T5 and stopped for 10 days followed by a final TU 14. **RESULTS**: In PR and CO increases in p70s6k and rpS6 phosphorylation (P<0.05) were detected at all time points (T1-T6) compared to T0. However, rpS6 and p70s6k was decreased from T1 to T4 in PR (p<0.05) but not in CO. Reduced signaling recovered after pausing RE in PR with an increase from T5 to T6 (p<0.05). Myofibrillar damage was increased in PR and CO (p<0.05) at T1 but gradually decreased up to T5 in both groups. There was a tendency for lower myofibrillar damage in PR at T4 and T5. Type I myofibres showed increased myofiber diameter (8%) at T5 (p<0.05) with no group differences. Type II fibers increased (12%) in both groups (p<0.05) but more in PR than CO at T5 (p<0.05).
CONCLUSIONS: While PR offers increased potential for type II myofiber hypertrophy and increases sarcomeric stability over the time course of repeated RE compared to CO, it is associated with decreased anabolic signaling upon repeated RE stimulation. Anabolic signaling does not reflect structural adaptability but its decreased sensitivity towards loading.

Amino Acid Transport and Metabolism Alterations Following 12 Weeks of Resistance Training with Supplementation

Paul A. Roberson[1], C. Brooks Mobley[1], Cody T. Haun[1], Petey W. Mumford[1], Matthew A. Romero[1], Wesley C. Kephart[1], Shelby C. Osburn[1], Christopher G. Vann[1], Christopher M. Lockwood[2], Michael D. Roberts[1]. [1]Auburn University, Auburn, AL. [2]Lockwood, LLC, Draper, UT.
(No relevant relationships reported)

PURPOSE: Amino acid transporters within skeletal muscle have gained attention for their potential role in stimulating muscle protein synthesis (MPS). The purpose of this study was to determine if amino acid transporters and proteins involved in amino acid metabolism are related to skeletal muscle hypertrophy following resistance training with different nutritional supplementation strategies. **METHODS:** 43 untrained, college-aged males were separated into a Maltodextrin Placebo (PLA, n=12), Leucine (LEU, n=14), or Whey Protein Concentrate (WPC, n=17) group and underwent 12 weeks of total-body resistance training performed 3 days per week while supplementing twice daily. Each group's supplement was standardized for total energy, fat, and LEU and WPC groups were standardized for total Leucine (6 g/d). Skeletal muscle biopsies were obtained prior to training (PRE) and ~72 h following subjects' last training session (POST). **RESULTS:** LAT1 protein levels demonstrated a time (p<0.001; 3.01-fold increase) and group effect (p=0.043), whereby PLA increased significantly more than LEU and WPC (p<0.05; 5.01-fold vs. ~2-fold increase). A time effect was observed for PAT1 (p=0.047; 1.36-fold increase) and BCKDHA (p<0.001; 1.81-fold increase) protein levels, while SNAT2, BCAT2, and ATF4 protein levels were unaltered (p>0.05). Changes in muscle fiber cross sectional area (CSA) demonstrated a time effect for Type I fibers (p=0.045; +370 µm) and Type II fibers (p<0.001; +1061 µm). No strong, significant correlations existed for changes in assayed proteins with changes in Type I or II fiber CSA, nor were PRE protein values indicative of alterations in muscle CSA. **CONCLUSIONS:** LAT1 protein levels increase in response to resistance training, and LEU and WPC supplementation reduced training-induced increases in this protein. Furthermore, proteins related to amino acid transport and metabolism do not appear to dictate skeletal muscle hypertrophy.

Resistance Training-Induced Muscle Hypertrophy is Related to Androgen Receptor Content not Intramuscular or Systemic Hormones

Robert Morton[1], Koji Sato[2], Michael Gallaugher[1], Sara Oikawa[1], Paul McNicholas[1], Satoshi Fujita[3], Stuart Phillips, FACSM[1]. [1]McMaster University, Hamilton, ON, Canada. [2]Kobe University, Kobe, Japan. [3]Ritsumeikan University, Shiga, Japan. (Sponsor: Stuart Phillips, FACSM)

(No relevant relationships reported)

There is substantial inter-individual variability in resistance exercise training (RET)-induced skeletal muscle hypertrophy. **PURPOSE:** To determine if systemic circulating and/or intramuscular hormones were related to the RET-induced hypertrophy. **METHODS:** Resistance-trained young men (mean ± SEM; 23 ± 1 yr, 86 ± 2 kg, 181 ± 1 cm, previously performing RET ≥2 times per wk for 4 ± 2 yr) undertook individually supervised RET four times per week for 12 wk. Fat- and bone-free (lean) body mass (LBM) and individual fibre type cross sectional area (CSA) were evaluated by dual x-ray absorptiometry and immunohistochemistry, respectively. Backwards elimination and principal component regression were used to evaluate shared variance between systemic proposedly anabolic hormones and RET-induced changes in muscle mass (n=49). Intramuscular free testosterone levels, dihydrotestosterone levels, 5α-reductase expression, and androgen receptor content were evaluated in the highest- (HIR; n=10; Δ LBM = 2.1 ± 0.8 kg) and lowest- (LOR; n=10; Δ LBM = 0.6 ± 0.9 kg) responders to the 12 wk of RET. **RESULTS:** No hormone measured before exercise, after exercise, pre-intervention, or post-intervention, using unadjusted or principal component regression, shared significant common variance with the change in type 1 CSA, type 2 CSA, or LBM. No hormone, in blood- or muscle, was different between HIR and LOR. The steroidogenic enzyme 5α-reductase increased following RET in the HIR (P<0.01) but not the LOR (P=0.32). Androgen receptor content remained unchanged with 12 wk of RET, but was higher in HIR versus LOR both pre- and post-intervention. **CONCLUSION:** Neither systemic nor intramuscular hormones are related to RET-induced skeletal muscle hypertrophy in resistance-trained young men. Instead, these data demonstrate that intramuscular androgen receptor content may be an important component of the individual variation between high- and low-hypertrophy responders to RET.

Ghrelin Attenuates Muscle Atrophy In Tumor-bearing Mice

Haiming Liu, Jose M. Garcia. *University of Washington, Seattle, WA.*

(No relevant relationships reported)

Cachexia is a multi-organ syndrome characterized by muscle and fat wasting. Ghrelin is a hormone known to release growth hormone and to stimulate appetite by binding to its receptor growth hormone secretagogue receptor (GHSR)-1a. However, recent data suggest that not all effects of ghrelin are mediated through this receptor. **PURPOSE**: To investigate if ghrelin attenuates cancer-induced muscle atrophy in a GHSR-1a-independent manner. **METHODS**: 5-6-month-old male C57BL/6J GHSR-1a wildtype (WT) and knockout (KO) mice were inoculated with 1×10^6 heat-killed (HK, control) or live Lewis Lung Carcinoma (LLC) cells in the right flank. When the tumor was palpable (1 wk), tumor-bearing mice were injected with vehicle (saline solution, TV) or ghrelin (0.8 mg/kg, TG), IP twice a day, while HK mice were injected with vehicle (n = 8-10). Body weight, lean body mass and fat mass were measured by NMR before tumor implantation and 2 weeks after tumor noted. Gastrocnemius (GAS) muscles were harvested for analysis 2 weeks after tumor noted. **RESULTS**: Tumor implantation induced a significant decline in body weight and fat mass in both strains. As expected, ghrelin attenuated the fat loss in WT (TV vs. TG: -52% vs. -23% from baseline, p = .009) but not in KO (TV vs. TG: -56% vs. -60%, p = .85). Tumor-induced muscle loss was attenuated by ghrelin from 16% to 8% in WT (p = .004) and from 25% to 19% in KO (trend in significance, p = .06). Similarly, the decrease in fiber cross-sectional area of GAS muscles was prevented by ghrelin in WT (TV vs. TG: p = .008; HK vs. TG: p = .472) but this difference did not reach significance in KO. In addition, the mRNA levels of 'atrogenes' atrogin-1 and MuRF-1 in GAS muscle significantly increased in response to tumor implantation in both strains. With ghrelin treatment, the increase of atrogin-1 and MuRF-1 in WT was decreased by 5-fold (p = .022) and 7-fold (trend, p = .058), respectively. In KO tumor-bearing mice, the attenuation of atrogin-1 and MuRF-1 by ghrelin was 5-fold (p = .008) and 6-fold (trend, p = .07), respectively. **CONCLUSION**: Ghrelin mitigates cancer-induced muscle atrophy at least in part through GHSR-1a-independent mechanisms.

Resistance Training-induced Decrease In Circulating C1q Is Associated With Attenuated Muscle Degradation In Senescent Mice

Naoki Horii[1], Masataka Uchida[1], Natsuki Hasegawa[1], Shumpei Fujie[1], Eri Oyanagi[2], Hiromi Yano[2], Takeshi Hashimoto, FACSM[1], Motoyuki Iemitsu[1]. [1]Ristumeikan University, Kusatsu, Japan. [2]Kawasaki University, Kurashiki, Japan. (Sponsor: Takeshi Hashimoto, FACSM)

(No relevant relationships reported)

Our recent study has showed that reduction of aging-induced elevation of serum C1q level by resistance training was involved in muscle hypertrophy in old adults. C1q activates Wnt/β-catenin in aged muscle, resulting in enhancement of muscle protein degradation-related genes, such as MuRF-1 and Atrogin-1. Although resistance training attenuates muscle protein degradation, it is still unclear that resistance training-induced decrease in serum C1q level is associated with attenuation of muscle protein degradation. **PURPOSE**: The purpose of this study was to investigate whether resistance training-induced change in circulating C1q level affects muscle protein degradation in senescent mice. **METHODS**: Male 13-week-old SAMP1 mice (Young) and 38-week-old SAMP1 mice (Aged) were randomly divided into three groups; young-sedentary control (Young-Con), aged-sedentary control (Aged-Con) and aged-resistance training (Aged-RT) groups (n=10 each group). Resistance training was performed 3 days a week for 12 weeks using a climbing ladder with 70% of 1 repetition maximum weight. **RESULTS**: Muscle strength and mass and cross-sectional area (CSA) of tibialis anterior muscle in the Aged-Con group significantly decreased as compared with the Young-Con group (p<0.05), whereas those in the Aged-RT group significantly increased as compared with the Aged-Con group (p<0.05). Serum C1q level and expression levels of muscle β-catenin, MuRF-1 and Atrogin-1 proteins significantly increased in the Aged-Con group as compared with the Young-Con group (p<0.05), whereas those expression levels in the Aged-RT group significantly decreased as compared with the Aged-Con group (p<0.05). Additionally, serum C1q level was positively correlated with protein expression levels of muscle MuRF-1 (r = 0.713, p<0.05) and Atrogin-1 (r = 0.584, p<0.05), but was negatively correlated with muscle mass (r = -0.469, p<0.05) and CSA (r = -0.595, p<0.01). **CONCLUSIONS**: These results suggest that resistance training-induced decrease in serum C1q level is associated with attenuation of muscle protein degradation thereby leading to muscle hypertrophy in senescent mice.

Relationship Between Variability Of Posterior Lower Extremity Muscles And Speed In Individuals With Parkinson's Disease

Kerry J. Bollen, Clinton J. Wutzke, Caitlin A. Bryson, John P. Collins. *George Mason University, Fairfax, VA.* (Sponsor: Randall E. Keyser, FACSM, FACSM)

(No relevant relationships reported)

Background: Individuals with Parkinson's Disease (PD) demonstrate progressive decreases in gait speed and difficulty with intralimb coordination when walking. Commonly, people with PD walk with reduced step length that may be associated with suboptimal activation of flexor muscles including the gastrocnemius and hamstrings. Individuals with PD often increase cadence to overcome reduced step length regardless of walking speed. Therefore, investigation of variability in locomotor muscles while walking overground may provide insight into walking behavior during community ambulation. **Purpose**: To determine associations between variability of lower extremity muscle activation and gait speed during the stance phase to swing phase transition in individuals with PD. **Methods**: Adults with idiopathic PD completed the 10-meter walk (10MW) overground at their preferred walking speed while on their anti-Parkinson's medication. Surface EMG was placed bilaterally on the biceps femoris (BF), medial hamstrings (MH), and medial gastrocnemius (MG). Gait events (heel contact, toe off) were identified via lower extremity kinematics using a motion capture system. Coefficients of variation during (CV) during 50-60% of the normalized gait cycle, identified as terminal stance phase (tST) and 60-70% of the gait cycle, termed initiation of swing phase (iSW) were calculated for the three muscles. **Results**: 9 adults (7M, age $\bar{x}$=71.0, height $\bar{x}$=172.2cm, weight $\bar{x}$=78.0kg) walked overground

(x̄=16 steps used in analysis), with an average gait speed of 1.12 ± 0.19m/s. Those with slower gait speeds (<1.1m/s), had a higher mean CV of MG activation during iSW (p=0.02). There was no difference between the CV of the MH, BF during tST and iSW. However, there was an interaction between gait speed and CV of the MH and BF with variability in the MG activation during iSW (p<0.01). Variability was primarily due to differences in duration, timing, and magnitude of activation for these muscles during each step. **Conclusion**: Uniformity of the timing and magnitude of muscle activation was related to gait speed in individuals with PD. Increased step to step variability of MG, BF, and MH activation and timing suggests a less stable gait pattern with functional consequences in people with PD.

Different Elbow Positions Do Not Interfere In Handgrip Strength In Parkinson's Disease

Sacha Clael, Camila Wells, Elaine Brandão, Rafaela do Vale, José Celi, Junhiti Nagazawa, Tamara Paiva, Jhonatan Rodrigues, Liana Caland, Lidia Bezerra. *University of Brasília, Brasília, Brazil.*

(No relevant relationships reported)

The studies with handgrip strength have been using the protocol of American Society of Hand Therapists (ASHT), in which the elbow is maintained flexed at 90º. However, people with Parkinson's disease (PD) show general loss of strength and the contraction of the muscles used to sustain this position may be not possible and may reduce the value of handgrip strength. **PURPOSE:** The aim of the study was to analyze if there is difference in handgrip strength in people with PD between the two elbow positions: flexed (ASHT protocol) and extended. **METHODS:** Handgrip strength was measured in both arms in 31 persons (22 men and 9 women), age 66.06 ± 8.48, diagnosed clinically with PD with the elbow at two positions: flexed (ASHT protocol) and extended. Positions comparisons were made using paired t-test and clinical effect with test d Cohen. A p-value of ≤ 0.05 was adopted. **RESULTS:** Handgrip strength of the right arm with the extended elbow was similar to that obtained with the flexed elbow (p > 0.05; d = -0.04). Handgrip strength of the left arm with the extended elbow was similar to that obtained with the flexed elbow (p > 0.05; d = -0.12). There are not statistical difference between elbow positions in both arms side.
Table 1 - Comparisons between elbow positions.

Side	Elbow in Extension (Mean ± SD)	Elbow in Flexion (Mean ± SD)	p	d
Right	31.48 ± 8.77	31.87 ± 9.24	0.64	-0.04
Left	28.58 ± 8.04	29.61 ± 8.63	0.07	-0.12

p = significantly; *d* = Cohen test
CONCLUSIONS: There are no differences between elbow positions, people with PD can do handgrip strength with elbow in extension if will be more comfortable.

Analysis Of Cortical Hemodynamics During Dual Task Walking In Individuals With Parkinson's Disease

Takuto Fujii, Taeyou Jung, Ovande Furtado, Travis Watkins, Justin Shamunee, Eunbi Lee. *California State University, Northridge, Northridge, CA.*

(No relevant relationships reported)

In addition to motor deficits, cognitive issues are common among individuals with Parkinson's disease (PD). Executive function plays an important role in performing multi-tasks, such as dual task walking (DTW). Compromised gait and cognitive functions are often observed in people with PD when they perform DTW, which can affect their activities of daily living. Limited research examined the brain activity during DTW in people with PD.
PURPOSE: To analyze cortical hemodynamic activities of the prefrontal cortex (PFC) during DTW in individuals with PD. **METHODS:** 11 individuals with PD (aged 72.8 ± 5.53) and 10 controls (71 ± 10.56) participated in this cross-sectional study. All participants completed a series of walking trials under three test conditions including usual walking (W), walking with serial three subtraction (WS3), and walking with autobiographical memory tasks (WQA). They were asked to walk at a comfortable pace while a functional near-infrared spectroscopy (fNIRS) system captured oxyhemoglobin (HbO2) values of the PFC. All participants completed five trials for each test condition on a 30-meter walkway. Each walking trial consisted of 20-second quiet standing, 30-second walking, and 20-second quiet standing.
RESULTS: The PD group showed overall higher HbO2 values across all three test conditions than the control. Repeated measures analysis of variance (ANOVA) revealed significant differences among three conditions in both groups (all *p*-values <.05). Post hoc analyses showed that the PD group significantly increased HbO2 values from W to WS3 by 39.6% as well as from W to WQA by 26.7 %, but no change was noted between WS3 and WQA. The control group showed significant differences in HbO2 values in all pairwise comparisons among three conditions. In addition,

a significant groups x conditions interaction was found in HbO2 values (*p*<.01).
CONCLUSION: DTW elicited a greater level of brain activation with an increase of cortical hemodynamics in individuals with PD as compared to control. Furthermore, our results suggest that cortical hemodynamic responses to various level of difficulties in concurrent tasks were different between people with and without PD. These findings should be considered when providing dual task motor training is provided for people with PD.

Differences in Muscle Activity During Cycling in Healthy Aging and Parkinson's Disease: Pilot

Rebecca J. Daniels, Christopher A. Knight. *University of Delaware, Newark, DE.*

(No relevant relationships reported)

DIFFERENCES IN MUSCLE ACTIVITY DURING CYCLING IN HEALTHY AGING AND PARKINSON'S DISEASE: PILOT
Rebecca J. Daniels, Christopher A. Knight
University of Delaware, Newark, DE
Coordination in cycling, defined by EMG burst timing, is well studied in healthy adults and trained cyclists. Little is known about these parameters in older adults (OA) and people with Parkinson's disease (PD), though cycling is a commonly prescribed exercise modality in these populations. **PURPOSE:** To investigate muscle activity patterns during cycling in OA and PD compared to healthy young adults (YA). It was hypothesized that people with PD would exhibit less discrete bursts, evidenced by prolonged burst duration, compared to OA and YA. **METHODS**: Participants were 4 OA (73.3±4.9 years, BMI=27.2±5.7 kg•m^{-2}, 3 males), 6 adults with PD (71±11.9 years, BMI=30.7±7.3 kg•m^{-2}, 6 males, Hoehn & Yahr stage 1-3), and 5 YA (21±1.6 years, BMI=22.6±1.8 kg•m^{-2}, 4 males). Electromyograms (EMG) were recorded from the vastus lateralis (VL), medial gastrocnemius (GA), biceps femoris, soleus (SO), tibialis anterior (TA), and rectus femoris (RF) of the dominant leg during recumbent bicycling. Subjects cycled at 60, 80, and 100 revolutions per minute (RPM) at the lowest resistance setting. EMG was rectified and normalized to the peak EMG during the 80 rpm condition in each muscle. A 4rth order low pass Butterworth filter with a cutoff of 7 Hz was used to create linear envelopes. Timing of the EMG burst onset and offset were calculated in relation to top dead center, as well as EMG burst duration over 10 revolutions per subject in the 60 and 100 RPM conditions. A 2x3 repeated measures analysis of variance was used to compare the timing of EMG activity for each muscle between the 60 and 100 rpm conditions among the groups. Significance was set at p<0.05. **RESULTS**: There were no significant group by cadence interactions. Cadence effects were observed in burst duration of TA (F=9.53, p<0.01), SO (F=12.98, p<0.01), VL (F=10.97, p<0.01), RF (F=6.21, p=0.02), and GA (F=7.89, p=0.01). Compared to YA, people with PD had 86.6° longer burst durations in TA (F=6.34, p<0.01), 69.1° in VL (F=8.73, p<0.01), and 65.7° in GA (F=5.57, p=0.01). **CONCLUSION**: Although preliminary, these results suggest that increased burst durations in key muscles during cycling alter coordination in people with PD.

Spatial Measures Of Straight-line Walking And Walking With A Turn In People With Parkinson's Disease

Caitlin A. Bryson. *George Mason University, Fairfax, VA.*
(Sponsor: Randall Keyser, FACSM)

(No relevant relationships reported)

Dynamic balance is often impaired in people with Parkinson's Disease (PD). Control leading to and during a turn for people with PD further challenges dynamic balance and is a common contributor to a loss of balance. During a task with a turn, people with PD modify walking patterns in order to maintain dynamic balance. These modifications, however, may vary among people with PD. Identification of walking behaviors that contribute to impaired dynamic balance is key to improve function and development of balance-focused interventions for people with PD.
PURPOSE: To determine differences in spatiotemporal measures between straight-line walking and walking with a turn in people with PD.
METHODS: Ten adults with PD (2F/8M, age: 69.9±8.9; height: 169.6±8.1cm; weight: 75.3±8.3kg) walked across a 6m pressure sensitive walkway in 1) a forward direction (F) and 2) a forward walk including a 180° turn (T). The right (R) leg was identified as the OUT leg and the left (L) identified as the IN leg. Participants were categorized based on time to complete the Timed Up and Go (TUG) test. Five adults had TUG times faster than the mean, 9.27s, and five were slower. Step length (SL), width (SW), and foot angle (FA) were examined during both trials. An unpaired, Welch's t-test was used for analysis between groups.
RESULTS: Those with faster TUG times had larger SL (L: p=0.0006; R: p=0.0004) and SW (L: p=0.0004; R: p=0.0008) bilaterally during F trial compared to slower. During the T trial, the faster group increased SL bilaterally (L: p=0.0022; R: p<0.0001) and increased SW on the L (p=0.035), but not the R. FA was less in the faster group during F trial for the R leg (p=0.0352), but was greater for the R leg in the T trial (p=0.0001).

CONCLUSIONS: Individuals with faster TUG times demonstrated increased SL, SW, and reduced R FA during straight-line walking. Individuals with decreased SW may have compensated for impaired stability by decreasing SL. When walking included a turn, individuals with faster TUG times increased SW in the IN leg and increased the FA of the OUT leg compared to those with a slower TUG time, suggesting that people with PD who have functional impairments may utilize different strategies than those with without. Increased understanding of spatiotemporal aspects including during a turn is critical to optimize treatment.

Breathing And Vision Effects On Balance, Attention, And Respiratory Complexity During Standing In Parkinson's Patients

Luis Hernandez, John Manning, Christina Odeh, Shuqi Zhang. *Northern Illinois University, Dekalb, IL.*
(No relevant relationships reported)

INTRODUCTION: Regulation of balance requires attentional involvement inversely proportional to efficacy of postural control system. Sample entropy (SE) of center of pressure (CoP), a non-linear measure, reflects complexity of postural control system indicating attentional involvement. Parkinson patients (OAP) may requisite more attention during balance than healthy controls (OAH). Due to internal perturbances during standing, respiration may affect balance in individuals with deteriorated postural control systems.
PURPOSE: To investigate 1) effects of breathing and visual conditions on attention and balance 2) group effect on respiratory complexity, attention, & balance between OAP & OAH.
METHODS: 12 subjects, OAH (n=6) & OAP (n=6), were recruited and instructed to stand on force plate, feet oriented 15° apart and look at 5cm-diameter spot eye level on wall 1.5m away. Subjects were asked to maintain balance for 2 minutes under eyes open and eyes closed conditions and thoracic (Th), abdominal (Ab), & neutral breathing conditions. Meanwhile, Th and Ab motion was record through Biocapture system, all equipment synched. SE was calculated in Matlab for CoP in anteroposterior (X) ($SampEn_{CoPx}$) and mediolateral (Y) ($SampEn_{CoPy}$) directions and Th ($SampEn_{Th}$) and Ab ($SampEn_{Ab}$) motion. CoP-related measures were calculated in Bioanalysis software for average velocity ($\bar{v}$) (cm/s), 95% sway area (SA) (cm^2), and average displacement in X (D_x) and Y (D_y) directions (cm).
RESULTS: Group, breathing, & visual effects were examined on non-linear and CoP-related measures via Factorial MANOVA with later application of ANOVAs as needed. Significant group and visual effects were seen in CoP-related measures, Wilks' Lambda = .363 (p< .000) and .781 (p<.034), respectively. OAP showed greater D_x (.5363 ± .2411 vs .2963 ± .1424), SA (10.7677±10.6678 vs. 4.8564±3.6306), and $\bar{v}$ (3.1264±1.1616 vs. 2.4184 ± .9371) than OAH, while EC showed greater $\bar{v}$ than EO (3.1904±1.2207 vs. 2.3343 ± .7770).
CONCLUSION: OAPs showed similar attentional involvement and respiratory complexity with OAH during standing balance, though OAP displayed worse balance performance than OAH. Breathing condition did not significantly affect attentional involvement or balance performance. Visual condition significantly affected balance performance.

The Effects of Cadence on Torque Asymmetry

Ashley N. Fox, John W. Farrell, III, Rebecca D. Larson. *University of Oklahoma, Norman, OK.* (Sponsor: Christopher Black, Ph.D., FACSM)
(No relevant relationships reported)

Bilateral asymmetry in peak crank toque has been observed in both cyclist and non-cyclist. However, the relationship between exercise intensity, cadence rates, and bilateral asymmetry is not fully understood. Additionally, a need for establishment of normative values for bilateral asymmetry still exists. **PURPOSE:** Therefore, the purpose of the current study was to examine bilateral asymmetry in peak crank torque during 3 graded exercise tests (GXT) at 3 different cadence zones. **METHODS:** 20 subjects, 10 females and 10 males, participated in this study. Subjects were classified to either a cycling trained group (CT, n=8) or no-cycling trained group (NCT, n=12). Over the course of 3 visits subjects, both groups performed 3 GXTs at 3 different cadence zones. Cadence zones consisted of Self-Selected (SS), High (100 to 115 rpm), and Low (55 to 70 rpm). The first GXT was performed at the SS cadence with the remaining two being performed either at High or Low cadence, which was randomly assigned. Peak crank torque was measured using a dual power meter on cycle ergometer, and calculated as the absolute difference between the lower limbs. Peak crank torque was assessed at the initial stage (IS), the stage in which the onset of blood lactate accumulation (OBLA) occurred, and the stage in which peak power output (PPO) was achieved for the 3 different GXTs. Two way repeated measures ANOVA was used to determine if significant differences between groups and conditions existed. **RESULTS:** Significant group by condition interactions were present. No significant condition differences were present between all cadences zones (IS, OBLA, or PPO)

(P>0.05). No significant group differences were present at IS or OBLA. However, significant group differences were present at PPO (CT 7.69±5.61 vs. NCT 4.42±4.47). **CONCLUSION:** The findings of the current study suggest that torque is unaffected by cadence selection at IS, OBLA, and PPO. The current study also showed that significant differences did not exist between the CE and NCE in torque asymmetry until PPO. This finding suggests that at PPO cyclist may be altering their kinematics in order to maintain desired cadences or power outputs more so than non-cyclists. Therefore, further research is needed to understand the potential effect on cycling performance.

Fast Six-minute Walking Induced Abductor Hallucis Muscle Recruitment In Individuals With Flatfoot

Chieh-Ning Huang, Chu-Yuan Chiang, Kuang-Wei Lin, Wen-Wen Yang, Yun-Chi Chang, Li-Ling Pan, Li-Wei Chou. *NATIONAL YANG-MING UNIVERSITY, Tapiei, Taiwan.*
(No relevant relationships reported)

Purpose: This study examined lower extremity muscle activities before and after six-minute treadmill walking at highest speeds in individuals with flatfoot. **Methods:** Eight individuals with flatfoot (4 women, 4 men, age= 24.8±2.4 years) with no other history of lower extremity injury in six months and no neurological disease, participated in this study. Subjects were first screened using subtalar static navicular drop tests. Surface electromyography (BIOPAC system, USA) of the abductor hallucis muscle (AbdH), tibia anterior, gastrocnemius, and peroneus longus muscles were recorded during maximum voluntary isometric contractions (MVIC). Next, three-dimensional motion capture system (Vicon motion system, UK) was used to assess dynamic navicular mobility during walking. Subjects were then asked to walk on the treadmill at their maximal pace for 6 minutes. After walking, the MVIC and dynamic navicular mobility were assessed again. Median frequency (MedF) of EMG during MVIC was calculated for both before and after 6-minute walking. **Results:** Our preliminary results show substantial increase in the MedF of the AbdH (10.2Hz ± 29.9Hz), suggesting an increase in motor unit recruitment in AbdH with 6-minute fast treadmill walking. MedF of tibia anterior was significantly decreased 16.7 ± 11.5Hz after fast treadmill walking, but no significant change was observed in peroneus longus and gastrocnemius. Subjects exhibited similar navicular drop before (17.3 ± 5.4 mm) and after (16.0 ± 5.2 mm) fast treadmill walking. **Conclusion:** Six-minute fast treadmill walking induced greater muscle recruitment of the AbdH in individuals with flatfoot. We infer that the AbdH of flat foot doesn't function as a dynamic stabilizer during walking. However, how increased work loads in other lower extremity muscles results in greater activity of AbdH remains to be investigated. The observation that muscle activity of AbdH increased when the other extrinsic muscle fatigue indicates that 6 minutes walking can serve as functional training of the intrinsic muscles to support the medial longitudinal arch.

Heel Strike Provokes 'Position of No Return' during Side-Cutting Maneuver.

Issei Ogasawara, Ph.D.[1], Yohei Shimokochi, Ph.D.[2], Ken Nakata, Ph.D., M.D[1]. *[1]Osaka University, Osaka, Japan. [2]Osaka University of Health and Sport Sciences, Osaka, Japan.*
(No relevant relationships reported)

Knee valgus (VL) and internal rotation (IR) combined with hip adduction (AD) and IR, so called "position of no return (Ireland 1999)", is a risky position for non-contact ACL injury. To date, what motion factor induces this multi-articular excursion is not well studied.
PURPOSE: To examine whether a foot strike pattern (forefoot or heel first) differentiates the multi-articular loading pattern and results in the risky hip and knee kinematics during side-cutting.
METHODS: Twenty-five collegiate athletes performed side-cutting on the force plate (FP) in heel impact (HC) and forefoot impact (FC) conditions. In HC, subjects were asked to strike heel first when they touch the FP, in FC, the subjects used their forefoot to touch the FP throughout the stance phase. Kinematic and ground reaction force data were measured with the optical motion capture system and FP from 10 trials for each condition. The hip and knee 3D moments were calculated. The occurrence rate of simultaneous knee VL+IR combined with hip AD+IR moments in each time increment of 100 % stance phase was compared between conditions (Chi-square test, $p < 0.01$). The peak knee and hip joint angular velocities (JAVs) were also compared between conditions using paired sample t-test with $p < 0.01$.
RESULTS: HC showed significantly higher occurring rate of the hip AD+IR combined with knee VL+IR moments than that of FC in first 50 % of stance phase (HC vs FC, maximally 22 % vs 13 %, $p < 0.01$, Fig.1). Peak knee VL, hip AD and hip, IR JAVs in HC were significantly higher than those in FC (HC vs FC, 178.3 ± 84.2 vs. 136.6 ± 70.2, 170.5 ± 65.1 vs. 127.6 ± 73.0, 165.4 ± 84.1 vs. 103.7 ± 50.1, [unit : deg/s], $p < 0.01$).

Abstracts were prepared by the authors and printed as submitted.

CONCLUSION: The heel strike was found to induce the knee VL+IR combined with hip AD+IR moments, which forced the joints to move toward the 'position of no return', implying that the heel strike may increase the risk of ACL injury. Decelerating with forefoot is therefore recommended for a safety multi-articular biomechanics.
Fig 1. Time course difference of the rate of simultaneous occurring of the Knee VL+IR combined with hip AD+IR during side-cutting motion. Gray-shaded zones showed the significant rate differences between foot conditions.

Motor Unit Discharge Characteristics And Walking Performance Of Individuals With Multiple Sclerosis.

Leah A. Davis[1], Awad M. Almuklass[2], Hamilton Landon[1], Taian Vieira[3], Alberto Botter[3], Roger M. Enoka[1]. [1]University of Colorado Boulder, Boulder, CO. [2]King Saud bin Abdulaziz University for Health Sciences, Riyadh, Saudi Arabia. [3]Politecnico di Torino, Torino, Italy.
(No relevant relationships reported)

PURPOSE: To examine the associations between strength, force steadiness, and motor unit discharge characteristics of lower leg muscle with assessments of walking performance and disability status in individuals with multiple sclerosis (MS).
METHODS: Persons with MS (n=23, 9 men, 53 ± 7 yrs) attended 1 to 3 evaluation sessions that were performed before, immediately after, and 4 wks after a clinical trial of neuromuscular electrical stimulation. Outcomes included 3 questionnaires (Patient Determined Disease Steps [PDDS], Modified Fatigue Impact Scale [MFIS], and MS Walking Scale-12 [MSWS-12]), 25-ft walk test, 6-min walk test, and maximal torque and force steadiness (10 and 20% MVC) for lower leg muscles. High-density surface EMG recordings were obtained from the tibialis anterior (TA), soleus (Sol), and medial gastrocnemius (MG) during the steady contractions and decomposed into discharge times of motor unit action potentials.
RESULTS: Greater levels of self-reported disability (PDDS, MFIS, MSWS-12) were associated with less distance walked in 6 min and longer times to walk 25 ft. Mean interspike intervals (ISI) were 110 ± 23 ms and 102 ± 22 ms (10% and 20% MVC force, respectively) for TA motor units (n= 1,634), 138 ± 36 ms and 135 ± 34 ms for MG motor units (n=696), and 150 ± 33 ms and 145 ± 34 ms for Sol motor units (n = 902). A multiple regression model explained 40% (P=0.001) of the variance in 6-min distance with two predictor variables: mean ISI of MG (partial r = -0.48) and MVC dorsiflexor torque of the more affected leg (partial r=0.37). Similarly, another multiple regression model explained 47% of the variance (P<0.001) in 25-ft time with three predictor variables: mean ISI of soleus (partial r=0.51), MVC dorsiflexor torque of the more affected leg (partial r = -0.43), and force steadiness of the plantar flexors (partial r = 0.39).
CONCLUSION: Moderate amounts of the variance in two walking tests for persons with MS were explained by mean discharge times of action potentials by motor units in plantar flexor muscles during steady submaximal contractions, the strength of the dorsiflexor muscles in the more affected leg, and force steadiness during an isometric contraction.

Overground Locomotor Training in Incomplete Spinal Cord Injury: Effects on Balance and Gait

Brian T. Neville, Clinton J. Wutzke, Donal Murray, Caitlin A. Bryson, Kerry J. Bollen, John P. Collins, Andrew A. Guccione. *George Mason University, Fairfax, VA.* (Sponsor: Randall Keyser, FACSM)
(No relevant relationships reported)

Introduction: Restoration of ambulatory function in individuals with motor-incomplete spinal cord injury is the primary aim of rehabilitation. However, optimal training methods to improve balance and gait in this population have not been established. **Purpose:** To determine changes in balance and gait following a task-specific, performance-based training protocol for overground locomotor training (OLT) in individuals with motor-incomplete spinal cord injury (iSCI). **Methods:** Convenience sample, pilot study. Nine males and three females (38.5±16.4 years old,

AIS C or D, >6 months post-SCI) participated in two 90-minute OLT sessions per week for 12 to 15 weeks. OLT sessions are built on three principles of motor learning: practice variability, task-specificity, and progressive overload (movement complexity, resistance, velocity, volume). Training uses only voluntary movements without body weight support, robotics, or other assistive devices. Subjects used ambulation aids as necessary. Outcome measures collected at baseline and post-intervention. Measures of interest include Berg Balance Scale (BBS) and Functional Ambulation Inventory (SCI-FAI) for all participants. Spatiotemporal measures were collected from six participants that walked on a pressure-sensitive walkway. **Results:** 11 participants completed OLT and one participant completed 15 of 24 sessions due to scheduled surgery. The BBS scores showed a mean score improvement of 4.33±4.64 (p<0.01). SCI-FAI scores showed a mean score increase of 2.17±3.76 (p=0.07), with six of the participants scoring at least 18 out of 20 possible points post-training. One individual progressed from using a rolling walker pre-training to no assistive device post-training. SCI-FAI score for this individual did not change [19/20] but preferred gait speed increased 168% [0.30 to 0.81 m/s], step length increased 104% [0.33m to 0.68m], and mean center of pressure to center of mass (CoP-CoM) distance in the sagittal plane increased 132% [2.55cm to 5.91cm] after training. **Conclusion:** This pilot demonstrates improvements in balance and some gait characteristics using a novel task-specific, performance-based OLT for chronic motor incomplete SCI.

Decline in Gait Speed Across Clinical Populations Indicates Increased Risk of Falling

Cortney Armitano, Steven Morrison. *Old Dominion University, Norfolk, VA.*
(No relevant relationships reported)

The process of aging is typically associated with a general decline in sensorimotor and neuromuscular function that become apparent during different movements including gait. Spatiotemporal measures at preferred walking speed have be used to quantify functional capacity of a person's walking ability and, clinically, to assess the impact neurological disorders have on gait. For example, persons with multiple sclerosis (MS) and Type 2 diabetes (T2DM) often present with gait and balance problems which can lead to increased risk of falling. **PURPOSE:** This study was designed to assess differences in gait and falls risk for healthy individuals compared to persons diagnosed with MS or T2DM. **METHODS:** Twenty three healthy adults (controls), 23 persons diagnosed with MS, and 23 individuals with T2DM participated in this study. Falls risk was assessed using the Physiological Profile Assessment (PPA). For gait, participants performed 3 trials at their preferred gait speed while walking across a pressure sensitive mat. Measures of velocity, step length, stride length, and step time were used to assess gait. A within-subject, repeated-measures generalized linear model was used to analyze the data. **RESULTS:** The results revealed significant differences in falls risk between the three groups with the MS persons exhibiting the greatest risk score (MS 2.51±1.4, T2DM 0.84±0.7, control 0.22±0.6). There was significant group difference in walking velocity with the MS persons walking at a significantly slower velocity (mean 89.6m/s) compared to the controls (mean 117.2m/s) and the T2DM group (mean 111.8 m/s; $F_{2,64}$=14.12, p<0.001). The differences in walking speed were also reflected by significant differences in step length ($F_{2,64}$=12.50, p<0.001) and stride length ($F_{2,64}$=11.39, p<0.001) between the three groups. The changes in step/stride length were not reflected by similar changes in step/stride time. **CONCLUSION:** Overall, significant differences in walking speed and spatiotemporal parameters were found between healthy adults and individuals with MS and T2DM. The decline in gait speed appears to be associated with an increased risk of falling. The basis for the reduction in gait speed would appear to be driven by reductions in the length of the step/stride taken rather than alteration of the duration of the step/stride events.

Influence Of Different Sole Thickness On Biomechanical Parameters Of Human lower Extremity

Yi Jia[1], Li Li, FACSM[2]. [1]North University of China, TaiYuan, China. [2]Georgia Southern University, Statesboro, GA.
(No relevant relationships reported)

Background: Different athletic shoe outsole thickness can influence human movement from the aspects of both performance enhancement and injury prevention.
Purpose: To investigate the influence of different outsole thickness on lower extremity muscle activity, kinematics, and kinetics during walking and running.

Method: Twelve male college students (age: 20.9±0.7, height: 172.0±2.1cm, body mass: 63.0±3.4 kg) were tested. Four sole thickness (original commercial shoe, 1, 2, and 3 cm increased outsole thickness) were tested. Elastic modulus was tested using a universal testing machine (Instron-5544, US). The running tests were performed on a treadmill with a fixed speed (3.33 m/s) and continued for 8min. Walking tests were performed on a force platform (AMTI, US, 400×600mm). A motion capture system (VICON, Oxford, UK) was used to obtain kinematic data. Wireless surface electromyography testing system (Noraxon, US) was used to obtain the surface electromyography (sEMG) data. One-way analysis of variance with repeat measures (ANOVA) was used to compare differences in muscle activity, kinematic, and kinetic outcome variables. Statistical significance was set at $\alpha = 0.05$.

Results:

The 1 cm sole thickness has the highest elastic modulus (0.80MPa) and the 3cm is the lowest (0.25MPa). The co-contraction index value of 1cm group was significantly less than the others in both initial (0.55±0.14, P<0.05) and final (0.53±0.13, P<0.05) stage of running. At the toe off, the knee angle of 2 cm (131.0±9.5 deg, P<0.05) and 3 cm (132.7±4.6 deg, P<0.05) group increased significantly comparing to 0cm (125.0±5.4 deg) group in walking test.

Conclusion:

The outsole thickness of 1cm reduced muscle co-contraction during running. Knee joint increased with the increasing of sole thickness at the time of toe off when walking.

How Pain Management for Osteoarthritic Knee Influences Gait: A Case Study

Jason V. Slack, Michael J. Bohne, Chris Killpack, Tyler Standifird. *Utah Valley University, Orem, UT.* (Sponsor: Scott Drum, FACSM)

(No relevant relationships reported)

Osteoarthritis (OA) is the most common joint disorder in the US. Pain management has been a commonly investigated treatment for knee OA, little is known about the effects pharmacologic interventions have on gait. **PURPOSE:** To investigate the effects of pharmacological interventions on gait. **METHODS:** A 47-year-old male (1.7 m, 75 kg) with a diagnosed left knee medical compartment OA with severe bone on bone joint space narrowing with marginal osteophytes and subchondral sclerosis participated in this study. Three medication regimens (no medication (NM), over the counter NSAID (NSAID), and a prescription pain medication (PPM)) were used for this study. Trials were randomized and data was collected at the end of a week with a 7 day wash out period before the next trial. Testing consisted of a 5-minute walk at a self-selected pace on an instrumented treadmill. Data was collected using Vicon Nexus and sagittal plane kinematics and kinetics were analyzed using Visual 3d. **RESULTS:** At the ankle the PPM led to a peak plantarflexion moment that was two times greater at push-off (0.66 Nm/kg) compared to the NM condition (0.31 Nm/kg) in the affected limb. At the knee, the NM condition had more flexion at both foot contact and flexion during loading compared to both the PPM and NSAID in the affected limb. The loading knee extension moment of the affected limb was elevated in the NM condition (2.3 Nm/kg) compared to the PPM condition (1.5 Nm/kg). When comparing the affected limb to the unaffected limb, the loading knee extension moment was more symmetrical between the two sides in the PPM condition compared to both the NM and the NSAID condition. The affected knee experienced greater loading in the sagittal plane in both of these conditions. **CONCLUSION:** The results of this case study suggest that medications alter lower extremity biomechanics of both the affected and unaffected limb during gait. In the sagittal plane it appears that at the knee the use of prescription medication leads to more symmetrical gait in loading and reductions in knee loading moments. At the ankle the prescription pain medication appears to allow for the push-off moment to be increased and more similar to healthy gait. When considering the sagittal plane at the ankle and knee the prescription pain medication appears to restore normal and healthy gait patterns in a subject with knee OA.

The Effect of Change on Stride Length on Muscular Activity and Energy Cost during Walking

Hae Ryong Chung[1], Travet Witherspoon Jr[1], Moroni de Moors[1], Jin hee Jeong[2], Chris Pitsikoulis[3]. *[1]Clayton State University, Morrow, GA. [2]Augusta University, Augusta, GA. [3]Aurora University, Aurora, IL.*

(No relevant relationships reported)

Human bipedalism is the most unique locomotive form in the terrestrial environment and can be performed for a prolonged period of time. To maintain this form of locomotion humans have adopted physiological and mechanical strategies to minimize and conserve energy. **PURPOSE:** To study the effects of stride length change on the electromyographic (EMG) activity of the quadriceps and hamstring muscle groups and oxygen consumption. **METHODS:** Male (n=6) subjects (age = 23.25 ± 0.95 years) were recruited for this study. Height, weight, body composition

---

(bioelectrical impedance analysis), and stride length (SL) were measured. Surface EMG activity of the right quadriceps and hamstring muscle group, heart rate, and oxygen consumption(VO_2) were measured during walking at self-selected (SS) speed at the following stride lengths: (1) SS, (2) 10% below SS, (3) 20% below SS, (4) 10% above SS, (5) 20% above SS, and (6) 30% above SS. Repeated measures ANOVA were used to determine serial patterns and paired t-tests for differences between different SL. **RESULTS:** VO_2 was significantly lower at SS SL than 20% below SS SL and VO_2 of 20% below SS SL was lower than 10% below and 10% above SS SL. VO_2 of 10% and 20% above SS SL was lower than 30% above SS SL (P < 0.05). Heart rate was significantly lower at SS SL than 20% below and 10% and 30% above SS SL. Heart rate of 10% and 20% above SS SL was lower than 30% above SS SL (p<0.05). EMG activity in the quadriceps muscle was significantly lower at SS SL than 20% below SS SL and EMG activity of 20% below SS SL was significantly lower than 10% below SS SL. EMG activity of 10% above SS SL was lower than 20% above SS SL (P<0.05). There were no differences in the EMG activity of the hamstring muscle group. **CONCLUSION:** Preliminary results from this ongoing study demonstrate that energy costs increase at values above and below self-selected stride length at a SS speed, resulting in a U-shape curve in oxygen consumption and muscle activity in quadriceps muscle. SS SL appears to be optimal in terms of walking energy efficiency compared to shorter and longer SL. These results suggest that the SS locomotive pace in humans is that at which the most efficient energy cost can be maintained. Further studies are necessary to investigate the effect of stride length alteration training on the energy cost and efficiency of walking.

Does Music-Based Rhythmic Auditory Cueing Alter the Correlation Structure of Stride Times?

Scott W. Ducharme, Dylan C. Perry, Colleen J. Sands, Elroy J. Aguiar, Christopher C. Moore, Catrine Tudor-Locke, FACSM. *University of Massachusetts, Amherst, Amherst, MA.* (Sponsor: Catrine Tudor-Locke, FACSM)

(No relevant relationships reported)

The time interval from heel strike to subsequent heel strike (i.e., stride time) has been shown to be statistically persistent, i.e., long or short stride times are likely to be followed by subsequent stride times of similar magnitude. This persistence is thought to represent complex, adaptive locomotor behavior. Rhythmic auditory cueing (RAC) entails instructing participants to synchronize their foot strike timing to an auditory metronome. While RAC reduces stride time variability, it also eliminates stride time persistence, which may indicate reduced adaptability. Alternatively, matching foot strike timing to a musical tempo instead of a metronome may yield less precise temporal synchronization, thereby preserving the correlation structure of the time series. **PURPOSE:** To determine if music-based RAC reduces the persistence of stride time variability. **METHODS:** Nine young, healthy adults (mean±SD age 22.9±2.0 years, height 171.0±11.7 cm, mass 75.4±14.9 kg) walked along an oval course (40 m) for six 5-minute trials. Three of the trials consisted of walking at self-selected slow, normal, and fast walking speeds. The remaining three trials entailed participants walking while matching their foot strike timing to the tempo of a song. Using a commercially available app, the tempo of a single song was altered to 80, 100, and 125 beats per minute. Participants performed separate, randomly ordered trials while matching each song tempo. Stride times were obtained via an ActiGraph accelerometer at the right heel. Detrended fluctuation analysis was used to quantify the extent of statistical persistence of stride times. A repeated-measures ANOVA was used to test for effects of RAC on stride time persistence. **RESULTS:** There was a main effect of RAC on stride time persistence ($F_{1,8} = 5.26$, $p = 0.05$), as persistence decreased when participants entrained to music, compared to self-selected walking. However, this effect was not consistent across all participants, as 3 of the 9 individuals exhibited greater persistence during RAC trials. **CONCLUSION:** Similar to reports of metronome entrainment, synchronizing step timing to music resulted in an overall modified correlation structure closer to random, which is associated with less adaptive behavior. Future studies may consider testing RAC to more complex songs with various beats.

Does Arm Swing Frequency Match Alterations in Stride Frequency during Treadmill Walking?

Sarah M. Garcia, Jacqueline T. Brine-Doyle, Marcella J. Myers. *St Catherine University, St. Paul, MN.* (Sponsor: Mark Blegen, FACSM)

(No relevant relationships reported)

PURPOSE: To determine whether arm swing frequency matches alterations in stride frequency above and below preferred stride frequency while walking on a treadmill at a range of speeds.

METHODS: At each of 4 self-selected speeds, 10 female participants (mean age: 27.6 yr, range: 20-47 yr) walked on a treadmill while attempting to match their stride frequency to the beat of an audio metronome beating at one of three different

---

frequencies: 90%, 100%, and 110% of the preferred stride frequency at that speed. Speeds used were: Low (slowest kinematically smooth speed), Mid1 (0.2 mph below "most comfortable" speed), Mid2 (0.2 mph above "most comfortable" speed, and High (fastest normal walking speed). On three separate days, participants completed, in a randomized order, 12 5-minute trials at each combination of the 4 walking speeds and 3 stride frequency levels. From video of the third test session, actual stride frequency and arm swing frequency was determined for 10 consecutive strides/swings in both the third and fourth minutes of the trial.

RESULTS: Seven of the ten participants were able to maintain actual stride frequencies very close to the nominal frequency of the metronome; actual SF values were different from nominal SF values by an average of only 1.6% (range 0.7% to 7.4%) in this group, while the other three participants were unable to match the nominal SF successfully (range 15% to 21% different from nominal). For the seven participants who could achieve the nominal SF, the correlation between arm swing frequency and stride frequency was almost exact (r2=0.99). Interestingly, the three participants who could not achieve the nominal SF also had arm swing frequencies that correlated very strongly with their stride frequency (r2=0.99).

CONCLUSIONS: The very tight coupling of the frequency of alternation of the arms and legs in our participants, even when using stride frequencies above or below the preferred frequency for a given speed, indirectly supports a common central pattern generator source for the pacing of these movements.

This research project was funded by a 3M Faculty/Student Collaborative Grant through the St. Catherine University, St. Paul, Minnesota.

Local Dynamic Stability is Affected By Soldier-Relevant Torso Loads and Gait Speeds

Kari L. Loverro[1], Elliot Saltzman[1], Leif Hasselquist[2], Cara L. Lewis[1]. [1]Boston University, Boston, MA. [2]Natick Soldier Research Development and Engineering Center, Natick, MA.
(No relevant relationships reported)

For soldiers, falling while carrying heavy loads can lead to serious injury. Nonlinear analyses, such as local dynamic stability (LDS), can quantify gait stability. LDS can be affected by both load and speed. Studies on soldier-relevant torso loads at multiple speeds are lacking.
PURPOSE: To determine if soldier-relevant loads at 3 speeds affect LDS of the trunk and pelvis during gait.
METHODS: 10 healthy adults (5M, 5F) walked on a treadmill at 3 speeds (1.15, 1.35, 1.55 m/s) under 3 loaded vest conditions (1.3, 15, 27 kg). Trunk and pelvis marker data were collected for 2 min. Short term local divergence exponents (LDE) of marker velocity data in the mediolateral, anteroposterior and vertical directions (ML, AP, V) were calculated to quantify LDS by measuring the rate at which each stride changes from the prior stride. Larger LDE values indicate decreased LDS. Linear regressions analyses tested the effects of load (L1, L2, L3) and speed (S1, S2, S3).
RESULTS: LDS decreased with increased load in all directions at the trunk (LDE Mean±SD; ML: 0.44±0.02, 0.45±0.02 for L2 and L3 respectively, $p = 0.001$; AP: 0.39±0.02, 0.41±0.01, 0.43±0.01 for L1, L2 and L3, $p ≤ 0.009$; V: 0.68±0.04, 0.72±0.04, 0.77±0.04 for L1, L2 and L3, $p ≤ 0.021$) and in the vertical direction at the pelvis (0.55±0.04, 0.58±0.40, 0.62±0.39 for L1, L2 and L3, $p ≤ 0.019$). Conversely, ML and AP LDS increased with increasing speed at the trunk (ML: 0.48±0.02, 0.44±0.02, 0.41±0.02 for S1, S2 and S3, $p < 0.001$; AP: 0.43±0.01, 0.41±0.01, 0.39±0.02, $p < 0.001$ for S1 vs S2 and S1 vs S3) and pelvis (ML: 0.32±0.02, 0.30±0.01, $p = 0.004$ for S1 vs S2; AP: 0.42±0.02, 0.37±0.03, 0.36±0.02, $p ≤ 0.001$ for S1 vs S2 and S1 vs S3). However, vertical LDS decreased with increasing speed at the trunk (0.71±0.04, 0.71±0.05, 0.75±0.04, $p ≤ 0.012$ for S1 vs S3 and S2 vs S3) and pelvis (0.57±0.04, 0.57±0.05, 0.61±0.02, $p ≤ 0.006$ for S1 vs S3 and S2 vs S3).
CONCLUSIONS: Preliminary results suggest that increasing speed with a heavier load increases stability. However, the decrease in vertical LDS with increased speed indicates that more energy may be required to control the vertical motion of the trunk and pelvis, and may lead to earlier fatigue. Inclusion of more participants may reveal interaction effects of load and speed not yet detected.

Long Term Functional Metrics Following Direct Anterior Total Hip Arthroplasty

Brianne Borgia[1], Julia Freedman Silvernail[1], Cass Nakasone[2], Christopher Stickley[3], Ronald Hetzler, FACSM[3], Kara Radzak[1]. [1]University of Nevada, Las Vegas, Las Vegas, NV. [2]Straub Hospital, Honolulu, HI. [3]University of Hawaii, Manoa, Honolulu, HI. (Sponsor: Ronald Hetzler, FACSM)
(No relevant relationships reported)

Total hip arthroplasty (THA) is an effective treatment for patients suffering from end-stage primary hip osteoarthritis. The most common reported outcomes of THA relate to restoration of mobility and decrease of pain. Gait velocity and the Timed Up and Go (TUG) provide functional metrics to quantify improvements during rehabilitation.
PURPOSE: The purpose of this study was to examine differences in gait velocity and TUG measures in direct anterior approach THA patients during recovery compared to healthy controls.
METHODS: Eight unilateral THA patients and 11 healthy controls were recruited for participation. Data collection occurred pre-operatively and at 6 time-points up to 2 years post-operatively. Participants performed 6 walking trials over a 4-m walkway to determine self-selected velocity and 3 TUG trials. A 2x7 repeated measures ANOVA assessed differences in mean gait velocity and TUG (α<0.05).
RESULTS:A significant interaction was found for both velocity (p = 0.002) and TUG (p < 0.01). Post-hoc analysis identified a significant time effect in the THA group for velocity (p <0.01) and TUG (p = 0.01). Post-hoc independent t-tests identified that THA velocity was less than controls at three-weeks post-operatively; there was a significant effect of time in the THA group (Figure 1a). There were no significant group differences in TUG at any time point, but there was an effect of time in THA group TUG measures (Figure 1b).
CONCLUSIONS: Improvements in gait velocity and TUG measures within in THA group supports THA as a successful treatment. However, changes in velocity over time may suggest functional degradation at the 2 year time-point. While there are no differences between 1 and 2 year velocities, we observed THA participants exhibiting a faster velocity at 1 year than six-weeks post-operatively. Yet at 2 years, velocity was no longer faster. This suggests that long-term maintenance of functional measures should remain a clinical consideration for THA patients.

Figure 1a. Average self-selected gait velocities for total hip arthroplasty patients (THA) and healthy control (CTRL) groups across data collection time-points. * p <0.05 for difference between groups. For THA group only, † p < 0.05 for difference compared to pre-surgery, ◊ p < 0.05 for difference compared to 3 weeks post-surgery, Υ p < 0.05 for difference compared to 6 weeks post-surgery.
Figure 1b. Average Timed Up and Go completion times for total hip arthroplasty patients (THA) and healthy control (CTRL) groups across data collection time-points. For THA group only, * p < 0.05 for difference compared to pre-surgery, † p < 0.05 for difference compared to 3 weeks post-surgery.

Concurrent Validity Of A Gait Analysis Application Vs. Slow-motion Video For The Assessment Of A 400 M Walk Test

Nathan W. Saunders, Alexandra Colacino, Meghan Hess, Brianna Gassman, Uriel Ibarra-Moreno, Alyssa Braun, Morgan Kiser, Kennady Miller, Abigail Matsushima, Megan Salvatore. University of Mount Union, Alliance, OH.
(No relevant relationships reported)

Our lab developed a cell phone application to assess gait parameters during a 400 m Walk Test. It has the potential to improve the feasibility and effectiveness of allied healthcare professionals. **PURPOSE:** To test the concurrent validity of a cell phone gait assessment application by comparing results to those found through slow motion video analysis of participants completing a 400 m walk test. The hypothesis is that there will be agreement between the application and video for gait speed, cadence, and turn duration. **METHODS:** Seven female and six male apparently healthy adults (Age = 40.7 ± 7.5 years) participated in this study. Participants completed a single trial of a 400 m walk test at a self-selected pace on a 25-meter, linear course. Ends of the course were marked with a cone, and dashed lines were positioned 2.5 meters inward from each cone. Two investigators were present at each test session. One video recorded the participant with a cell phone camera at 30 fps, which was later analyzed for steady-state gait speed, cadence, and turn duration. A second investigator used the gait application to assess the same parameters in real time. Paired t-tests were used to test for significant differences between the two assessment methods. Significance was

established *a priori* at alpha = 0.05. **RESULTS:** There were no significant differences between the gait application and video for gait speed (1.694 ± 0.352 vs. 1.693 ± 0.347 m/s, respectively) or turn duration (4.165 ± 0.761 vs. 4.171 ± 0.762 s, respectively). There was, however, a small but significant difference between the gait application and video for cadence (129.9 ± 14.0 vs. 129.1 ± 13.6 steps/min , respectively). **CONCLUSION:** For middle aged adults across a broad spectrum of gait speeds, the gait application is a valid method to evaluate steady-state gait speed and turn duration of a 400 m walk test. Although there was a significant difference between the gait application and video for cadence, the one step per minute difference is not likely to be clinically meaningful.

Amputee's Gait Assessment for Successive Steps by Miniature Triaxial Load Cells

Harcharan S. Ranu, FACSM. *American Orthopaedic Bimechanics Research Institute, ATLANTA, GA.*
(No relevant relationships reported)

PURPOSE: To Evaluate the Amputee's Gait for Successive Steps.
An evaluation and assessment of human gait has been studied by using many systems to perform and analyze the spatio-temporal, kinematic, kinetic, neuro-muscular and energetic data. In order to understand the disorders of the human foot, it is essential to know its anatomy and biomechanics. Since the mechanics of the abnormal foot can adversely affect the normal functioning of the ankle, knee, hip and back, it was the purpose of this investigation to quantify the forces under different regions of amputee's foot and evaluate their gait. METHODS; Ranu's (1) system was used to evaluate specific aspects of foot functioning during abnormal gait. It consisted of a miniature triaxial load cell 8 mm in thickness and 19 mm square. A shoe was instrumented with five load cells, three on the sole and two on the heel. This system was used to measure forces under different areas of the feet of below knee amputees for successive steps. RESULTS: Six below knee amputees of mean age 47.2 years and mean weight 64.5 kg were investigated. The gait of amputees were studied from 1st step on a temporary pylon (1st Run) to a final 'normal' gait on a permanent prosthesis (2nd Run, one month later). Results for forces (Heel-Lateral, 1st Run) 40.5 ± 1.4, forces (1st Metatarsal, 1st Run) 2081.3 ± 62.4 and forces (Big Toe, 1st Run) 72.2. ± 2.46. Results for forces (Heel-Lateral, 2nd Run) 122.3 ± 4.1, forces (1st Metatarsal, 2nd Run) 156.1 ± 5.21 and forces (Big Toe, 2nd Run) 254.3 ± 8.8. These data clearly show a significant improvement in amputees gait from the 1st run and as compared with the 2nd run, 202 (Heel-Lateral), 93(1st Metatarsal) and 114 (Big Toe) % improvement, p > 0.10. CONCLUSIONS : It is concluded that this method of analyzing gait is sensitive, simple, accurate, and can be used as a diagnostic tool in the management of patients with lower extremity disabilities for successive steps. For amputees it was possible to identify misalignments from the output of the various load cells. This method also allowed in identifying and correcting problems in the painful below knee stump. It helped below knee amputees to walk nearly normally.

Non-linear Lower Extremity Joint Torque Changes Observed during Preparation for Walk-to-run Gait Transition

Li Li, FACSM[1], Jiahao Pan[2]. *[1]Georgia Southern University, Statesboro, GA. [2]361° (CHINA) CO., LTD, Xiamen, China.*
(No relevant relationships reported)

PURPOSE: To investigate lower extremity torque components changes in preparation for gait transition with increased walking speed. **METHODS**: 11 male and 3 female college students (age: 22.6 ± 1.9 years, body mass: 75.4 ± 12.8 kg, height: 1.73 ± 0.08 m) were recruited for this study. Participants walked on a force plates embedded treadmill (AMTI, MA, USA) with continuously changed walking speed approaching walk-to-run transition. Ground reaction forces and kinematic data (VICON, Oxford, UK) were obtained at sampling rate of 1000 Hz and 200 Hz, respectively. The results of inverse dynamics were further decomposed into net joint torque (NET), gravitational torque (GTT), motion-dependent torque (MDT), contact torque (EXT), and generalized muscle torque (MST) for the last five strides before gait transition. Owe-way MANOVA employed to exam the difference among the five strides. Post hoc polynomial trend analyses were also employed to examine the trend with the five strides whenever suitable. **RESULTS**: Significant difference of all three lower extremity joints was detected during stance phase. Positive / negative values represent extension / flexion torque. EXT and MST of ankle (0.15 ± 0.02 vs. 0.15 ± 0.03 vs. 0.16 ± 0.02 vs. 0.15 ± 0.02 vs. 0.01 ± 0.01 nm/kg; -0.18 ± 0.02 vs. -0.18 ± 0.03 vs. -0.19 ± 0.03 vs. -0.18 ± 0.02 vs. -0.04 ± 0.01 nm/kg); knee (-0.60 ± 0.11 vs. -0.64 ± 0.11 vs. -0.74 ± 0.12 vs. -0.70 ± 0.11 vs. -1.34 ± 0.12 nm/kg; 0.51± 0.09 vs. 0.55 ± 0.09 vs. 0.63 ± 0.09 vs. 0.59 ± 0.10 vs. 1.25 ± 0.09 nm/kg) displayed significantly decrease / increase at last stride before gait transition during early stance phase (*p* < .05), as were the knee (-0.27 ± 0.03 vs. -0.31 ± 0.04 vs. -0.28 ±0.04 vs. -0.28 ± 0.04 vs. -0.13 ± 0.02

nm/kg; 0.36 ± 0.03 vs. 0.41 ± 0.03 vs. 0.39 ± 0.04 vs. 0.38 ± 0.04 vs. 0.23 ± 0.02 nm/kg) and hip (0.74 ± 0.08 vs. 0.78 ±0.07 vs. 0.73 ± 0.08 vs. 0.75 ±0.09 vs. 0.21 ± 0.04 nm/kg; -1.11± 0.07 vs. -1.15 ± 0.07 vs. -1.13 ± 0.06 vs. -1.15 ± 0.07 vs. -0.74 ± 0.03 nm/kg) responses at end of stance phase (*p* < .05). These variables also displayed significantly quadratic trend as speed increase (*p* < .05). **CONCLUSIONS**: Nonlinear changes in active / passive torques magnitudes observed during gait transition through continuously increased walking velocity. Gait transition was initiated during strides before gait transition.

The Effect Of Soccer History On Tibial Strain During Load Carriage

Henry Wang[1], D. Clark Dickin[1], Julie Hughes[2]. *[1]Ball State University, Muncie, IN. [2]U.S. Army Research Institute of Environmental Medicine, Natick, MA.*
(No relevant relationships reported)

Tibia stress fracture (TSF) is common in military recruits. Female Soldiers experience a higher rate than their male counterparts. TSF occurs most frequently in Basic Combat Training (BCT) and has been partially attributed to repetitive impact loading from tasks such as load carriage. Tibia mechanical properties could be improved as a result of training with multi-directional loading (MDL) (e.g. soccer). However, it has yet to be determined whether the improved tibia strength observed with MDL could result in resistance of bone deformation (lower strains) due to load carriage. **Purpose:** To examine the effects of a soccer history and incremented load carriage on tibial bone strain. **Methods:** 20 female soccer players (20±1 yr) and 20 mass- and height-matched healthy women (21±1 yr) participated in this study. They completed four walking tasks with 0kg, 10kg, 20kg, and 30kg loads on a force instrumented treadmill at 1.67 m/s. Participants' tibia CT models were combined with subject-specific musculoskeletal models for forward-dynamic computer simulations and finite element analyses. Strains from the middle third of the bone shaft were analyzed. One-way ANOVAs were performed. α = 0.05. **Results:** Significant differences in strains were found among walking conditions and between the two groups (All p<0.0001). The mean ± SE strains during load carriages (0kg, 10kg, 20kg, and 30kg) were 562±3 μs, 634±3 μs, 736±7 μs, and 825±4 μs in tension for soccer players, and 684±3 μs, 791±3 μs, 1152±7 μs, and 1015±4 μs, for controls, respectively, resulting in an 18-36% difference in strains during load carriage. Compressive strains were 849±4 μs, 960±4 μs, 1092±10 μs, and 1180±7 μs in soccer players and 1039±4 μs, 1179±7 μs, 1749±11 μs, and 1552±7 μs in controls showing similar percent differences as tensile strains (18-38%). **Conclusion:** Participants with a soccer history benefited from significantly lower strains than healthy controls during incremental load carriage. Lower tibial strains during load carriage may be protective from TSF in those with a history of soccer, although this has yet to be demonstrated experimentally. These findings suggest that physical training involving MDL may be an ideal exercise modality for preconditioning prior to BCT for female recruits. US ARMY #W81XWH-15-1-0006.

Older Adults That Choose To Not Report Their Falls History Biomechanically Present as Fallers

Eryn N. Murphy, David W. Keeley, Robert H. Wood. *New Mexico State University, Las Cruces, NM.*
(No relevant relationships reported)

Purpose: This study aimed to better understanding the gait biomechanics of individuals that voluntarily choose to not report their history of falling, or lack thereof, against older adults who self-reported a history of falling or not falling. **Methods**: The sample included 1390 people over the age of 60 years (failed to report = 182, fallers = 605, non-fallers = 603). Participants were recruited from multiple testing sites across the Southwest United States. Multiple analysis of variance was conducted to test for differences between individuals that failed to report (FTR), fallers (F), and non-fallers (NF), as well as group differences within variables of the pace factor, including cadence, gait velocity and stride length. For the multivariate analysis, alpha was set at α = 0.15 with follow-up analysis alpha corrected using the Bonferroni technique and set at α = 0.05. **Results**: MANOVA analysis for differences on the set of pace factor variables revealed that there is a significant difference between groups (p<0.001) on the set of variables inclusive of cadence, gait velocity and stride length. Follow-up univariate analysis revealed significant differences in each of the pace factor variables (p<0.05). Pairwise comparisons indicated the position of these differences. Specifically, with regard to cadence, there was no difference between FTR and F, however there is a significant difference between FTR and NF, with NF having significantly faster cadence (FTR = 93.5156spm, NF = 97.5341spm, p=0.005). Similarly, there was no difference between FTR and F in gait velocity, however there was a significant difference between FTR and NF, with NF presenting with significantly higher gait velocities (FTR = 60.6517cm/s, NF = 69.8126cm/s, p<0.01). Finally, in regards to stride length, FTR was not different from F, but was significantly different from NF, with NF presenting with significantly longer stride lengths (FTR = 77.3885cm, NF = 86.2104cm, p<0.01). **Conclusion**: In many falls

screenings, individuals are asked to self-report a history of falling. Based on these results, clinicians should understand that across pace factor variables established to be predictive of falls risk, individuals that choose not to self-report their history of falling appear to present with biomechanical measures that more closely resemble fallers.

Influence Of Short, Disrupted Sleep And High-intensity Interval Exercise On Fasting And Post-prandial Blood Lipid And Lipid-related Antioxidant Responses In Healthy Men

Matthew N. Peterson[1], Zacharias Papadakis[1], Jeffrey S. Forsse[1], Fernando Gutierrez[1], J. Kyle Taylor[2], Li Qian[2], Omar Brito-Estrada[2], Kathryn Dugan[2], Peter W. Grandjean, FACSM[1]. [1]Baylor University, Waco, TX. [2]Auburn University-Montgomery, Montgomery, AL. (Sponsor: Peter W. Grandjean, FACSM)
(No relevant relationships reported)

Exercise is known to impart transient blood lipid responses that appear consistent with reduced cardiovascular disease risk; yet, it is unclear how short, disrupted sleep (SDS) modifies post-exercise fasting and postprandial blood lipid and lipid-related antioxidant responses to a single episode of exercise. **PURPOSE:** To determine the influence of a single night of SDS on fasting and postprandial blood lipid and lipid-related antioxidant responses after HIIE. **METHODS:** Fifteen male participants (age 31.1 ± 5.3 yr; weight 83.5 ± 11.4 kg; BMI 25.8 ± 2.7 kg/m²; VO_2max 49.1 ± 8.5 ml/kg/min) completed a non-exercise control trial after 9 to 9.5 hrs of reference sleep (REF), HIIE by treadmill running (90% and 40% of VO_2reserve in 3:2 min ratio) to expend 500 kcals after reference sleep (REF+EX) and HIIE after 3 to 3.5 hrs of short and disrupted sleep (SDS+EX) in a randomized crossover design. Blood samples were obtained by the same technician under standardized conditions just before, immediately after (IPE), 1 hr after exercise (1 HR) and just before a high-fat meal - 1240 kcals (56 g fat; 145 g carbohydrate; 38 g protein) and again 2, 4 and 6hrs after meal ingestion and at equal intervals during REF. Total, high-density and low-density lipoprotein cholesterol (HDLC and LDLC) and paraoxonase-1 concentration were measured up to 1 hr post-exercise. Post-prandial triglyceride was measured and area under the curves - total (AUCt) and incremental (AUCi) were calculated. Lipid and lipid-related antioxidant responses were analyzed using 3 (condition) by 3 (sample point) repeated measures ANOVAs. AUCt and AUCi were measured using one-way, 3 (condition) repeated measures ANOVAs. **RESULTS:** HDLC (+6.3%, p = 0.0023) and paraoxonase-1 (+10.8%, p <0.0001) increased and triglyceride (-18.5%, p <0.0001) decreased after REF+EX and SDS+EX; TAUCt and AUCi remained refractory to exercise and short, disrupted sleep. **SUMMARY:** Exercise transiently increased fasting HDL cholesterol and related antioxidant concentrations and reduced triglyceride levels, but did not modify total or incremental triglyceride AUC in response to a post-exercise high-fat meal. Short, disrupted sleep did not influence these responses.

Effects Of Pre-exercise Sucrose Ingestion On Thermoregulatory Responses To 5-km Running

Patrick Wilson. Old Dominion University, Norfolk, VA.
(No relevant relationships reported)

PURPOSE: Carbohydrate feeding, in particular fructose, is associated with increased dietary thermogenesis and body temperature at rest. Whether these effects influence the thermoregulatory responses to heavy exercise remains uncertain. **METHODS**: A total of 28 runners (26 men, 2 women; 35.2 ± 9.6 years) with the ability to finish a 5-km in 16 to 23 minutes completed this randomized, double-blind, placebo-controlled trial. Runners were pair-matched based on their self-reported maximal 5-km running speed and assigned to consume a beverage containing 750 mL of water plus either 100 g of sucrose or 0.8 g of aspartame. Beverages were consumed 60 minutes before the 5-km, which was conducted at 93% of maximal 5-km speed in a temperate environment (21-22°C, 53% relative humidity). Gastrointestinal temperature, Thermal Sensation Scale (TSS) and Feeling Scale (FS) were recorded before beverage ingestion, every 10 minutes during rest, and every 1-km during the 5-km run. Rating of Perceived Exertion (RPE) was also recorded every 1-km. Two-way mixed ANOVAs with repeated measures and independent t-tests were used to examine treatment effects. **RESULTS**: Treadmill speed for the 5-km run was well-matched (13.8 ± 1.0 vs. 13.8 ± 1.0 km/h; $p = 0.98$) between the groups. Gastrointestinal temperature was not different between the carbohydrate (38.7 ± 0.4°C) and placebo (38.6 ± 0.4°C) groups by the end of the

5-km ($p = 0.49$). No group x time interactions or main effects for group were found for gastrointestinal temperature, TSS, FS, or RPE. A group x time interaction was found for TSS (F = 2.1, $p = 0.02$, partial $\eta^2 = 0.075$). Significant time effects were found for gastrointestinal temperature, TSS, FS, and RPE (all $p < 0.001$, partial $\eta^2 = 0.38$ to 0.91), with temperature, TSS, and RPE increasing, and FS decreasing, over time. **CONCLUSIONS**: Ingestion of 100 g of sucrose 60 minutes before exercise does not affect gastrointestinal temperature during near-maximal 5-km running in a temperate environment, and therefore does not likely modify the risk of heat illness.

Blood Glucose Control Following Single-Leg and Double-Leg Cycling

Shane Draper, John McDaniel. Kent State University, Kent, OH.
(No relevant relationships reported)

When exercise is confined to a small muscle mass, greater blood flow to that muscle allows for greater muscle specific intensity compared to whole body exercise. The greater muscle specific intensity results in greater glucose oxidation for any given VO_2 which may optimize exogenous blood glucose uptake following the exercise. **PURPOSE:** Thus, the purpose of this study was to determine the influence of reduced muscle mass exercise (single leg cycling) on post exercise blood glucose control. **METHODS:** Seven healthy college age students completed the study in which they arrived fasted and were administered an oral glucose tolerance test (OGTT) following 4 conditions: no exercise, following 30 minutes of single leg cycling, following 30 minutes of double leg cycling matched for VO_2, and following 30 minutes of double leg cycling matched for power. VO_2, RER, and carbohydrate oxidation were recorded throughout the exercise. Two 4 x 2 repeated measures ANOVAs were performed on condition (single leg, double leg VO_2 and double leg power) and time (baseline and average blood glucose as well as baseline and peak blood glucose). **RESULTS:** Despite the fact that carbohydrate oxidation was greater during the single leg cycling ((1.4 ± 0.45 grams) of carbohydrate utilized per minute during single leg compared to (1.0 ± 0.49 g/min) during double leg matched for VO_2 and (0.87 ± 0.43 g/min) during double leg cycling matched for power), there was no difference ($p > 0.05$) in average blood glucose uptake between single leg cycling (126 ± 8 mg/dL) and double leg cycling when matching for VO_2 (121 ± 10 mg/dL) and power (125 ± 10 mg/dL) when compared to baseline (124 ± 13 mg/dL). Additionally, there was no difference in peak blood glucose between single leg cycling (160 ± 17 mg/dL) and double leg cycling when matching for VO_2 (154 ± 20 mg/dL) and power (155 ± 19 mg/dL) when compared to baseline (159 ± 18 mg/dL). **CONCLUSION:** We conclude that the greater glucose utilization during single leg cycling had no effect on blood glucose uptake following an OGTT.

Influence of Acute Resistance Exercise on Post-Exercise Glycemic Control

William A. Braun, FACSM, Helene Miller, Daniel Hauck, Schuyler Harting, Acacia Rightmyer, Gabriel Hirsch. Shippensburg University, Shippensburg, PA.
(No relevant relationships reported)

PURPOSE: To study the effects of acute resistance exercise on the body's ability to regulate blood sugar in active, resistance trained, adults. **METHODS**: The study included eight participants (2 female, 6 male; age: 20.63±1.85 years; mass: 80.99±24.67 kg; height: 173.31±9.96 cm; body fat: 16.73±6.65%). Initially, informed consent, 10-repetition maximum (10-RM) for the three resistance exercises (squat, biceps curl, and bench press) and demographic measurements were obtained. Subjects completed three trials on separate days. One resting trial and two exercise trials (squat only; full body: all three exercises) were completed. The subjects performed five sets (6 reps/set) using the 10-RM load. In each exercise trial, the subject consumed a 25% carbohydrate beverage (4ml/kg of body mass) after completion of exercise. All trials (resting included) involved a 75-minute oral glucose tolerance test (OGTT). Blood glucose (BG), heart rate (HR), blood pressure (BP) and blood lactate (BL) measures were collected before and following exercise. Blood pressure, and HR were also measured following the OGTT. **RESULTS**: OGTT response was not significantly different based on trial. Area under the curve (AUC) did not differ significantly by trial. Resting AUC was 5.8% greater than the squat only trial and 2.5% greater than the full body trial. There were no significant differences between exercise trials for BL, HR, or mean arterial pressure (MAP). Rate of perceived exertion was significantly greater for full body (15.88 ± 1.81) vs. squat (13.63 ± 1.06). **CONCLUSIONS**: Resistance exercise was not shown to significantly affect glucose regulatory response during recovery. The volume of active muscle did not seem to influence the OGTT response. Resistance exercise may not be as potent as aerobic

exercise in promoting acutely enhanced glycemic control. Future investigations into post-exercise glycemic control should be expanded to include a larger sample size and varied resistance exercises.

Accuracy, Precision And Comfort Of A Microdialysis Device For Continuous Real-time Blood Lactate Monitoring

Ben J. Lee[1], Julianne Doherty[1], Ania M. Hiles[1], Daniel Carney[2], Mark C. O'Connell[2]. [1]University of Chichester, Chichester, United Kingdom. [2]Probe Scientific, Thurleigh, United Kingdom.

BACKGROUND: In critically ill patients blood lactate is measured as a marker of tissue perfusion, with increasing lactate being associated with insufficient perfusion and poorer prognosis. Serial monitoring of blood lactate is a valuable tool in predicting in-hospital mortality, with a better prognosis observed when blood lactate concentrations are decreasing. A device that allows for automated, continuous monitoring of blood lactate removes the need for a practitioner to draw samples, and could provide more effective patient monitoring. **PURPOSE:** Evaluate the performance of a peripheral intravenous microdialysis device and online *in-vitro* diagnostic lactate biosensor system for continuous automated blood lactate monitoring. **METHODS:** Twenty volunteers (age 27 ± 8 years; stature 175 ± 10 cm; mass 76.5 ± 13.8 kg) completed one experimental visit. An 18-gauge catheter was inserted into an antecubital vein, and a microdialysis device (MicroEye® PME012, Probe Scientific, UK) inserted into the catheter. The MicroEye® was perfused at 1mL/hour with 0.9% sodium chloride containing anticoagulant (Fondaparinux). The outlet of the MicroEye® was connected to the inlet of a lactate flow cell (ContinuMon®, Probe Scientific, UK) for continuous lactate monitoring. A second catheter was introduced into a peripheral vein in the contralateral forearm for reference blood sampling. Venous blood was sampled at 10-minute intervals throughout 30 minutes of rest, and at the end of five 3-minute incremental exercise stages, beginning at 70 watts and increasing by 35 Watts per stage. Comfort for each arm was assessed using a 9-point scale ranging from unnoticeable (8) to painful (0). The relationship and agreement between reference and MicroEye® values assessed via least mean square and Bland-Altman analysis. **RESULTS:** Paired samples falling within the clinical range (0-4 mM; n = 152) gave an R^2 of 0.93 (y = 1.002), a mean bias of 0.027 mM, and an upper and lower limit of agreement of 0.54 and -0.49 mM respectively. Subjective comfort was not different between the MicroEye(R) (7 ± 1) or reference arm (7 ± 1) at any point in the trial. **CONCLUSION:** The MicroEye(R) microdialysis cathetar and ContinuMon(R) continuous lactate monitoring system exhibits good agreement when following exercise induced blood lactate changes in the clinical range.

Influence Of Muscle Action On Energy Expenditure: Concentric Vs. Eccentric Vs. Both

Ben M. Meister, Zackary J. Valenti, Colleen E. Lynch, Cody B. Revel, Alison C. Schwartz, Michael E. Quarantillo, Samantha R. Guarnera, William A. Fountain, Nicholas A. Carlini, Kerry E. Lynch, Nicole C. Lindner, Amar L. Naboulsi, Paola J. Paco, Scott A. Mazzetti. *Salisbury University, Salisbury, MD.*
(No relevant relationships reported)

PURPOSE: Previous studies have found the energy cost of eccentric exercise to be approximately 1/7 to 1/4 that of concentric exercise, but no study has directly compared concentric–and eccentric–only resistance exercise. Therefore, we compared energy expenditure between squats performed with concentric or eccentric muscle actions.
METHODS: 12 healthy men (20.9 ± 1.1yrs) with a BMI<26 performed three exercise protocols once weekly designed to compare energy expenditure between different muscle actions: concentric (CON), eccentric (ECC), and a trial incorporating both concentric and eccentric (BOTH). Subject's 1RM was determined using a plate-loaded squat machine. Each protocol was randomly assigned in a counterbalanced order and required subjects to perform 4 sets of 10 reps with 50% of 1RM. Repetition speed (2sec), ROM, and rest intervals were identical across protocols. Expired air was collected continuously before (15min), during (12min), and after (30min) each exercise protocol using a metabolic cart. Data were analyzed using a two-way repeated measures ANOVA, with Fisher's least significant difference (LSD) post hoc analyses wherever appropriate.
RESULTS: Rates of energy expenditure (kcal·min⁻¹) were significantly greater (p<0.05) during sets 1 through 4 of CON and BOTH compared to ECC (see Table). CON was also greater than BOTH for sets 2 and 4. After exercise, CON > ECC at +5 and +10min, and BOTH > ECC at +5min. Significant differences (p<0.05) in total energy expenditure (kcal) included CON (58.1 ± 6.27) > BOTH (50.7 ± 5.92) > ECC (40.9 ± 3.33).

CONCLUSION: When squats were performed with 2sec CON or ECC muscle actions and 50% of 1RM, the energy cost of ECC was 2/3 to 3/4 that of CON exercise, whereas previous studies have reported ECC was about 1/4 of CON. A possible explanation may be that slower muscle actions used in our study resulted in elevated energy cost of eccentric muscle actions due to increased time under tension.

	Set 1	Set 2	Set 3	Set 4	+5min	+10min
Energy Expenditure (kcal·min⁻¹)						
CON	4.3±0.44 #	4.5±0.45 #*	4.3±0.51 #	4.4±0.50 #*	2.6±0.59 #	2.0±0.32 #
ECC	3.3±0.30	3.0±0.27	3.0±0.33	2.9±0.33	2.0±0.39	1.7±0.30
BOTH	4.4±0.65 #	3.5±0.42 #	4.2±0.58 #	3.5±0.38 #	2.3±0.25 #	1.9±0.18

Values are MEANS±SD; # denotes p<0.05 vs corresponding ECC value; * denotes p<0.05 vs corresponding BOTH value; significance for this study was set at p<0.05.

The Effects Of Exercise To Bmp-4-mediated Browning On White Adipose Tissue In Obese Rats

Liang Chunyu, Yan Yi. *Beijing Sport University, Beijing, China.*
(No relevant relationships reported)

PURPOSE: Bone morphogenetic protein-4(BMP-4) play a key role in regulating adipocyte differentiation and browning. The aim of this study is to observe the effect of treadmill running on the protein expression of BMP-4 and UCP-1 which is a marker protein associated with thermogenesis to discuss the effect of exercise on adipogenesis and browning in adipose tissue roundly.
METHODS: Before the formal experiment, we established a rat model of obesity with 8-week high-fat diet. The 20 11-week obese rats were obtained, and randomly divided into sedentary high-fat-diet group(SHD) and exercise high-fat-diet group(EHD). Other 20 11-week chow-diet rats were randomly divided into sedentary chow-diet (SCD) and exercise chow-diet (ECD) groups. Rats in the ECD and EHD had 8 weeks training (60%-70% VO$_2$max, 50 minutes/day, 5 days/week). The white adipose of Inguinal subcutaneous tissue (SAT), Periepididymal white adipose tissue (PAT) were collected.
RESULTS:1) In SAT, obesity has a very little effect in promoting protein expression of BMP-4 and UCP-1. Exercise significantly increased the protein expression of BMP-4 and UCP-1 on obese rats , but had little effect on chow diet rats. 2) In PAT, obesity can decrease the expression of BMP-4 protein, but little effect on UCP-1.Exercise significantly increased the protein expression of BMP-4 and UCP-1 on chow diet rats, but had little effect on obese rats.(The data are shown in table)
CONCLUSIONS: The effect of high-fat diet on adipocyte differentiation and browning is different in different tissues in obese rats, and exercise can exacerbates this differences.

Expression of BMP-4 and UCP-1 protein in adipose tissue

Acute Exposure to a High-Fat High-Sugar Diet Alters Wheel Running Activity

Katherine A. Stiegel, Ayland C. Letsinger, Jorge Z. Granados, Cedric Cerda, J. Timothy Lightfoot, FACSM. *Texas A&M University, College Station, TX.* (Sponsor: J. Timothy Lightfoot, FACSM)
(No relevant relationships reported)

BACKGROUND: Literature shows that chronic exposure to a high-fat high-sugar (HFHS) Western diet decreases voluntary physical activity, mainly through decreased duration of activity. **PURPOSE:** To determine if acute exposures to standard chow and a HFHS diet affect voluntary activity levels in male mice. **METHODS:** Eight-week-old male C57BL/6J male mice (n=20) were singly housed and provided with running wheels. Wheel running activity was measured daily via mounted odometers. Distance (km) and duration (min) were used to calculate average speed (m/min). Mice were randomly assigned to two experimental groups that alternated between the HFHS diet (20% protein, 35% carbohydrate, 45% fat, with 20% fructose water) and a standard chow diet (24.3% protein, 40.2% CHO, 4.7% fat) in three 5-day cycles followed by two 8-day cycles. At study initiation, Group 1 began with the HFHS diet and Group 2 began with standard chow. At the end of each cycle period, both groups switched to the opposing diet. Data were analyzed using a repeated measures model

---

Abstracts were prepared by the authors and printed as submitted.

with distance, duration, and speed for each cycle as dependent variables and diet, group, and diet*group interaction as fixed effects. Alpha value was set a priori at 0.05 and post-hoc tests used Tukey's HSD. **RESULTS:** Acute exposure to the HFHS diet decreased speed (p=.0075), while distance (p=.7527) and duration (p=.1077) were not altered. No overall group effects on distance (p=.3670), duration (p=.3747), or speed (p=.5266) were observed; however, animals exposed to the chow diet first (Group 2) showed an increase in activity duration (p=.0040) when exposed to a HFHS diet in all cycles. **CONCLUSION**: Acute exposure to a HFHS diet only decreased speed, which is surprising given the literature on chronic HFHS exposure that has shown decreases in distance. The observed increase in activity duration in mice that had chow at the initiation of wheel-running exposure (Group 2) suggests that acute and chronic effects of a HFHS diet on physical activity level differ in mice.

The Effect Of Interval Training On Aerobic Capacity In Mice Growth Restricted In Early Life

Olivia S. Lord, William J. Clark, Ashley N. Triplett, David P. Ferguson. *Michigan State University, East Lansing, MI.*
(No relevant relationships reported)

Previous research has found that early life undernutrition increases the risk of cardiovascular disease later in life. It is hypothesized that exercise training could mitigate the cardiovascular impairments of early life undernutrition. PURPOSE: To evaluate the effects of early life undernutrition on changes in exercise capacity after 8 weeks of treadmill (TM) training in a mouse model. METHODS: Using a cross fostering model, pups were undernourished during gestation (GUN), lactation (PUN), or both (GUN+PUN) by feeding FVB mouse dams a low protein (8%) diet. The control (CON) group was fed an isocaloric diet (20% protein) during all windows of development. At PN21 (21 days post-natal), all mice were weaned and fed the control diet. Thus, all physiological effects of undernutrition were isolated to early life. To evaluate exercise capacity, maximal work on a TM was performed at PN39 (baseline), PN67 (midpoint), and PN95 (post). Starting at PN41, 28 mice were trained on the TM 5 days/week for 8 weeks with alternating 8 mins at 85% and 2 mins at 55% of their max workload for 1 hour. The sedentary group of 30 mice ran on the TM 3 days/week for 15 mins at 10m/min. Data were analyzed using a repeated measures ANOVA to detect change in exercise capacity over time and an ANOVA with Tukey post-hoc test (alpha level p<0.05) to detect differences in exercise capacity between groups. RESULTS: After 4 weeks of TM training, there was a significant difference in exercise capacity change over time between the TM trained (+5.0±3.9 J[FD1] oules (J)) and sedentary groups (+2.5±6.0J) (p=0.03). Differences in exercise capacity change over the first 4 weeks were trending toward significance between groups (GUN: 2.8±1.4J, PUN: 1.7±1.2J, PUN+GUN: 6.0±1.2J, CON: 4.6±1.4J,) (p=0.057). No significant changes were observed from weeks 4 to 8 between or within groups. CONCLUSION: Results indicate that 4 weeks of exercise training can improve exercise capacity in mice who were undernourished during gestation and gestation plus lactation, but not undernutrition during lactation only. PN1-21 is associated with cardiac growth and the nutrient restriction could potentially limit cardiac growth factors preventing stroke volume adaptations with training.

Effects Of High-fat Diet And Exercise On Total Plasma Macronutrient Contents By Fourier-transform Infrared Spectroscopy

Jarrett Walbolt, Raegan Chunn, David Gresch, Arish Bheraiya, Susanna Hamsley, Olatunde Olademehin, Sung Kim, Yunsuk Koh. *Baylor University, Waco, TX.*
(No relevant relationships reported)

High fat-low carbohydrate (HFLC) diets are increasingly considered by endurance athletes to enhance their performances and overall health. Total macronutrient contents in plasma may be affected by diets and exercise. **PURPOSE**: To examine the effects of HFLC diet and an acute bout of exercise on total plasma macronutrient contents in trained males. **METHODS**: Eight trained distance runners (age = 39.5±9.9 years and VO₂max = 47.9±7.6 mL/kg/min) that were on high-carbohydrate (HC) diets adopted the HFLC diet for 3 weeks, which consisted of 70% of overall caloric intake from fats and no more than 50g of carbohydrates. At the end of each diet trial, participants performed an indoor treadmill exercise for 50 minutes at varying race paces followed by an outdoor 5-km time trial. Overnight fasting blood samples were collected at pre- (baseline) and post-exercise (24-hours) to analyze changes in total plasma lipids, proteins, and carbohydrates using attenuated total reflectance Fourier-transform infrared spectroscopy (ATR FT-IR). The O-H stretch vibrational band of water was used to normalize the IR spectra and the protein content was quantified by measuring the amide I peak intensity at 1600 - 1700 cm⁻¹. To quantify the lipids and carbohydrates, the samples were lyophilized and measured by the intensities at 2800 - 3000 cm⁻¹ and 800 - 1200 cm⁻¹, respectively. **RESULTS:** The ATR FT-IR analysis showed that total plasma proteins remained unchanged (HC baseline = 135.20±4.20 and HFLC baseline = 135.24±3.91AU). However, the HC diet at baseline

showed a significant accumulation of lipids (30.06±7.75 AU, 95% CI = 6.93) and carbohydrates (42.92±11.62 AU, 95% CI = 10.39). Additionally, total lipids in the HC diet significantly decreased at 24-hours post-exercise (from 30.06±7.75 to 28.51±7.91 AU, p=0.016). **Conclusion:** A short-term high-fat diet does not significantly alter any macronutrient contents in plasma, whereas a high-carbohydrate diet increases an accumulation of lipids and carbohydrates. Elevated plasma lipids and carbohydrates with a high-carbohydrate diet may be due to decreased insulin sensitivity, which consequently led to increased plasma lipid contents. Notably, decreased total plasma lipid content following an acute bout of exercise suggests that lipids were the primary energy substrate.

Methodological Considerations to Evaluate the Effect of Physical Activity on Fluoride Metabolism in Children

Liane B. Azevedo[1], Fatemeh Vida Zohoori[1], Lilian Aparecida Ferreira[2], Larissa Grizzo[3], Melissa Thiemi Kato[4], Marilia Afonso Rabelo Buzalaf[5], Anne Maguire[6], Ruth A. Valentine[6], Sandra L. Amaral[2]. [1]*Teesside University, Middlesbrough, United Kingdom.* [2]*São Paulo State University, Sao Paulo, Brazil.* [3]*University of Sao Paulo, Sao Paulo, Brazil.* [4]*Faculty of Centro Oeste Paulista, Bauru, Brazil.* [5]*University of Sao Paulo, Bauru, Brazil.* [6]*Newcastle University, Newcastle, United Kingdom.*
(No relevant relationships reported)

Physical activity can influence absorption and excretion of fluoride (F). However, the evidence is still limited and often contradictory; studies in rats showed a significant reduction in plasma F concentration at light exercise intensity, while a study with healthy human adults had an increase in plasma concentration and a decline in renal clearance rate of F, with increasing exercise intensity. **PURPOSE**: To investigate recruitment and acceptance of an experimental protocol (phase I) and the development of methodological procedures (phase II). **METHODS**: Parents of children (5 to 8 years) were recruited from schools in Brazil. In phase I, parents were asked to complete socio-economic, physical activity (Netherlands Physical Activity Questionnaire) and feasibility questionnaire. The latter explored parents' willingness for their child to participate and reasons for refusing consent. In phase II, children participated in two test conditions: high intensity exercise and resting with blood lactate and F in urine and saliva samples collected before and after the exercise trial. **RESULTS**: Only 77 out of 350 parents approached agreed to participate. The majority (54.6%) of the families were from middle socio-economic class. Seventy percent of the children were considered predominately inactive according to an established cut-off point. Fifty-five percent of the parents who responded, would consent their child to participate in the study. The main reason for refusal of consent was collection of blood samples from children (62% and 69% said "no" for finger prick and vein blood collection respectively). In phase II, four children were recruited and one provided assent for blood collection. F concentration of parotid saliva from this participant was 0.01 μg/ml, both at rest and after exercise. Blood lactate concentration and mean F concentration increased from before (Pre) to after (Post) exercise (Lactate Pre: 4.3 mmol/l vs. Post: 14.4 mmol/l; Mean F concentration urine Pre: 0.58 μg/ml vs. Post: 0.63 μg/ml). **CONCLUSIONS**: Some of the questions related to recruitment rate and acceptability of measurements were answered in this study. However, participants' willingness to be randomized and their acceptance of and compliance with a high intensity exercise protocol still needs be explored in a randomized feasibility trial.

Relationships Among Fatigue Thresholds Derived From Neuromuscular, Metabolic, and Ventilatory Parameters

Rachel N. Tauber, Blake J. Moulton, Peter J. Chomentowski, Clayton L. Camic. *Northern Illinois University, Dekalb, IL.*
(No relevant relationships reported)

A number of fatigue thresholds have been developed to describe fatigue-induced changes in various physiological factors including muscle activation, blood lactate, and gas exchange. These fatigue thresholds, however, may correspond to different exercise intensities depending on the variable from which they were derived as well as their underlying mechanisms. **PURPOSE:** The purpose of the present study was to examine the relationships and compare power outputs among fatigue thresholds derived from neuromuscular, metabolic, and ventilatory parameters. **METHODS**: Fifteen college-aged males (mean age ± SD = 22.1 ± 1.7 years, 78.0 ± 9.4 kg, 176.5 ± 5.6 cm) volunteered to perform an incremental test to exhaustion on an electronically-braked cycle ergometer for determination of their physical working capacity at the fatigue threshold (PWC$_{FT}$), lactate threshold (LT), ventilatory threshold (VT), and gas exchange threshold (GET). The incremental test involved recording electromyographic (EMG) signals from the vastus lateralis as well as measurements of blood lactate from the fingertip and gas exchange using open circuit spirometry. **RESULTS**: The results of the one-way ANOVA with repeated measures and follow-up paired samples *t*-tests indicated that the LT (132 ± 14 W) occurred at a significantly ($P < 0.05$) lower power

output than the PWC_{FT} (153 ± 33 W), GET (155 ± 33 W), and VT (177 ± 27 W). In addition, the VT occurred at a higher output than the LT, PWC_{FT}, and GET, whereas there was no difference in power outputs between the PWC_{FT} and GET. Furthermore, there were no significant inter-correlations among any of the fatigue thresholds (r = -0.03 - 0.35), except between the GET and VT (r = 0.70). **CONCLUSIONS**: Based on the significant mean differences in power outputs and non-significant correlations, the findings of the present study indicated there were no relationships among indicators of fatigue identified through changes in muscle activation (PWC_{FT}), blood lactate (LT), and measurements of gas exchange (VT and GET). These findings suggested there is a dissociation among the exercise intensities associated with the PWC_{FT}, LT, VT, and GET, and thus, each originate from separate physiological mechanisms.

Hemodynamic and Body Fluid Response to Water Ingestion

John Wygand, FACSM, Robert M. Otto, FACSM, John Petrizzo, Melhaney Reichelt, Jessica Machaby, Abigail LeBlanc, Daniel Hagan, Lauren Yanni, Glen Reid. *Adelphi University, Garden City, NY.*

(No relevant relationships reported)

Despite a paucity of information regarding the hemodynamic changes associated with moderate fluid ingestion, the popular, unsubstantiated recommendation for most adults to ingest 8 x 8 ounce glasses of water daily (1888 mL) remains prevalent. **PURPOSE:** The purpose of this study was to determine the hemodynamic and body fluid changes associated with consuming water at temperatures of 4º C & 37º C and two volumes of 7 & 21 mL/kg. **METHODS:** 10 subjects (age 22.3 ± 1.3 yr, ht. 1.74 ± .15 m., body mass(bm), 75.1 ± 18.5 kg, 4♂) reported to the lab in a euhydrated state and refrained from ingestion of food and beverage (except water) for 10 hrs and no water 2 hours pre-trial. 30 minutes of rest preceded venipuncture for hematocrit (H), plasma specific gravity (PSG), and plasma density (PD) analyzed by digital refractometry. Hemodynamic values of heart rate (HR), stroke volume (SV) and cardiac output (Q) were obtained by a non-invasive impedance cardiography system. All measures were obtained pre-water ingestion (PRE) and at 20 minute intervals following water ingestion (T1, T2, & T3). Immediately following the PRE, subjects ingested C7, C21, H7 or H21 with the volume calculated from individual bm at a mean of 526 and 1577 mL for 7 and 21 trials, respectively. Subjects served as their own control in the randomized assignment of trials. **RESULTS:** Statistical analysis by ANOVA was applied to these data and revealed NSD (p>.05) among all trials. Mean values for all four trials are depicted in the following table:

	PRE	T1	T2	T3
H (%)	46.2 ± 4.4	47.2 ± 6.8	46.1 ± 6.5	46.9 ± 5.9
PSG (gm/cm³)	1.035 ± .02	1.031 ± .02	1.026 ± .01	1.026 ± .01
PD (gm/mL)	1.025 ± .01	1.024 ± .01	1.024 ± .01	1.025 ± .01
HR (b/min)	62 ± 7	60 ± 7	59 ± 7	58 ± 7
SV (mL/b)	90.3 ± 14.5	93.8 ± 18.2	95.9 ± 15.8	98.7 ± 17.3
Q (L/min)	5.60 ± .80	5.60 ± .83	5.62 ± .79	5.72 ± .72

CONCLUSION: The ingestion of water in volumes and temperatures mimicking current practices among many adults results in minimal expansion of blood volume or changes in hemodynamic function. Apparently, consuming considerable water without excessive loss of fluid from either environmental conditions or exercise induced temperature regulation, is safe with no adverse impact on non-exercising individuals.

Comparison Of Intramuscular Adipose Tissue Content Using Two-point Dixon Imaging With Two Segmentation Techniques Based On T1-weighted Imaging

Madoka Ogawa, Noriko Tanaka, Akito Yoshiko, Hiroshi Akima. *Nagoya University, Aichi, Japan.* (Sponsor: Katsumi Asano, FACSM)

(No relevant relationships reported)

The adipose tissue infiltrated within the muscle is known as intramuscular adipose tissue (IntraMAT) and increasing of IntraMAT have a potential risk of insulin resistance. T1-weighted (T1W) imaging is one of the basic pulse sequences to measure IntraMAT using a histogram-based thresholding technique based on signal intensity. The Otsu and the Midpoint methods based on T1W imaging have been used to measure IntraMAT in the literature. Now two-point Dixon is recognized as the gold standard sequence to determine adipose tissue content. However, it is unknown that relationship between adipose tissue content determined by Dixon imaging and that determined by T1W imaging. **PURPOSE:** The purpose of this study was to compare IntraMAT content determined by Dixon imaging with T1W imaging which was calculated by

two different thresholding techniques, i.e. Otsu and Midpoint methods. **METHODS:** Subjects were 13 older (72 ± 6 years) and 19 young (26 ± 5 years) men. Axial images of the mid-thigh were taken using two-point Dixon and T1W imaging. From these images, IntraMAT content of vastus lateralis (VL) and biceps femoris-long head (BF-L) was calculated. For the T1W images, we applied two different segmentation algorithms, known as the Otsu and Midpoint methods, to determine adipose tissue. Using fat and water images by Dixon technique, IntraMAT content of VL and BF-L was also calculated. **RESULTS:** IntraMAT content in VL determined by Dixon and Otsu was significantly higher than that of Midpoint (Dixon 12.2 ± 2.4%, Otsu 11.0 ± 4.4 and Midpoint 0.6 ± 0.8%, p<0.01). IntraMAT content in BF-L determined by Dixon and Otsu were significantly higher than Midpoint (Dixon: 12.7 ± 3.2%, Otsu: 21.4 ± 10.0% and Midpoint: 1.7 ± 2.9%, p<0.01). Furthermore, IntraMAT content in BF-L determined by Otsu was significantly higher than Dixon (Dixon: 12.7 ± 3.2% and Otsu: 21.4 ± 10.0%, p<0.01). There were significant correlations of IntraMAT content between Dixon and Otsu in both muscles (VL: r=0.686 and BF-L: r=0.790, p<0.05) and between Dixon and Midpoint in both muscles (VL: r=0.403 and BF: r=0.766, p<0.05). **CONCLUSION:** Although Otsu method overestimates IntraMAT content of BF-L, it could apply with caution depending on muscle. Midpoint method is likely to underestimate compared with any other techniques, therefore, we should extra care to use it.

Impact of Sitting on a Stability Ball on Metabolism and Vascular Resistance During Arm Ergometry.

Charles RC Marks, Jennifer Duggan, Emmanuel Jianis, Cecelia Goulette. *Oakland University, Rochester, MI.* (Sponsor: Jonathan K. Ehrman, FACSM)

(No relevant relationships reported)

Past studies demonstrated that sitting on a stability ball (SB) elevates submaximal VO_2 without affecting heart rate or blood pressure during arm ergometry when compared to sitting on a chair (C). However, no reports have been made to determine if nutrient metabolism or vascular resistance (VR) are also affected. **PURPOSE:** To determine if sitting on a SB affects fat and carbohydrate metabolism and vascular resistance during arm ergometry when compared to C. **METHODS:** Eighteen Female (22 +/- 3 yrs) and eleven male (23 +/- 3 yrs) apparently healthy participants underwent two stages of submaximal arm ergometry for two conditions (order randomized): sitting on a SB or sitting on a C. VO_2 and VCO_2 were recorded after the third minute of each stage and used to determine indicators of fat g/min (FAT) and carbohydrate g/min (CHO) use. Cardiac Output (Q) was assessed by CO_2 rebreathing and was measured immediately after the VO_2 and VCO_2 recordings. Blood Pressure (BP) was measured following the Q. BP was used for calculating mean arterial pressure (MAP) and then MAP and Q for calculating VR. Repeated Measures ANOVA was used to determine sitting mode effects (alpha = 0.05). **RESULTS:** There were no significant sitting mode effects for VR ($P = 0.334$) and CHO ($P = 0.120$). However, there was a significant sitting mode effect for FAT ($P = 0.017$). FAT was 24% to 36% higher on the SB (Stage 1: 0.114 +/- 0.112 g/min; Stage 2: 0.059 +/- 0.075 g/min) than on C (Stage 1: 0.087 +/- 0.102 g/min; Stage 2: 0.038 +/- 0.013 g/min). **CONCLUSION:** When compared to sitting on a C, exercising on a SB during arm ergometry can elevate an indicator of fat metabolism without affecting an indicator of carbohydrate metabolism or vascular resistance.

The Influence of Environmental Temperature on Metabolic Flexibility in Young Healthy Adults During Exercise

Alexus McCue, Dominique D. Gagnon. *Laurentian University, Sudbury, ON, Canada.*

(No relevant relationships reported)

Metabolic flexibility is the ability of an organism to match fuel oxidation to its availability. It tends to be compromised in individuals suffering from metabolic diseases, lipo- and glucotoxicity, and mitochondrial dysfunctions. Recent incremental maximal oxygen consumption exercise studies performed in cold environments have demonstrated an increase in lipid oxidation over a wide range of exercise intensities. Whether metabolic flexibility is compromised or altered by a drive in lipid utilization during exercise in the cold remains unclear.
PURPOSE
The aim of the present study was to investigate whether metabolic flexibility is altered during incremental maximal exercise to volitional fatigue in a cold environment.
METHODS
Ten healthy participants (22 ± 1 yrs, 68.1 ± 7.8 kg, 169.7 ± 4.9 cm, 21.1 ± 9.7 %BF) dressed in shorts and a t-shirt, performed four maximal incremental treadmill tests to volitional fatigue, in a fasted state. Tests were performed in a cold (0.89°C ± 1.8) (CO) or a thermoneutral (TN) environment (22.0°C ± 0.9), with and without a pre-exercise ingestion of a 75-g glucose solution. Paired t-tests were performed to compare the effects of temperature using the difference between glucose and non-glucose conditions. Differences in averaged respiratory exchange ratio (ΔRER) during the

entire exercise period, maximal fat oxidation (ΔMFO), and where MFO occurred along the exercise intensity spectrum (ΔFat$_{max}$) were analysed via whole-body indirect calorimetry.
RESULTS
No statistical differences in fat utilization during CO exercise when compared to TN as indicated by ΔRER (0.05 ± 0.02 *vs.* 0.05 ± 0.02; p = 0.584), ΔMFO (0.21 ± 0.18 *vs.* 0.16 ± 0.13 g•min^{-1}; p = 0.133) and ΔFat$_{max}$ (13.3 ± 19.0 vs. 0.6 ± 21.3 %VO$_{2peak}$; p = 0.266) in CO and TN, respectively.
CONCLUSION
A cold environment increases lipid contribution as metabolic fuel during exercise, and may be considered in training and health-intervention strategies. In the present study, an acute glucose ingestion causing a shift in carbohydrate utilization, was similar in both the cold and thermoneutral environment, indicating that exercising in a cold environment does not compromise metabolic flexibility. Future exercise studies should investigate the metabolic influences of high-fat diets and acute lipid overload in cold and warm environments.

Attenuated Fat Oxidation Rates in ME/CFS Patients

Jeff Cournoyer, Graham Salmun. *Nova Southeastern University, Miami, FL.*
(No relevant relationships reported)

Chronic Fatigue Syndrome (CFS) is a condition characterized in part by inexplicable severe fatigue, and post-exertional malaise (PEM), which is defined by crippling exhaustion coupled with flu-like symptoms resulting from physical and/or mental exertion. Fear of severe PEM in CFS patients often leads to extended inactivity periods and as a consequence, the disease state is characterized by a highly sedentary lifestyle with activity levels far below those typically observed in sedentary healthy controls (HC). Prior studies on CFS have observed impairments in aerobic capacity (VO$_2$ max) coupled with increased rates of perceived exertion during a GXT; however, no study to date has examined if these impairments in aerobic capacity are correlated with a reduced fat oxidative capacity at increasing exercise intensities. **PURPOSE** The purpose of our study is to identify changes in fat oxidation patterns during increasing exercise intensities as a result of the CFS disease state. **METHODS** Twenty male patients (39.6 ± 12.4 yrs) were divided into two groups: CFS (N=14) and HC (N=6). Participants were asked to perform a maximal exercise test on a cycle ergometer, with an initial resistance of 60 Watts and increasing by 30 Watts until volitional fatigue was reached or a peddling cadence of 55-65 RPM was no longer maintained. VO2 Max, time to exhaustion (tE), Maximal Fat Oxidation (MFO) and Total Fat Oxidation (TFO) were recorded for all participants and 2-tailed T-tests were used to determine significant differences between the two groups. **RESULTS** MFO (HC mean: 617 g/day, CFS mean: 339.5 g/day; p<0.05) and TFO (HC mean: 10 kcal, CFS mean: 2.8 kcal; p<0.05) were lower in CFS patients, but no significant difference was observed in tE (HC mean: 11.2 minutes, CFS mean: 8.1 minutes; p<0.05), VO2 Max (HC mean: 27.9 ml/kg/min, CFS mean: 26.3 ml/kg/min; p=0.66) or FatMAX (CFS: 41.2% of VO2 Max, HC: 48.9% of VO2 Max; p>0.05). **CONCLUSION** Patients diagnosed with CFS displayed significantly lower capacity for fat oxidation than HC, though their tE was not significantly less. This might indicate a propensity for CFS patients to spend more time in an anaerobic state.

High Doses Of Branched-chain Amino Acids Supplementation Associated To Sprint Interval Training Improves Metabolic Profile

Elias de França, Ana Paula Xavier, Erico Chagas Caperuto. *Universidade São Judas Tadeu, São Paulo, Brazil.*
(No relevant relationships reported)

High doses of BCAA supplementation have unclear effects on cardiovascular diseases (CVD) biomarkers and energy metabolism in humans, even more when its associated to sprint interval training (SIT).
PURPOSE: The aims of this study was to evaluate the effects of BCAA supplementation associated with SIT on energy metabolism and CVD biomarkers.
METHODS: 40 overweight and sedentary volunteers (height: 169 ± 8cm; age: 32 ± 7 y; weight: 74.5 ± 10.7 Kg) were randomly distributed into 4 groups: S-PLA= sedentary + placebo; S-BCAA= sedentary + BCAA; SIT-PLA= SIT + placebo and, SIT-BCAA= SIT + BCAA. Supplementation was 300 mg/kg^{-1}/dia^{-1} of BCAA (plus 200 mg/kg^{-1}/dia^{-1} of maltodextrin) or 500 mg/kg^{-1}/dia^{-1} of waxy maize (placebo), 3 times-a-day, for 8 weeks. During this period, SIT-PLA and SIT-BCAA groups did cycle ergometer training 3 days/wk (4-8 sets of 30-s "all-out" bouts, with 4.5 min. recovery between sets). Pre- and post-treatment CVD biomarkers variables were evaluated: VO$_{2peak}$, total cholesterol (TC) and their fractions (HDL and LDL), triglycerides, C-reactive protein (PCR), HbA1c, %BF, also respiratory exchange ratio (RER), blood glucose [Gl] and lactate [La] concentration, at rest and during exercise, as energy metabolism variables
RESULTS: Post-treatment VO$_{2peak}$ increased (p<0.05) significantly in the SIT-PLA (95% CI: 2 to 7.6 mL.kg^{-1}.min^{-1}, Cohen's *d*= 0.41) and SIT-BCAA (1 to 7.7, -0.50)

groups only, with no difference between them; There was no treatment effect (p> 0.05) in %BF, TC and PCR in any groups; However, in the SIT-BCAA group only, there was a decrease (p<0.05) in HbA1c (-5.03 to -0.88%, 0.85), LDL (-42.90 to -1.03 mg/dl, 0.51) and an increase in HDL (2.91 to 18.85 mg/dl, -1.24), while triglycerides decreased (p<0.01) in both S-BCAA (-185.96 to -7.95 mg/dl, 1.09) and SIT-BCAA (-119.68 to -28.74 mg/dl, 1.19) groups only; Treatment effect was observed on RER which decreased in SIT-BCAA group only (p<0.01, η= 0.218) and tend to decrease in SIT-PLA group only (p= 0.06, η= 0.069); [Gl] decreased in S-BCAA (p<0.01, η= 0.440), SIT-PLA (p<0.01, η= 0.287) and SIT-BCAA (p<0.001, η= 0.460) groups only, with no difference between them; [La] decreased in SIT-PLA group only (p= 0.02, η= 0.220).
CONCLUSIONS: BCAA supplementation associated with SIT promotes some synergistic changes on CVD biomarkers and energy metabolism.

L-glutamine and L-alanine Improve Energy Status and Skeletal Muscle Cytoprotection in Rats Submitted to Heavy Resistance Exercise

Julio -. Tirapegui, Raquel Raizel, Audrey Coqueiro, Andrea Bonvini, Thaís Hypólito, Amanda Garcia, Rafael Lara. *University of São Paulo, São Paulo, Brazil.*
(No relevant relationships reported)

Strenuous exercise results in muscle damage and low cellular energy levels, which activates the AMP-activated protein kinase (AMPK), a sensor of energy status, as well as induces the expression of forkhead box O1 (FOXO1), linked to delayed skeletal muscle regeneration. Glutamine and alanine are the most important gluconeogenic and cytoprotection-related amino acids, and have been demonstrated to attenuate exercise-induced muscle damage and inflammation. However, whether these amino acids have a role in regulating energy status and muscle damage during heavy resistance exercise (HRE) remain largely unknown. **PURPOSE:** To evaluate the effects of chronic oral supplementation with L-glutamine and L-alanine in their free form (GLN+ALA, ALA) or as the dipeptide L-alanyl-L-glutamine (DIP) on energy status, muscle damage and cytoprotection markers in skeletal muscle of rats submitted to heavy resistance exercise (HRE). **METHODS:** Forty adult male Wistar rats (n 8/ group) were submitted to 8-week HRE, which consisted of climbing a ladder with progressive loads (25 to 100% of body weight), and to supplementation delivered in a 4% solution in drinking water, in the last 21 days of HRE. Phosphorylation of AMPK and FOXO1, as well as the expression of apoptosis-inducing factor (AIF) and the 27 kDa heat shock protein (HSP27) were assayed in tibialis anterior muscle by western blotting. **RESULTS:** HRE promoted skeletal muscle damage by increasing AIF and HSP27 contents in muscle of CTRL (by 85%) and ALA (by 158%) groups (p<0.05 vs sedentary). Conversely, GLN+ALA and DIP attenuated these effects. Additionally, supplements containing L-glutamine decreased the exercise-induced phosphorylation of AMPK by 24% (p<0.05 vs. CTRL and ALA groups) and of FOXO1 by 53% in muscle of rats treated with GLN+ALA and DIP (p<0.05 vs. SED, CTRL and ALA groups). **CONCLUSION:** Chronic oral supplementation with L-glutamine (given along with free L-alanine or as dipeptide) improved muscle energy status by decreasing AMPK phosphorylation and promoted muscle protection by decreasing FOXO1 phosphorylation and HSP27 and AIF contents in response to HRE.

3323   Board #192   June 2 9:30 AM - 11:00 AM

Effects Of A Liquid Breakfast With Varying Doses Of Whey And Soy On Appetite, Energy Intake And Hormone Response

Svetlana Nepocatych, Caroline E. Melson, Takudzwa A. Madzima. *Elon University, Elon, NC.* (Sponsor: Eric Hall, FACSM)
(No relevant relationships reported)

PURPOSE: The study examined the effects of a liquid breakfast meal containing varying doses of whey (WP) and soy protein (SP) on appetite, subsequent energy intake, and hormone response.
METHODS: Seventeen participants (age: 27 ± 7 y, body fat: 21.5 ± 6.9%, basal metabolic rate: 1741 ± 391 kcals/day) in randomized order consumed one of five isoenergetic liquid breakfast meals (~ 500kcals) including control (CHO), low WP (LWP; 21.5 g), high WP (HWP; 43 g), low SP (LSP; 25 g) and high SP (HSP; 50 g) followed by an *ad libitum* lunch 3 hours later. Appetite profile was measured before, immediately after and hourly during the 3 hour postprandial period. Plasma concentrations of leptin and insulin were measured before, at 30 and 180 minutes after the meal and were analyzed via ELISA. A 5 x 3 (meal x time) repeated measures ANOVA were used to analyze data. Significance was accepted at $p < 0.05$.
RESULTS: Energy intake at lunch per kilogram of body weight was significantly higher after CHO (11 ± 3.6 kcal/kg) compared to LWP (9.5 ± 2.9 kcal/kg), HWP (9.1 ± 3.0 kcal/kg), and HSP (9.1 ± 3.0 kcal/kg) but not compared to LSP (10.2 ± 2.7 kcal/kg). Participants hunger, desire to eat, and estimated amount of food to be consumed

were higher, whereas, satiety and fullness were lower after CHO ($p < 0.05$) compared to LWP, HWP and HSP but not compared to LSP. There were no significant differences ($p > 0.05$) observed in postprandial leptin or insulin responses between meals, however, a significant change over time was observed for insulin ($p = 0.02$) but not leptin ($p > 0.05$). Insulin increased by 293 ± 89 ng/ml at 30 min and decreased by -291 ± 92 ng/ml at 180 min post meal, whereas, leptin decreased by -37 ± 29 ng/ml and -10 ± 5 ng/ml at 30 and 180 min, respectively.
CONCLUSIONS: Liquid breakfast meals with higher doses of whey and soy protein reduced subsequent energy intake at lunch and were rated as more satiating compared to an isoenergetic CHO meal. In addition, postprandial levels of leptin and insulin did not differ between meals suggesting that acute changes in energy intake and satiety perception may not be influenced by circulating leptin levels.

Dietary Amino Acid Availability and Anabolic Signaling Molecule Phosphorylation is Blunted in Maintenance Hemodialysis Patients

Nicholas A. Burd, Stephan van Vliet, Sarah K. Skinner, Joseph W. Beals, Hsin-Yu Fang, Alexander V. Ulanov, Scott A. Paluska, FACSM, Kenneth R. Wilund. *University of Illinois at Urbana-Champaign, Urbana, IL.* (Sponsor: Scott A. Paluska, FACSM)
(No relevant relationships reported)

Skeletal muscle mass loss is a common feature in patients with renal failure receiving maintenance hemodialysis (MHD) therapy. Dietary protein (amino acids) is one of the main anabolic stimuli to skeletal muscle tissue in humans, and impairments to anabolic stimuli over time may lead to muscle mass loss. However, there are major gaps in our knowledge of how muscle mass is regulated by protein intake in MHD patients. **PURPOSE:** To compare dietary protein digestion and absorption kinetics and phosphorylation of anabolic signaling proteins after mixed meal ingestion in MHD patients and age- and BMI-matched controls. **METHODS:** 8 MHD patients (age: 56±5 y; BMI: 32±2 kg/m²) and 8 controls (age: 50±2 y; BMI: 31±1 kg/m²) received primed continuous infusions of L-[1-¹³C]leucine and ingested a mixed meal (546 kcal, 20 g protein, 59 g carbohydrate, 26 g fat) with protein provided as intrinsically L-[5,5,5-²H₃] leucine labeled eggs. Breath, blood, and muscle biopsies were collected to determine amino acid concentrations, leucine enrichments, and phosphorylation of mTORC1 on Ser2448 during a 5 postprandial period. **RESULTS:** Postprandial release of dietary leucine into circulation over 5 h was reduced in MHD patients (41±5%) vs. controls (61±4%; P=0.03). The feeding-mediated increase in mTORC1 phosphorylation was blunted in MHD patients (0.6-fold above basal) vs. controls (1.1-fold above basal; P=0.006) at 5 h of the postprandial period. **CONCLUSION:** Our data demonstrated impaired kinetics of digestion/absorption of dietary proteins and reduced postprandial plasma amino acid availability in circulation after mixed meal ingestion in MHD patients when compared to age- and BMI-matched controls. This diminished dietary amino acid availability may have partly contributed to the blunted anabolic signaling mechanisms in MHD patients.

G-44　　Free Communication/Poster - **Behavioral Aspects and Correlates of Concussions**

Concussion History Moderates Relationships Between Neural and Clinical Outcomes in Special Operations Forces Personnel

Cassie B. Ford[1], Michael J. Cools[1], Stephen M. DeLellis[2], Shawn F. Kane, FACSM[2], Robert H. Lutz[2], James H. Lynch, FACSM[2], Jason P. Mihalik[1]. *[1]The University of North Carolina at Chapel Hill, Chapel Hill, NC. [2]United States Army Special Operations Command, Fort Bragg, NC.*
Reported Relationships: C.B. Ford: *Contracted Research - Including Principle Investigator; UNC received funding from the United States Army Special Operations Command to conduct this work.*

Computerized neurocognitive tests such as Immediate Postconcussion Assessment and Cognitive Test (ImPACT) evaluate athletes at baseline and post injury in clinical and research settings. Visual and sensory performance (VSP) assessments evaluate and improve performance in both healthy and post-injury populations. These assessments are differentially sensitive to concussion history. The relationship among injury history, neurocognitive testing, VSP assessments and structural neuroimaging within the Special Operations Forces (SOF) population is unknown.

PURPOSE: To test whether cortical thickness (CT) mediates, and concussion history moderates, relationships among cognitive and visual-sensory tests. **METHODS**: SOF personnel completed the following: 3T high-resolution MRI, ImPACT, and VSP tests (Nike SPARQ or Senaptec Sensory Station). The SOF personnel were categorized by self-reported concussion history (none, 1+). We used FreeSurfer to reconstruct and segment the cerebral cortex. After examining bivariate correlations between all variables, path analyses tested whether CT mediated select relationships between ImPACT composites and VSP outcomes, with concussion history as a moderator. **RESULTS**: 155 SOF personnel (149 males; 54 self-reported concussion history) were imaged and completed ImPACT; 147 also completed VSP tests (127 Nike SPARQ; 20 Senaptec) during healthy baseline testing. There was a significant total effect of ImPACT Verbal Memory and CT (for regions associated with motor function and semantic responses) on Perception Span for those with a concussion history. Conversely, we found significant effects of ImPACT Motor Speed and CT on Go/No-Go, but only for those without concussion history. Although we found significant relationships between variables, there was no evidence that the effect of ImPACT composites on VSP outcomes was due to differences in CT. **CONCLUSIONS**: Concussion history differentially moderated the relationship among clinical outcome variables and neural structure, but neural structure did not mediate relationships between clinical outcomes. Understanding these relationships may help us better understand the effects of concussion and direct research towards tracking specific outcomes of clinical importance.

3326　　　Board #195　　　　　　June 2 9:30 AM - 11:00 AM
Concussion History Predicts Reduced Cortical Thickness in Special Operations Forces Personnel

Jason P. Mihalik[1], Cassie B. Ford[1], Michael J. Cools[1], Stephen M. DeLellis[2], Shawn F. Kane, FACSM[2], Robert H. Lutz[2], James H. Lynch, FACSM[2]. *[1]The University of North Carolina at Chapel Hill, Chapel Hill, NC. [2]United States Army Special Operations Command, Fort Bragg, NC.*
Reported Relationships: J.P. Mihalik: *Contracted Research - Including Principle Investigator; UNC received funding from the United States Army Special Operations Command to conduct this work.*

Special Operations Forces (SOF) personnel are at high risk for repetitive blast and head impact exposure. Non-invasive neuroimaging techniques, such as magnetic resonance imaging (MRI), have identified concussion-related structural differences even when observable behavioral and cognitive deficits are absent. The relationship between injury history, neuroimaging, and standard clinical tests has not previously been defined in the SOF population.
PURPOSE: To compare cortical morphology, symptom scores, and neurocognition in SOF personnel with and without concussion history. **METHODS**: SOF personnel completed an assessment battery including 3T high-resolution MRI and the Immediate Postconcussion Assessment and Cognitive Test (ImPACT). We examined symptom reporting and the ImPACT composite scores for verbal and visual memory, visual-motor processing speed, reaction time, and impulse control. The SOF personnel were categorized by self-reported concussion history (no history vs. 1+ concussions). We used FreeSurfer (v6) to reconstruct and segment the cerebral cortex. Cortical thickness was regressed on concussion history controlling for estimated total intracranial volume. The symptom reporting and ImPACT composite scores were regressed on concussion history. **RESULTS**: We imaged 166 SOF personnel (160 males; 65 self-reported concussion history) using MRI. Of these, 155 completed the ImPACT during a healthy baseline testing session. Two brain regions had reduced cortical thickness associated with concussion history, controlling for the total intracranial volume: left pericalcarine (t_{164}=2.00, p=0.04); and left parahippocampal (t_{164}=2.81, p=0.006). One region had larger cortical thickness in those with a concussion history: right transverse temporal (t_{164}=2.35, p=0.02). Concussion history did not predict symptom or ImPACT composite score differences (p>0.05). **CONCLUSIONS**: Concussion history predicted cortical thickness in brain regions associated with vision and memory, which are cognitive functions affected following concussive injury. The ImPACT composites were not sensitive to concussion history.

3327　　　Board #196　　　　　　June 2 9:30 AM - 11:00 AM
Predicting Concussion Incidence from Baseline Data in High School and Collegiate Football Athletes

Anna Klotz, Jana Ranson, Brain D. Stemper, Alok S. Shah, Michael A. McCrea, Lindsay D. Nelson. *Medical College of Wisconsin, Milwaukee, WI.*
(No relevant relationships reported)

PURPOSE: Sport-related concussions (SRCs) occur at an estimated rate of 300,000 per year with the highest number occurring in high school and collegiate football. It has been found that unsafe playing styles cause about 25% of football SRCs, making behavior—and the motives, attitudes, and personality traits that drive it—a credible

SRC risk factor that is largely overlooked. **METHODS:** The current study examined associations between self-report personality measures, head impact telemetry (HITS) data, and SRC incidence in a sample of high school and collegiate football players. Data were retrieved from Project Head-to-Head II, a large (*N=1,154*), prospective SRC study conducted between the 2015-2017 football seasons. Participants were categorized as either "concussed" (those who completed baseline testing and were concussed during the evaluation period) or "nonconcussed" (athletes from the same teams who did not get concussed). Cumulative risk metric (CRM) is a cumulative head impact severity estimate from the HITS data and was used to operationalize playing style. **RESULTS:** Results from binominal logistic regression showed that concussion group membership was significantly ($p \leq .05$) predicted by physically expressed anger, aggression, meanness, negative affect/emotionality psychoticism, detachment, and alienation, which corroborates related literature suggesting that such personality traits could lead to potentially hazardous playing styles. Nonconcussion group membership was significantly predicted by older age, more years of playing experience, communal positive emotionality, social closeness, and resilience. This suggests that maturity, playing experience, and having a pro-social personality may promote safer playing styles which could curtail the risk of concussion in football athletes. There was a great deal of uniformity among the personality traits that predicted concussion risk and the traits that predicted playing style (CRM). **CONCLUSIONS:** These findings highlight the potential role of personality in concussion risk and should be considered by coaches and athletic trainers to help develop prevention and intervention strategies that encourage on-field safety and reduce the risk of SRC.

Collegiate Football Player Parents' Perceptions of Concussion Risk

Samuel J. Haag, Angela H. Nippert, Katie J. Fischer, Lana L. Huberty. *Concordia University, St. Paul, St. Paul, MN.*
(No relevant relationships reported)

Concussion is one of the most common sports-related injuries in the United States and is especially prevalent in youth sports such as football, ice hockey, and soccer. While all stakeholders are concerned about head trauma in youth sport, parents have an especially strong influence on their children's participation in organized sports. However, few studies have analyzed how parents' knowledge of concussion in sport may affect their decisions regarding youth sport participation. **PURPOSE**: To explore parental perceptions regarding concussion risk in football and how these perceptions influence subsequent advice offered to other parents contemplating their children's participation in football. **METHODS**: A mixed-methods approach was employed using an online questionnaire distributed to 100 parents of current NCAA Division II football players at a small Midwestern university. The questionnaire included items related to their son's football participation and concussion history as well as their own awareness and perception of concussion risk. Several items included open-ended follow-up questions to allow for qualitative responses, which were coded through inductive analysis and grouped into thematic categories. **RESULTS**: Thirty-four parents of collegiate football players completed the questionnaire (34% response rate). Thirteen (38%) respondents believed their son had experienced a concussion and nine (26%) reported their son had been diagnosed with at least one concussion while playing football. Fourteen (41%) reported the benefits of football participation outweighed the risks and 29 (85%) would still have allowed their son to play football. Only four (12%) parents reported they would discourage other parents from allowing their children to participate in football. Overall, qualitative analysis showed parents perceived the benefits of football participation outweighed the risks and would advise other parents to conduct their own risk-benefit analysis during the decision making process. **CONCLUSIONS**:
Parents of collegiate football players believe the benefits of football participation outweigh the risks and generally would not discourage other parents from allowing their children to participate in football.

Adolescent and Collegiate Knowledge and Behavior Regarding Concussion

Brent Harper, Adrian Aron, Alex Siyufy. *Radford University, Roanoke, VA.* (Sponsor: A. Lynn Millar, FACSM)
(No relevant relationships reported)

PURPOSE: To compare adolescent concussion knowledge and behaviors regarding concussion to that of collegiate students using a modified Rosenbaum Concussion Knowledge and Attitudes Survey (RoCKAS) questionnaire.
METHODS: Two groups (n=222) completed the questionnaire. Group 1 (HSS) included female and male 9th and 10th grade high school students (n=190) with a mean age of 15.1 ± 0.8 years (64.7% female; 35.3% male) and group 2 (CS) included female and male collegiate students (n=32) with a mean age of 19.1 ± 1.1 years (78.1% female; 21.9% male). Of HSS, 59.4% reported belonging to a competitive sports team compared to 87.5% of CS (p=0.007). A sampling of questions from the RoCKAS

questionnaire was used to assess groups for: (1) general concussion knowledge and (2) the demonstration of safe behaviors in situational decision making ("safe" or "unsafe").
RESULTS:
Sample survey questions evaluated if the participants were actually reading and answering the questions thoughtfully. Scores were high in both groups with no statistically significant difference (HHS 88.5%; CS 93%; p=0.13). General concussion knowledge was correctly answered by 83.8% of the HSS compared to 93% of the CS (p=0.007). HSS not participating in athletics were less knowledgeable than those participating in sports (20.1% compared to 13.5%, p=0.01). HSS males not participating in sports answered incorrectly 23.4% of the time compared with HSS males in sports (12.2%, p=0.03). No statistical significance comparing HSS females in relation to sports participation. Responses to the four situational questions analyzed identified that HSS answered unsafely on the behavior questions in a higher proportion compared to CS (87.1 % vs. 17.1%, p=0.0001). In fact, actual age of the participants negatively correlated with the behavior answers (r=-0.4, p=0.0001). Although older college students have safer attitudes, there was a significant difference between females and males (89.2% compared to 64.3%, p=0.005).
CONCLUSIONS: HSS and CS are knowledgeable about concussion. Age is positively associated with increased knowledge. HSS participating on sporting teams are more knowledgeable, especially males. HS students make more unsafe situational decisions compared to their collegiate counterparts and female CS demonstrate the safest behavior.

Sedentary Behavior Predicts Headache Pain Following Mild Traumatic Brain Injury: Mediating Role Of Pain Catastrophizing.

Christopher Carey[1], Kelly M. Naugle[1], Jonathan Saxe[2], Fletcher A. White[3]. *[1]IUPUI, Indianapolis, IN. [2]St. Vincent Health, Indianapolis, IN. [3]Indiana University School of Medicine, Indianapolis, IN.*
(No relevant relationships reported)

The acute management of mild traumatic brain injury (mTBI), particularly in athletes, typically includes a period of physical rest during symptom resolution. However, evidence for the use of rest versus physical activity to aid in mTBI recovery is mixed and may depend on symptom type and severity. Post-traumatic headaches (PTH) are one of the most common and long-lasting symptoms of mTBI. While physical activity is often used in the non-pharmacological management of primary headache disorders, the relationship between PTH's and physical activity behavior in the first month post-injury remains poorly understood. **PURPOSE**: To determine if self-reported physical activity behavior predicts headache pain in mTBI patients within 1 month of head injury, and whether psychological factors mediate this relationship. **METHODS**: Twenty-seven mTBI patients recruited from Emergency Departments completed study sessions at 1-2 weeks and 1-month post head injury. The McGill Pain Questionnaire (MPQ) provided a quantitative evaluation of the patient's headache pain experience. The International Physical Activity Questionnaire - short form assessed the amount of time in the past week participants spent on vigorous and moderate intensity activity, walking, and sitting. Participants also completed the Pain Catastrophizing Scale, which assesses negative mental responses to anticipated or actual pain. Simple and multiple linear regressions were used to test whether physical activity behavior and pain catastrophizing predicted headache pain at 1 month post injury, and whether pain catastrophizing mediated this relationship. **RESULTS**: Separate simple regression analyses indicated the following: 1) time sitting at 2 weeks post-injury predicted pain on the MPQ at 1 month ($B=.41$, $p=.035$), 2) time sitting at 2 weeks predicted pain catastrophizing at 1 month ($B=.38$, $p=.049$), 3) pain catastrophizing predicted pain on the MPQ at 1 month ($B=.53$, $p=.003$). When pain catastrophizing and time sitting were both entered as predictors into the same regression model, pain catastrophizing was the only significant predictor of pain on the MPQ. **CONCLUSIONS**: Results suggest that increased sitting in the acute stage of mTBI predicted greater headache pain in the subacute stage of injury, and this relationship was mediated by pain catastrophizing.

Factors Associated with Intention to Disclose Concussive Symptoms among Service Academy Cadets: The BANK Study

Johna K. Register-Mihalik[1], Kenneth L. Cameron[2], Laura A. Linnan[1], Melissa C. Kay[1], Megan N. Houston[2], Karen Y. Peck[2], Heidi J. Hennink-Kaminski[1], Steven J. Svoboda[2], Paula Gildner[1], Zachary Y. Kerr[1], Kevin M. Guskiewicz, FACSM[1], Stephen W. Marshall[1]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC. [2]Keller Army Hospital, West Point, NY.*
(No relevant relationships reported)

Intention to disclose concussive symptoms is a significant factor often associated with actual concussion disclosure behaviors. Understanding ItD is key to developing

culturally relevant concussion-related interventions in high risk populations. **PURPOSE**: The purpose of this study was to examine factors influencing intention to disclose (ItD) concussion symptoms among first-year service academy cadets. **METHODS**: First-year service academy cadets at the United States Military Academy completed a validated cross-sectional survey based on the Theory of Planned Behavior, including: demographics, medical history, concussion-related knowledge (scale=0-39), attitudes (scale=6-42), subjective norms (scale=7-49), perceived control (scale=1-7), and ItD (scale=1-7). All scales had a Cronbach's alpha >0.75. Multiple linear regression predicted mean differences (MD) in ItD. Independent variables included: gender (female vs. male), race (non-Caucasian vs. Caucasian), ethnicity (non-Hispanic vs. Hispanic), previous concussion history (no vs. yes), previous concussion education (no vs. yes), socioeconomic proxy (parent without college education vs. with), concussion-related knowledge, attitudes, perceived social pressures, and perceived control over disclosure. Alpha level was set to 0.05 *a priori*. **RESULTS**: A total of 972 first-year cadets (201 Females; 281 Division I student-athletes) completed the survey (85% response rate). Average ItD was 5.9 ± 1.2 (IQR: 6.0, 7.0). In the multivariable model, stronger ItD was associated with: being non-Hispanic (MD=0.22; p=0.042); no previous concussion education (MD=0.20 p=0.005); more favorable attitudes (MD=0.19; p<0.001) and perceived social pressures (MD=0.55; p<0.001), and more perceived control over concussion disclosure (MD=0.17; p<0.001). **CONCLUSIONS**: Our data suggest perceived social pressures strongly influence ItD. Clinicians and health educators should consider culturally and organizationally appropriate intervention strategies among service academy cadets and their key social referents including classmates, cadre, and commanding officers. In context with other factors, ethnicity and concussion education may also influence ItD.

Innovative Curricula Technology in the Exercise Science Classroom: Perceptions of Faculty and Students

Katherine E. Clark[1], Judith A. Juvancic-Heltzel[2], Laura A. Richardson[2]. *[1]University of Mount Union, Alliance, OH. [2]University of Akron, Akron, OH.*
(No relevant relationships reported)

BACKGROUND: Selecting appropriate pedagogies for meaningful engagement of today's college students can be challenging. Adequate preparation to meet the advances and challenges in our rapidly evolving profession requires mutual collaboration and open mindedness by both faculty and students alike. **PURPOSE:** The purpose of this study was to examine perceptions of faculty and students on the use of technology-based pedagogies in Exercise Science curricula. **METHODS:** A survey exploring perceptions of the integration and utilization of technology-based tools in the classroom was administered to participants (N = 51). Survey data was also collected regarding the types of technologies integrated into their respective classrooms. **RESULTS:** Respondent demographics included 43% faculty (N = 22) and 57% students (N = 29). Results revealed 72.5% of respondents prefer enrolling in courses which utilize technology; 72.5% believe technology helps with retention of information; 43% find it frustrating to learn new technologies; and 35% find technology to be a distraction from the intended content. Results also revealed 82% of respondents have used a recorded lecture technology; 41% have used a synchronous web-based lecture tool; and 23.5% have used an in-class app. **CONCLUSIONS:** As the student profile continually changes with our rapidly evolving technological society, it is paramount that educators keep abreast and adapt curricula by implementing innovative pedagogies. Understanding students' perceptions of classroom tools provides tangible evidence that educators must not remain stagnant with teaching styles. Additionally, understanding perceptions of faculty is equally imperative as many faculty still view modified teaching styles and the incorporation of technology as a barrier to the learning experience. Future investigations should further examine the benefits and barriers of technology as a potential tool to enhance learning experiences in a higher education setting.

The Automated Wrist Blood Pressure Cuff as Teaching Tool

Marvin O. Boluyt, Carly Jones, Shannon Porterfield, Brad Spencer, Ann Brennan. *Washtenaw Community College, Ann Arbor, MI.*
(No relevant relationships reported)

PURPOSE: The teaching and learning potential of the wrist blood pressure cuff were explored. The hypothesis that physics (acceleration due to gravity) would explain the variance in blood pressure readings when the wrist was placed in different positions was tested.
METHODS: Subjects (n=27) were recruited from the student, staff, and faculty populations at Washtenaw Community College. In a seated position, systolic and diastolic blood pressures (BP) were obtained with a wrist cuff (Omron BP629) while the wrist was held in three different positions: above the heart (ear level) at the heart (chest level) and below the heart (thigh level). The differences in BP from chest level were plotted against the distance (cm) above or below the heart for each individual and compared to the theoretical slope calculated for the acceleration due to gravity.
RESULTS: While it was clear that gravity was the predominant factor involved in the changes in BP, the slope of the observed line was consistently less steep than that predicted. To explore potential physiological influences on the changes in blood pressure, heart rate (HR) and oxygen consumption (VO2) were measured in separate sets of experiments on 5 subjects each. Both HR and VO2 were significantly elevated when one or both arms were elevated (p < 0.05).
CONCLUSIONS: It was concluded that gravitational acceleration explains most, but not all of the variance in BP readings when the wrist is above or below the heart, and that physiological adjustments make a small but significant impact. he wrist BP cuff may provide opportunities for teachers and learners to experimentally explore physical and physiological factors that influence BP readings.

Effects of Situated Learning with Cooperative Learning Strategies for Older Adults on Functional Fitness

Chin-Yun Huang[1], Hui-Chuan Wei[2], Lan-Yi Chang[3], Li Lan Cheng[2]. *[1]Nanhua University, Chia-Yi, Taiwan. [2]National Chung Cheng University, Chia-Yi, Taiwan. [3]Transworld University, Yun-Lin, Taiwan.*
(No relevant relationships reported)

Situated learning emphasizes that learning is an important social situation that occurs within everyday functional fitness and social interaction. Such learning interaction originates from social relations, cultural history, specific commodities, real life situations, and physical activity learning environment. Although cooperative learning strategies were found to improve positive effects of interactive learning, there is a lack of research on the impacts of their use in situated cognition teaching design on fitness and cognitive function improvement in older adults. **PURPOSE:** To examine the effects of situated learning and cooperative learning strategies for older adults on functional fitness. **METHODS:** A 2x3 factorial design for experimental study. 120 older adults aged > 65 years from purposive sampling classified as high and high, high and low, and low and low were randomly assigned to ability treatment. Participants were classified as high-or low-ability according to performance on the pretest of pre-existing functional fitness. For the purpose of creating heterogeneous group of older adults for situated learning with cooperative strategies, high and low ability participants were combined into the group. The instructional module utilized a macro context design. After participants completed 18 weeks of functional fitness program, a post-test was delivered. **Results:** On instructional factor, older adults working situated learning group with cooperative learning significantly outscored those older adults on traditional learning environment. On ability factor, older adults working group with high and high, high and low pair significantly outscored those older adults on low and low pair. However, the group with high and high comparing to high and low pair was not significantly different condition. On Interaction, one of crucial findings to emerge from the study was older adults in the low ability /situated learning with cooperative group outscored those older adults in the low ability /traditional learning group. **Conclusions:** The structuring situations cooperatively may result in older adults processing functional fitness more effective learning than traditional instructional model.

Effects Of 8-week Physical Education Courses On Body Image, Anxiety, And Exercise Self-efficacy

Erica J. Roelofs, Sarah R. Du Bose. *Meredith College, Raleigh, NC.*

(No relevant relationships reported)

Exercise has been identified as a potential tool to mediate anxiety and improve self-efficacy and body image, however, the effectiveness of college physical education (PE) courses on psychological health needs further evaluation. **PURPOSE**: To examine the effects of 8-week PE courses on body image, anxiety, and exercise self-efficacy. **METHODS**: Seventy-five females (mean ± SD; Age: 20.8 ± 3.6 y; Height: 164.7 ± 7.0 cm; Weight: 68.5 ± 16.3 kg; Body fat percentage [BF%]: 27.3 ± 8.7 %) enrolled in college PE courses of Kickboxing (n=14), Beginning Jogging (n=8), Intermediate Jogging (n=22), Strength Training (n=14), and Conditioning (n=15) volunteered to participate in this study. Each course met 3 times a week for 50 minutes each class period during the 8-week long course. At the start and completion of each course, participants completed the Body Shape Questionnaire, Exercise Self-Efficacy (ESE), and Social Physique Scale, and height, weight, and BF%, measured by bioelectrical impedance analysis, were recorded.
RESULTS: There were no significant differences pre- to post-testing in weight or activity levels outside of PE in any of the 5 courses (p>0.05). BF% significantly decreased pre- to post-testing in Intermediate Jogging (p=0.03), but not in the other courses. Social physique anxiety decreased in Beginning Jogging (p=0.024) and Strength Training (p=0.05), but not in the other courses. All courses had a significant improvement in body image (p<0.05) and ESE (p<0.05). BF% had a significant negative correlation with body image (R= -0.53, p<0.05) and ESE (R= -0.24, p=0.02), and a positive correlation with anxiety (R=0.53, p<0.05). Individual heath rating had a significant positive correlation with body image (R=0.47, p<0.05) and ESE (R=0.44, p<0.05), and a negative correlation with BF% (R= -0.26, p<0.05) and anxiety (R= -0.42, p<0.05). ESE had a significant positive correlation with body image (R=0.40, p=0.003) and anxiety (R=0.32, p=0.033).
CONCLUSIONS: Lower BF% was associated with better body image, exercise self-efficacy, and lower anxiety. However, these results indicate regular exercise through 8-week PE college courses may aid in improving body image and exercise self-efficacy and decreasing anxiety even if there are no changes in weight or body fat percentage.

The Metabolic and Androgen Profiles of Exercising Women With Menstrual Disturbances

Kristen J. Koltun, Nancy I. Williams, FACSM, Mary Jane De Souza, FACSM. *Pennsylvania State University, University Park, PA.* (Sponsor: Mary Jane De Souza, FACSM)

(No relevant relationships reported)

Exercise associated menstrual disturbances (EAMD) are often attributed to hypothalamic inhibition of the reproductive axis secondary to energy deficiency. However, some exercising women with menstrual disturbances do not present with the traditional metabolic profile of suppressed resting energy expenditure (REE), decreased concentrations of total triiodothyronine (TT$_3$) and leptin, and elevated ghrelin concentration typical of energy deficiency. Hyperandrogenism may be an alternative or coexisting mechanism underlying menstrual dysfunction in a subset of exercising women. **Purpose:** To determine if there are differences between the metabolic profiles of exercising women with menstrual disturbances with and without hyperandrogenism (EAMD-HA, n=30; EAMD-NA, n=67). **Methods:** Fasting blood samples were collected to assess TT$_3$, leptin, ghrelin, sex hormone binding globulin (SHBG), and total testosterone (T) concentrations. Metabolic status was determined by TT$_3$, leptin, ghrelin, BMI, percent body fat (%BF, DXA-derived), and measured REE compared to Harris-Benedict predicted REE (mREE/pREE). Androgen status was determined by SHBG, total T, and calculated free T; hyperandrogenism was defined as a calculated free androgen index (FAI) value >2.92 [FAI=totalT/SHBG*100], which represented the upper bound of the 95% confidence interval for all subjects. Two-sided independent t-tests were used to compare differences between groups. **Results:** The EAMD-HA and EAMD-NA groups were similar with respect to age (22yrs), height (165.1cm), weight (57.19kg), and concentrations of ghrelin (1275.17pg/mL) and TT$_3$ (86.07ng/dL) (p>0.05). BMI (p=0.005), %BF (p=0.015), FAI (p<0.001), and leptin (p=0.025), total T (p<0.001) and cfree T concentrations (p<0.001) were all greater in EAMD-HA compared to EAMD-NA. SHBG concentrations (p<0.001) were lower in EAMD-HA compared to EAMD-NA. mREE/pREE was similar between groups and

below 0.90 (EAMD-HA: 0.87±0.01; EAMD-NA: 0.86±0.02, p>0.05). **Conclusion:** These findings support evidence that hyperandrogenism can coexist with an energy deficiency in exercising women and may contribute to menstrual disturbances. Proper screening must be conducted to ensure diagnosis and treatment of the appropriate etiology of menstrual disturbances.

Influence of Body Fat on Bioactive and Immunoreactive Growth Hormone Exercise Responses in Women

Matthew K. Beeler[1], Emily M. Post[1], Lydia K. Caldwell[1], William H. DuPont[1], John P. Anders[1], Vincent H. Hardesty[1], Emily C. Barnhart[1], Emily C. Borden[1], Jeff S. Volek[1], Wesley C. Hymer[2], William J. Kraemer, FACSM[1]. [1]*The Ohio State University, Columbus, OH.* [2]*The Pennsylvania State University, University Park, PA.* (Sponsor: William J Kraemer, FACSM)

(No relevant relationships reported)

Body fat has been observed to influence bioactive growth hormone (BGH) and immunoreactive growth hormone (IGH) in men, but is unknown in women. The complexity of GH release from the anterior pituitary has increased with the discovery of two somatotrophs: band I molecular weight isoforms (< 30 kD) called immunoreactive GH (IGH) and band II large molecular weight isoforms (> 60 kD) called bioactive GH (BGH).
PURPOSE: To determine the differences between untrained women with low and high body fat percentages.
METHODS: Recreationally active women of low % body fat (LF) (N= 10), mean ± SD: 22 ± 3.4 yr, 168 ± 5.3 cm, 67.8 ± 5.3 kg, 17.3 ± 2.0 % body fat, and women of high % body fat (HF) (N= 10); 23 ± 1.9 yr, 167 ± 4.3 cm, 68.4 ± 5.3 kg, 34.3 ± 3.7% body fat consented to participate in the study. The women were familiarized with the squat test protocol which consisted of 6 sets of 10 repetitions at 75% of their 1 RM with 2 minutes rest between sets after they were tested for 1 repetition maximum strength (1 RM) in the squat. All exercise tests were performed between 0630 and 1100 after an 8- to 12-h fast. Pre-exercise samples were obtained during the early follicular phase 15 min before test via standard venipuncture and a post-exercise sample was obtained immediately after the test. Plasma was collected and assayed for IGH using a monoclonal assay. Total BGH was assayed using the rat tibial line *in vivo* bioassay. A two-way analysis of variance (2 X 2) for group and time were used to analyze the data. A $p \le 0.05$ was used to define significance.
RESULTS: No differences were observed between the groups for 1 RM strength in the squat. Both groups significantly increased their IGH concentrations pre to post-exercise: (LF: 4 ± 3.1 to 18 ± 3.6 μgŸL^{-1}, HF: 3.9 ± 3.5 to 17.2 ± 3.0 μgŸL^{-1}). BGH did not increase pre to post-exercise, but both IGH and BGH values were significantly higher in the LF group than the HF group. Pre to post-exercise responses were: LF (4900 ± 433 to 5200 ± 393 μgŸL^{-1}), HF (1900 ± 433 to 2200 ± 323 μgŸL^{-1}). BGH was significantly higher than IGH values at all time points.
CONCLUSION As previously observed in young men, body fat impacts the response of IGH to resistance exercise, even when BGH responses remain unchanged acutely. BGH in women with lower % body fat do not see the suppression that occurs in women with higher % body fat, which may be linked to GH binding protein activity.

3338   Board #207   June 2 9:30 AM - 11:00 AM
Associations Among Age, Physical Activity, and Serum Resistin and Adiponectin Levels

Caitlyn A. Thomas, Victoria E. Warren, Kaitlin M. Frindt, Keenan R. Herman, Jennifer L. Shine, Kevin D. Ballard, Kyle L. Timmerman. *Miami University, Oxford, OH.* (Sponsor: Helaine Alessio, FACSM)

(No relevant relationships reported)

Adipose tissue was considered a passive reservoir for energy storage, but now is viewed as an active endocrine organ secreting adipokines such as resistin and adiponectin. Resistin tends to be inflammatory in nature, while adiponectin tends to be anti-inflammatory, with both being related to insulin resistance. Few researchers have examined the impact of age and physical activity level on serum resistin and adiponectin within the same study. The **PURPOSE** of this study was to assess the relationships among age, physical activity level, and resistin and adiponectin levels in healthy young and older adults. **METHODS:** A convenience sample was used consisting of 20 young (10 M/10 F; age: 21.0±1.2y; BMI: 24.3±4.5 kg·m^{-2}) and 20 older (6 M/14 F; Age: 68.4±4.0y; BMI: 25.5±3.1 kg·m^{-2}) adults. Physical activity frequency and intensity were determined in young and older subjects using the International Physical Activity Questionnaire (IPAQ) and the Community Healthy Activities Model Plan for Seniors (CHAMPS), respectively. Enzyme-linked immunosorbent assays were used for the detection and quantification of serum resistin and adiponectin. **RESULTS:** Young and older subjects had average resistin levels of 3.49 ± 0.97 ng·mL^{-1} and 2.97 ± 0.69 ng·mL^{-1}; and adiponectin levels of 101.40 ± 61.65 ng·mL^{-1} and 106.03 ± 59.39 ng·mL^{-1}, respectively. Physical activity level

was not correlated with either resistin or adiponectin. Resistin tended to be lower in older compared to young subjects (p= 0.056). There was no significant difference in adiponectin levels between young and old subjects (p= 0.57). Adiponectin was correlated with BMI within both groups (old: r = -0.45, p = 0.034; young: r = -0.46, p = 0.043) and when old and young subject data were combined (r = -0.45, p = 0.004). **CONCLUSIONS:** Body composition appears to be more predictive of serum levels of the anti-inflammatory adipokine, adiponectin, than either age or physical activity level. Surprisingly, resistin, a pro-inflammatory adipokine, was lower in older compared to young adults. Future studies with larger sample sizes and objective measures of physical activity level are warranted to better understand the relationships among age, physical activity level, and the expression of these adipokines.

3339   Board #208   June 2 9:30 AM - 11:00 AM

Association Between Bone Mineral Density And Vitamin D Receptor Gene Polymorphisms In Female Athletes

Mizuki Yamada[1], Naoki Kikuchi[1], Kayoko Kamemoto[2], Tomoka Matsuda[2], Mikako Sakamaki-Sunaga[1]. *[1]Nippon Sports Science University, Tokyo, Japan. [2]Graduate School of Nippon Sports Science University, Tokyo, Japan.*

(No relevant relationships reported)

Osteoporosis is an important health care problem in female athletes. Previous studies have shown that vitamin D receptor (VDR) gene polymorphisms are related to osteoporosis in the general populations; however, associations in female athletes are not known.**PURPOSE**: To investigate the association between bone mineral density (BMD) and VDR gene polymorphisms in female athletes. **METHODS**: One hundred and eighty seven female athletes (age: 20.3±1.2 years, height: 161.6±6.3 cm, body weight: 58.3±9.8 kg, percent body fat: 24.8±3.7%) participated in the present study. BMD of the whole-body, lumbar spine (L2~L4), and femoral neck was measured using dual-energy X-ray absorptiometry. Analyses of VDR genes Fok1, Apa1, and Taq1 polymorphisms were performed using TaqMan Genotyping Assay. **RESULTS**: The genotype frequencies of VDR genes Fok1, Apa1, and Taq1 polymorphisms were in Hardy-Weinberg equilibrium. The VDR genotype for Fok1, FF was found in 44.9%, Ff in 41.7%, and ff in 13.4% of the subjects (p=0.31). For Apa1, AA was found in 12.3%, Aa in 42.5%, and aa in 45.2% (p=0.51). For Taq1, TT was found in 72 %, Tt in 26.4%, and tt in 1.6% (p=0.54). There was no significant difference in physical characteristics among the VDR Fok1, Apa1, and Taq1 genotypes. No significant difference was observed between whole body BMD, lumbar spine (L2~L4) BMD, and femoral neck BMD in association with the VDR gene Fok1, and Taq1 polymorphisms. However, the aa genotype of the VDR Apa1 polymorphism was significantly associated with lower whole-body BMD than the AA genotype (p<0.05). **CONCLUSIONS**: An association with the VDR gene Apa1 polymorphism was shown in this study only for whole-body BMD. In conclusion, the VDR gene Apa1 polymorphism aa genotype is associated with decreased whole-body BMD in female athletes.

3340   Board #209   June 2 9:30 AM - 11:00 AM

Influence Of The Difference Of Exercise Intensity On Salivary Nitric Oxide In Young Men

Sone Ryota[1], Hayashi Koichiro[2], Eda Nobuhiko[3], Watanabe Koichi[1]. *[1]University of Tsukuba, Tsukuba, Ibaraki, Japan, Japan. [2]Kokugakuin University, Yokohama, Kanagawa, Japan, Japan. [3]Waseda University, Tokorozawa, Saitama, Japan, Japan.*

(No relevant relationships reported)

High-intensity exercise is related to increase the oxidative stress by excessive production of reactive oxygen species (ROS). Salivary nitric oxide (sNO) has been known to be a factor influencing the production of ROS. Therefore, there is a possibility of noninvasively evaluating ROS during exercise by measuring sNO. However, the influence of the difference of exercise intensity on sNO secretion are not well known. **PURPOSE**: The purpose of this study was to investigate the influence of different exercise intensity on salivary nitric oxide in young men. **METHODS**: Male collegiate students (21.6 ± 0.4 y.o.) were recruited and participated in this study (N = 5). All subjects carried out two different intensity exercises with random crossover design. One is a high-intensity condition that performs ergometer exercise at 80%HR$_{reserve}$ for 30 min, and the other is a moderate condition that performs ergometer exercise at 50%HR$_{reserve}$ for 30 min. Saliva samples were collected before (pre), immediately after (post), 30 minutes after (30 min), and 60 minutes after (60 min) each intervention. sNO concentration (μmoL/L) were analyzed by using the Griess reaction. sNO secretion rate (μmoL/min) was calculated by multiplying the absolute sNO concentration (μmoL/L) by the saliva flow rate (mL/min). **RESULTS**: Since there was no significant difference in the values before both interventions, the results are shown as the change from pre to post, 30 min and 60 min in sNO concentration and sNO secretion rate. The change from pre of sNO concentration in the high-

intensity significantly increased (*P* = 0.021) in 60 min (362 ± 58 μmoL/L), whereas the change in sNO secretion rate in both conditions did not significantly change in time. In the comparison between the interventions, the change in sNO secretion rate in the high-intensity (0.22 ± 0.05 μmoL/min) was significantly higher (*P* = 0.040) than the moderate (-0.01 ± 0.05 μmoL/min) at 60 min, while the change in sNO concentration was not significantly different (*P* = 0.075) between the high-intensity (362 ± 58 μmoL/L) and moderate (64 ± 69 μmoL/L) at 60 min. **CONCLUSIONS**: In this study, sNO concentration significantly increased after the high-intensity exercise, although it did not change after the moderate exercise. It was suggested that the difference of exercise intensity may affect the response of sNO.

Wearing Compression Garment During Prolonged Running Mitigated Tissue Vibration, Exercise-Induced Muscle Damage and Inflammation

Sahiro Mizuno[1], Tatsuhiro Maruyama[1], Akitoshi Makino[2], Mari Arai[3], Eri Yamada[3], Fumihiko Todoko[3], Masaki Ishikawa[2], Kazushige Goto[1]. *[1]Ritsumeikan University, Kusatsu, Japan. [2]Osaka University of Health and Sport Sciences, Osaka, Japan. [3]DESCENTE Ltd., Osaka, Japan.* (Sponsor: Robert R Kraemer, FACSM)

(No relevant relationships reported)

PURPOSE: To determine effect of wearing lower-body compression garment (CG) during prolonged running on tissue vibration and exercise-induced muscle damage and inflammatory responses. **METHODS:** Ten male subjects (170.5 ± 0.4cm, 62.6 ± 0.7kg, VO$_2$max; 50.6 ± 0.7mL/kg/min) performed 2 exercise trials in a random order. The exercise consisted of 120 min of uphill running (7% gradient) at 60 % of VO$_2$max. The exercise trials included 1) wearing lower-body CG with exerting 15 mmHg to thigh and calf [CG]; and 2) wearing lower-body garment with exerting below 5 mmHg to thigh and calf [CON]. During exercise, heart rate (HR), rating of perceived exertion (RPE), stride parameters (length and frequency) and tissue vibrations (3-axis acceleration of vastus lateralis, biceps femoris, tibia and gastrocnemius muscles) were evaluated. Jump performances and maximal voluntary contraction for knee extension (MVC) were evaluated before and immediately after, 60 min and 180 min after exercise. Blood variables were collected to determine blood glucose and lactate, serum myoglobin, and plasma IL-6, IL-1ra, IL-10, IL-8, TNF-α and MCP-1 concentrations. **RESULTS:** Average HR during 120 min of exercise was significantly lower in the CG trial than in the CON trial (163 ± 14 bpm vs. 167 ± 11 bpm, *P* = 0.042). Although stride parameters during exercise did not significantly differ between two trials, CG trials showed significantly lower tissue vibrations compared with the CON trial (*P* < 0.05). Jump performances and MVC were significantly decreased after exercise in both trials, whereas the CG trial showed significantly higher value of MVC at 180 min after exercise (92.4 ± 8.6 % vs. 85.0 ± 11.4 %, *P* = 0.044). There were significant increases in all of plasma cytokine concentrations after exercise in both trials (*P* < 0.05). Area under the curve (AUC) for IL-6 concentration during exercise and post-exercise period was significantly lower in the CG trial than in the CON trial (2,560 ± 1,686 pg/mL vs. 4,021 ± 3,234 pg/mL, *P* = 0.04). Furthermore, AUCs for plasma IL-1ra and IL-10 concentrations during post-exercise period tended to be lower in the CG trial. **CONCLUSION:** Wearing lower-body CG during 120 min of uphill running caused significantly lower exercise-induced increase in HR, tissue vibration, inflammation and faster recovery of muscular strength.

Hamstrings Muscle Activation During Different Strengthening Exercises

Darren Z. Nin[1], Pui W. Kong[1], Matthew T G Pain[2], Jonathan P. Folland, FACSM[2]. *[1]Nanyang Technological University, Singapore, Singapore. [2]Loughborough University, Loughborough, United Kingdom.*

(No relevant relationships reported)

Hamstring strain injuries (HSIs) occur when there is excessive strain on the muscle during eccentric contraction, with the biceps femoris (BF) being the most common injury site. The characterisation of muscle activation during different hamstring strengthening exercises may enable evidence-based prescription of preventative/rehabilitation exercises consistent with the aetiology of injury.

Abstracts were prepared by the authors and printed as submitted.

SATURDAY, JUNE 2, 2018

PURPOSE: To identify the hamstring strengthening exercise which elicits the highest muscle activation of the BF during eccentric contraction at longer muscle lengths. **METHODS:** Eleven resistance-trained males (age 22.1 ± 4.3 years) participated in this cross-sectional study. BF and semitendinosus (ST) electromyographic (EMG) amplitude was measured during the eccentric phase (three consecutive 15° sectors preceding the end range-of-motion (ROM)) of six different hamstring strengthening exercises (3 repetitions, 3RM load). Common and lengthened-state variants of hamstrings resistance training exercises were compared, specifically, knee- (conventional Nordics (CN); assisted Nordics (AN); seated leg-curl with hip flexed (SLC)) and hip- (inclined hip-extension (IHE); "good morning" (GM); straight-leg hip-extension (SHE)) exercises. EMG recordings of each exercise was normalised to EMG during maximal isovelocity (60°/s) eccentric contractions (highest of 4 efforts) measured on an isokinetic dynamometer (Con-Trex, CMV AG, Switzerland) at exercise specific knee- (KJA) and hip-joint angle (HJA) configurations. 2D sagittal plane video was used to analyse ROM of exercises. **RESULTS:** EMG amplitude was progressively higher towards the end of the eccentric phase for each exercise ($p < 0.001$). During the last 15° sector preceding end ROM, BF activity was highest in the CN (75.2 ± 8.2%), followed by GM (69.9 ± 6.6%) and SLC (67.8 ± 7.4%); BF/ST ratio was different between exercises ($p = 0.024$; CN < IHE & SHE; SLC < IHE & SHE). Muscle elongation (KJA-HJA) during end ROM was highest in the SLC (88.6°) and lowest during CN (-54.1°).
CONCLUSION: Differences in EMG amp with ROM sector suggest that besides contraction type, joint angle also influences muscle activation during these exercises. The high BF activity and muscle elongation of the SLC during end-ROM suggest that it may be an effective hamstring strengthening exercise.

Home-Based Exercise with Blood Flow Restriction to Restore Limb Symmetry Long After Knee Surgery

Matthew A. Kilgas, Lydia Lytle, Steven J. Elmer. *Michigan Technological University, Houghton, MI.* (Sponsor: Scott Drum, FACSM)
(No relevant relationships reported)

Rehabilitation following knee surgery (e.g., ACL reconstruction) is prolonged and many individuals do not completely regain their quadriceps size and strength. These persistent impairments give rise to limb asymmetry which increases risks for re-injury and osteoarthritis. **PURPOSE**: To establish exercise with blood flow restriction (BFR) as a home-based program to overcome persistent quadriceps size and strength impairments and restore limb symmetry long after knee surgery. **METHODS:** Five adults with an ACL reconstruction and/or meniscus repair (4.4 ± 2.5 years post-surgery) volunteered. Participants had at least 10% asymmetry in quadriceps size and/or strength. Participants exercised at home 4x/week for 4 weeks. Exercises included body weight squats, single-leg knee extension with resistance bands, and walking. Blood flow to the affected limb was restricted using a 15cm pressurized cuff inflated to 50% of limb occlusion pressure. Vastus lateralis and rectus femoris thickness along with knee extensor strength were measured before and after training. Percent difference between affected and contralateral limbs was used as an index of limb asymmetry. Post-training asymmetry indices were compared to healthy uninjured controls (n = 5). **RESULTS:** Following training, asymmetry in muscle thickness decreased for the vastus lateralis (9.9 ± 7.2 vs. 2.9 ± 4.0%, p = 0.04) and rectus femoris (11.9 ± 7.8 vs. 2.6 ± 3.5%, p = 0.03). Knee extension strength asymmetry decreased from 10.9 ± 2.6% to 2.6 ± 2.7% (p = 0.02). Post-training quadriceps size and strength asymmetry indices were not different from controls (<5%, all p > 0.05). **CONCLUSION:** These results extend upon early post-operative application of exercise with BFR and demonstrate that this modality can also be used to overcome persistent quadriceps impairments long after knee surgery. Exercise with BFR could serve as a cost-effective home option for improving function after supervised rehabilitation ends. Supported by Blue Cross Blue Shield of Michigan Foundation.

Body Composition Measures Associate with Physical Performance but not Disability in Individuals with Knee Osteoarthritis

Hope C. Davis[1], Malia N. Blue[1], Katie R. Hirsch[1], Brittney A. Luc-Harkey[2], Kara C. Anderson[1], Abbie E. Smith-Ryan, FACSM[1], Brian Pietrosimone, FACSM[1]. *[1]UNC Chapel Hill, Chapel Hill, NC. [2]Brigham and Women's Hospital, Boston, MA.*
(No relevant relationships reported)

Higher body mass index (BMI) is associated with more disability in individuals with knee osteoarthritis (KOA); however, BMI does not always provide accurate information about body composition, which may be a better predictor of disability in these patients. **PURPOSE**: Determine the associations between body composition and self-reported disability (Western Ontario and McMaster Universities Osteoarthritis Index [WOMAC] function) and physical performance (20m fast-paced walk, chair-stand, stair-climb) after accounting for BMI in individuals with KOA. **METHODS**:

Body mass and height were objectively measured, and percent fat (%FM) and lean mass (%LM) were determined using dual energy x-ray absorptiometry on 47 adults with radiographically defined KOA (Kellgren-Lawrence grade 2-4; 30% male; 60.2±8.3 yrs; BMI = 29.5±3.8 kg/m²). The WOMAC function subscale, 20m fast-paced walk (WALK), chair-stand (CHAIR), and stair-climb (STAIR) were completed on the same day. Separate linear regression analyses were conducted to determine the unique variance in WOMAC and each physical performance test explained individually by %FM and %LM after accounting for BMI (ΔR^2). Regression models accounted for sex and K-L grade, as both have been reported to associate with disability or body composition in individuals with KOA. **RESULTS**: Higher %FM significantly associated with better physical performance after accounting for BMI (WALK: $\Delta R^2 = 0.10$, p = 0.03; CHAIR: $\Delta R^2 = 0.16$, p = 0.01; STAIR: $\Delta R^2 = 0.13$, p = 0.02). Higher %LM significantly associated with better chair-stand performance but not 20m fast-paced walk or stair-climb tests (WALK: $\Delta R^2 = 0.04$, p = 0.17; CHAIR: $\Delta R^2 = 0.09$, p = 0.04; STAIR: $\Delta R^2 = 0.08$, p = 0.07). Neither %FM ($\Delta R^2 = 0.004$, p = 0.70) nor %LM ($\Delta R^2 = 0.001$, p = 0.84) associated with WOMAC after accounting for BMI. BMI did not explain a significant amount of variance in WOMAC or physical performance outcomes (R^2 range = 0.004 - 0.07, p > 0.05) as part of any regression model.
CONCLUSIONS: Lower %FM and higher %LM associated with better physical performance but not WOMAC. BMI did not significantly associate with WOMAC or physical performance. Future interventions should seek to increase %LM and decrease %FM, rather than focusing on overall reduction in BMI to improve physical performance. Supported by: NIH NIAMS 1R21AR067560-01.

Effects Of Whole Body Vibration On Neuromuscular Performance In Patients With Osteoarthrosis Of The Knee

Javier H. Carreño, Daniel D. Cohen, Rodrigo Argothy. *Universidad del Rosario, Bogotá, Colombia.*
(No relevant relationships reported)

Effects of whole body vibration on neuromuscular performance in patients with osteoarthrosis of the knee
Abstract
Background: The effect of whole body vibration on strength, power and force differences (asymmetries) during the sit to stand (STS) test and isometric strength test assessed with uniaxial force platforms in patients with osteoarthrosis of the knee.
Objective: To evaluate the effects of whole body vibration on neuromuscular performance and asymmetries in lower limbs in patients with or at risk of knee osteoarthrosis.
Methods: Randomized-Controlled trial with 60 subjects (mean age of 48 years ± 14.2) with diagnosis or at risk of knee osteoarthrosis (OA) but physically active, were randomly assigned to training program for 12 weeks: with vibration (WBV) and without vibration (CON). The force platforms was used for the strength measurements (Pasco fsample = 500Hz).
Results: The data was analiyzed with the software ForceDecks. Statistically significant differences were found for the CON group between Peak Vertical Force (PVF) pre-training: 655N and POST training: 837N (p = 0.00); the rate of force development (RFD) PRE= 935Ns, POST= 1634Ns (p = 0.05), while in the WBV group there was a non-significant increase: PVF (pre-training: 628N and POST training: 685N) (p = 0.29); the RFD (pre-training: 1280Ns and POST training: 1354Ns) (p = 0.57). In the WBV group there was a significant decrease of pain according to the Visual Analogue Scale (VAS). Significant differences were found between the groups being much greater in the group CON, in the isometric leg press test in RFD-200ms (P= 0.03) and relative peak force (P= 0.04).
Conclusion: In individuals with knee OA 12 weeks of strength training performed with whole body vibration led to lower neuromuscular performance gains than the same training performed without vibration, however pain intensity decreases at knee, hip and lower back level according to the (VAS).
Key words: Resistance training, acceleration training, Osteoarthrititis knee, Reflex startle, Muscle strength.

Does Blood Flow Restricted Training Improve Quadriceps Strength Following an ACL Injury?

Kathryn Lucas, Darren L. Johnson, Mary L. Ireland, FACSM, Brian Noehren, FACSM. *University of Kentucky, Lexington, KY.* (Sponsor: Brian Noehren, FACSM)
(No relevant relationships reported)

PURPOSE: Anterior cruciate ligament (ACL) injuries result in significant quadriceps weakness, causing pain and compensations in gait. High resistance strengthening is often not well tolerated after an ACL injury. Blood flow restricted training (BFRT), which uses partial occlusion of blood flow through applied cuffs, maybe an effective technique to maximize strength at low intensities. While BFRT has been well

studied in healthy populations, its effectiveness in an injured population has not been established. We hypothesized that a 4-week blood flow restricted quadriceps strengthening protocol will significantly improve quadriceps strength and the limb symmetry index of the quadriceps.
METHODS: Nine subjects status-post ACL injury participated in this study. After determining the subjects' preoperative isometric quadriceps strength on a Biodex and their 1 repetition maximum on each piece of exercise equipment, they then performed a 4-week BFRT protocol. Training was performed at 30% of the subject's 1 rep maximum with BFRT optimal pressure determined per manufacturer instructions. Four quadriceps strengthening exercises were performed at each session. Three sets of 10-30 repetitions were performed for each exercise. At the end of 4 weeks, quadriceps strength was reassessed. A paired t-test was used to compare pre and post intervention quadriceps strength normalized to body weight, and limb symmetry indexes were calculated.
RESULTS: Quadriceps strength of the involved side significantly increased (p<0.000) from 2.24 ± 0.67 Nm/kg to 2.82 ± 0.71 Nm/kg. The limb symmetry index improved from 0.70 pre-BFRT to 0.88 post-BFRT.
CONCLUSIONS: A four-week blood flow restricted training protocol significantly increases quadriceps strength in a preoperative ACL reconstruction population. By training at 30% of the individual's 1RM, the risk of further injury or pain is minimized. Restoring quadriceps strength before surgery may result in a faster recovery and better long term outcomes. Further research should investigate if blood flow restrictive training is appropriate for other injured populations and for postoperative care of patients who have had an ACL reconstruction.

Effect of Fatigue on The Neuromuscular Transmission of Hamstrings During Eccentric Muscle Action

Ziwen Pei, Jian Chen, Danyang Li. *Wuhan Sports University, Wuhan, China.*

(No relevant relationships reported)

Electromechanical delay (EMD) is a key to evaluate the ability of neuromuscular transmission, and fatigue is believed to be associated with altered neuromuscular transmission of hamstrings, which may increase the risk of non-contact anterior cruciate ligament (ACL) injury. However, experiment evidence supporting this relationship is insufficient.
PURPOSE: The purpose of this study is to investigate the effect of fatigue on electromechanical delay times of hamstrings during eccentric muscle action.
METHODS: Twenty female (20±2 yrs) volunteers participated in the study and EMD of semitendinosus (ST), semimembranosus (SM) and biceps femoris (BF) were determined before and after fatigue during eccentric muscle action at 120 and 240°/s. All subjects followed an isokinetic fatigue protocol until flexion torque fell below 50% of initial torque for three consecutive repetitions. A 2*2*3 ANOVA was used to calculate the effect of fatigue, movement velocity, type of muscle and their interaction on EMD. **RESULTS**: There was no significant difference in the EMD of the 3 muscles examined (BF: 119.0±25.3ms vs. SM: 118.9±24.0ms vs. ST: 12 0.3±24.9ms, P>0.05), irrespective of fatigue status or movement velocity. Fatigue caused a significant increase on EMD of 3 muscles examined (non-fatigue: 98.4±11.5ms vs. fatigue: 140±13.8ms, P<0.001). Irrespective of fatigue, EMD of the 3 muscles significantly increased with increasing movement velocity (low angular velocity: 107.8±20.9ms vs. high angular velocity: 131.0±22.5ms, P<0.001).**CONCLUSIONS**: Our findings suggest that fatigue decrease the ability of neuromuscular transmission of hamstrings during eccentric muscle action, irrespective of movement velocity. This would suggest that improving resistance to fatigue of hamstrings may be an effective prevention tool of non-contact ACL injury.

Differences In The Mitochondrial Capacity Of The Right And Left Biceps Brachii Muscle

Elizabeth Pryor, Katie Luquire, Kevin McCully, FACSM. *University of Georgia, Athens, GA.* (Sponsor: Dr. Kevin McCully, FACSM)

(No relevant relationships reported)

PURPOSE: Near infrared spectroscopy (NIRS) has been used to measure mitochondrial capacity of various muscles, but not specifically the biceps brachii. PURPOSE: Measure mitochondrial capacity using NIRS in the dominant and non-dominant arms of young healthy adults. **METHODS**: Five untrained subjects (mean age 20.4±0.7 years) were tested in the supine position with a NIRS device (Artinis, Ltd) placed in the middle of the biceps brachii muscle. Electrical stimulation (6 Hz, 25-40 mAmps) was used to activate the muscle. A 5 cm blood pressure cuff was placed proximal to the NIRS device and used for arterial occlusion (225 mmHg). The protocol consisted of 30 seconds of resting metabolism, 30 seconds of post stimulation metabolism, three minutes of ischemia followed by reperfusion to measure the rate of reoxygenation, and two mitochondrial capacity tests. The mitochondrial capacity test consisted of electrical stimulation followed by a series of 22 ischemic cuffs

lasting from 5-10 seconds, each allowing muscle reoxygenation. **RESULTS**: There was no difference in mitochondrial capacity between the dominant and non-dominant arms of the untrained subjects (Lf Tc=43.8 ± 6.8 s, Rt Tc=43.4 ± 10 s, P = 0.93). **CONCLUSIONS**: The biceps brachii muscle had mitochondrial capacity values similar to the forearm values from previous studies, and slower than values for the gastrocnemius and quadriceps muscles. We found no evidence for differences between the dominant versus non-dominant biceps brachii muscles. Supported in part by CURO Assistantship.

Impact of Discipline and Gender on Hamstring and Quadriceps Strength in Elite Alpine Skiers

Marine Alhammoud[1], Baptiste Morel[2], Regis Mecca[3], Erick Naël[4], Marie-Philippe Rousseaux-Blanchi[5], Christophe Hautier[6]. *[1]French Ski Federation, Annecy, France. [2]Le Mans University, Le Mans, France. [3]Ski and Snowboard National training Centre (CNSS), Albertville, France. [4]Physiotherapy Center of Seynod, Annecy, France. [5]High Level Sport Medicine Center, Hospital of Albertville-Moûtiers, Albertville, France. [6]University Claude Bernard Lyon 1, Villeurbanne, France.* (Sponsor: Lee Taylor, FACSM)

(No relevant relationships reported)

PURPOSE: Examine the influence of discipline and gender on hamstring and quadriceps strength of elite alpine skiers. **METHODS:** Twenty-eight French national team skiers (14 male) undertook isokinetic dynamometry evaluation. Skiers were split by discipline into technical (Slalom and Giant Slalom, GpT, n=14) or speed (Super Giant and Downhill, GpS, n=14). Maximal conventional ratios (i.e. concentric) at $60°.s^{-1}$ and $180°.s^{-1}$ and maximal functional ratios at $60°.s^{-1}$ and $90°.s^{-1}$ were calculated for Hamstring-to-Quadriceps (HQ) ratio, together with isoangular HQ ratios between 30° and 90° (0° representing full extension). **RESULTS:** No gender difference in HQ peak torque ratios was apparent, yet females demonstrated a delayed quadriceps Angle of Maximal Torque (AMT). Statistical parametric mapping demonstrated lower hamstring torque and a low HQ ratio near full knee extension in female skiers regardless of velocity. A greater hamstring AMT in GpT skiers compared to GpS was observed, along with greater dynamic quadriceps strength after 72° of knee flexion in GpT skiers. **CONCLUSION:** Discipline and gender both influence the HQ strength profile of elite alpine skiers, which are further modified according to the joint angle and angular velocity employed. The data provide normative values based on gender and discipline which may be of use during pre-season isokinetic screening, which is common in practice and often used to inform subsequent knee injury prevention intervention.

EMG Analysis of Lower Limb Muscle Activation During 6-Minute Treadmill Walking Following Novel Over-Ground Locomotor Training in Incomplete Spinal Cord Injury

Donal Murray, Andrew A. Guccione, Kerry J. Bollen, Brian T. Neville, Caitlin A. Bryson, Randall E. Keyser, FACSM. *George Mason University, Fairfax, VA.* (Sponsor: Randall E. Keyser, FACSM)

(No relevant relationships reported)

Physiological impairments in incomplete spinal cord injury (iSCI) can include muscle weakness and altered skeletal muscle activation. Reduced voluntary muscle activation in iSCI can cause inadequate fibre recruitment and in turn the muscle may undergo adverse morphological adaptations.
PURPOSE: The study aimed to characterize, the level of lower limb muscle activation using surface electromyography (EMG) during 6 minutes of treadmill walking in iSCI following 12 weeks of a novel overground locomotor training (OLT) program.
METHODS: A convenience sample of 3 individuals with iSCI (Age: 39±15.5 years, AIS C or D, >6months post-SCI) completed 12 weeks of OLT, which consisted of two 90-minute sessions per week. The principles of OLT included the motor learning concepts of task specificity, practice variability and progressive overload. Sessions were broken down into 5 segments: joint mobilization, muscle activation, task isolation, task integration and task rehearsal. Each session catered to a specific component of the gait cycle. Pre- and post-assessment included 6 minutes of treadmill walking, performed at participant's self-selected speed (0.5-1.4mph). Two sets of bipolar electrodes were placed on the muscle belly of the left lateral gastrocnemius (GA), left tibialis anterior (TA) and left bicep femoris (BF). EMG data was continuously collected over the 6 minutes. The root mean square (RMS) and peak activation of EMG during the last 10 seconds of minute 1, 3 and 6 was calculated using Matlab programming code. The values for each minute were normalized to the RMS

SATURDAY, JUNE 2, 2018

and peak value of the first 10 seconds of the walking bout. Cohen's d was calculated to determine effect size (ES) of EMG signal pre- and post-OLT, as well as comparing minute 1 to minute 6 of walking.
RESULTS:Following OLT the RMS during minute 6 of the GA and BF increased, difference of 37.522mV with strong ES >0.8. Comparing pre-OLT minute 1 to minute 6 shows a trend of reduced activity in the GA, TA and BF (Δ-29.11mV, Δ-8.71mV, Δ-28.7mV, ES>0.63, ES>0.88 ES>0.75), yet post-OLT the trend is positive (Δ-=48.73mV, Δ-10.49mV, Δ26.51mV, ES>0.74, ES>0.13 ES>0.44).
CONCLUSIONS:Higher RMS of the EMG during minute 6 of the walking trail could indicate greater activation of measured muscles in iSCI following OLT.

Relationships Between Quadriceps Femoris Quality And Locomotor Functions In Disabled Patients

Hisashi Maeda[1], Ken Imada[2], Koji Ishida[1], Hiroshi Akima[1]. [1]Nagoya University, Nagoya, Japan. [2]Kinkai Rehabilitation Hospital, Tottori, Japan. (Sponsor: Katsumi Asano, FACSM)
(No relevant relationships reported)

The patients often suffer from impairments of their lower limbs and disability of locomotion. Quadriceps femoris (QF) is one of the key muscles contributing to locomotor functions and it has been established that QF quantity is associated with locomotor functions in disabled patients. Muscle quality is defined as ratio of adipose tissue to muscle tissue. QF quality of patients could become worse by increased ratio of adipose tissue to muscle tissue. As far as we know, there were no studies showing that QF quality has a relationship with locomotor functions in disabled patients. **PURPOSE**: The purpose of this study was to assess the relationships between QF quality and locomotor functions in disabled patients. **METHODS**: Fourteen hospitalized patients (11 patients with stroke and 3 patients with lower extremity fracture; age, 71.2 ± 16.3 years; height, 157.1 ± 9.6 cm; weight, 55.2 ± 14.7 kg; body mass index, 22.1 ± 3.7 kg/m^2) participated in this study. The QF muscle quality based on echo intensity and muscle thickness as an index of muscle quantity at the mid-thigh were assessed using ultrasonography. Timed up and go (TUG) test, berg balance scale (BBS) and functional independence measure (FIM) stairs scale were assessed as locomotor functions. **RESULTS**: TUG time was significantly correlated with QF thickness (r= -0.68, P<0.05). BBS and FIM stairs scale were significantly correlated with QF echo intensity and thickness, respectively (r= -0.57, P<0.05; r= 0.83, P<0.05; r= -0.57, P<0.05; r= 0.69, P<0.05). **CONCLUSIONS**: These results suggest that not only QF quantity but also quality are associated with locomotor functions in disabled patients. Furthermore, QF quality may be essential factor to influence on locomotor functions in disabled patients.

Long-term Electrically Induced Muscle Exercise Duration Modulates Distinct Gene Signaling Pathways In People With Spinal Cord Injury

Michael A. Petrie, Manish Suneja, Richard K. Shields. *The University of Iowa, Iowa City, IA.*
(No relevant relationships reported)

Exercise as a form of medicine attenuates the development of chronic non-communicable diseases (CNCDs) in people with intact nervous systems as they age. However, there is a knowledge gap regarding the influence of electrically induced skeletal muscle exercise on CNCDs in people with spinal cord injury (SCI). Gene signaling pathway analysis offers an opportunity to understand the long term effects of electrically induced exercise on people with chronic and complete paralysis from SCI; providing a basis for interventions to be studied in future clinical trials. **Purpose:** To determine if long term electrically induced skeletal muscle exercise regulates complex network signaling pathways associated with improved health in people with SCI. **Methods:** 17 males with a complete SCI participated in this study. Participants completed 3, 6, or 12 months of a unilateral exercise training program using electrical muscle stimulation. After exercise training, participants underwent muscle biopsies of the trained and untrained limbs. RNA was extracted and hybridized to an exon microarray. Resulting gene expression signals were analyzed using a geneset enrichment analysis and applied to a network connectivity map. **Results:** We analyzed over 17,000 genes and 1,900 genesets curated from the Reactome database. We found that the genesets significantly increased (<25% FDR; p<0.05) depended on the duration of training. 52, 44, and 242 genesets were upregulated in the trained limb at 3, 6, and 12 months of training. Of the 242 genesets upregulated in the trained limbs at 12 months, 21% were directly associated with hypertrophy and metabolism/oxidative phosphorylation. Among the genes with the highest expression levels in trained muscles were MYH7(4.87±6.7) and MYH6(2.65±3.11); while MSTN(0.66±0.31) and ACTN3(0.68±0.53) were among those genes with the greatest suppression in the trained limbs. **Conclusions:** Overall health is dependent, in part, on skeletal muscle size and metabolic capacity. 6 months of chronic electrically induced exercise was sufficient to reverse hypertrophy gene pathways and improve metabolic signaling to a

more oxidative state. Future studies are underway to ascertain if electrically induced exercise attenuates the development of CNCDs in people with SCI. Supported by NIH Grants R01HD084645 and R01HD082109

Low Frequency Electrically Induced Muscle Exercise Modulates Glucose Tolerance In People With SCI

Richard K. Shields, Michael A. Petrie, Jinhyun Lee, Jessica R. Woelfel. *The University of Iowa, Iowa City, IA.*
(No relevant relationships reported)

Regular exercise is an important strategy to prevent the development of several chronic non-communicable diseases (NCDs), including metabolic inflexibility and diabetes. Skeletal muscle increases glucose uptake through two distinct pathways: Insulin receptor sensitivity pathway and the exercise induced AMPK pathway. Because people with paralysis are unable to move, they never reap the benefits of muscle exercise/activity following a meal. **Purpose:** To determine if electrically induced exercise regulates the glycemic response after an oral glucose load in people with and without a SCI. **Methods:** 8 and 14 people with and without a SCI participated in this study. Participants completed 2 sessions of a 2 hour oral glucose tolerance test at least 7 days apart. 15 minutes after ingesting 75g glucose beverage, participants sat passively (control) or were given a dose of electrically induced muscle stimulation delivered at a 3Hz frequency for 1-hour, then rested for the next hour. Glucose and insulin were measured from venous blood draws at baseline and 120 minutes. Capillary glucose measurements were performed at baseline, 30, 60, 90, and 120 minutes. A mixed design analysis of variance was used for all comparisons with pairwise comparisons where appropriate. **Results:** At baseline, neither glucose (85.5±9.4 and 93.1±6.8 mg/dL, p>0.62) or insulin (13.2±8.8 and 7.8±1.4 μI/mL, p>0.84) was significantly higher for people with a SCI compared to those without. During the oral glucose tolerance test, there was a significant decrease in the glucose AUC during the electrically induced exercise session for people with a SCI (7,763±3,670 (STIM) and 8,904±4,039 (CTL),p=0.003), but no difference for people without a SCI (5,205±2,487 (STIM) and 5,500±2,355 (CTL), p=0.58). Significantly less insulin was needed during the exercise as compared to the control session (124.1±34.8 and 190.2±40.8, p=0.013). **Conclusions:** A dose of low frequency electrically induced muscle exercise attenuated the severe glycemic response in people with SCI after a meal. These findings offer a unique strategy for people who are paralyzed to improve their glucose tolerance after a meal. Supported by NIH Grants R01HD084645 and R01HD082109

Muscle-tendon Elasticity: Friend or Foe When Measuring Activity-related Energy Expenditure following Exercise Training

Stephen J. Carter[1], Laura Q. Rogers, FACSM[1], Heather R. Bowles[2], Gary R. Hunter, FACSM[1]. [1]University of Alabama at Birmingham, Birmingham, AL. [2]National Cancer Institute, Bethesda, MD. (Sponsor: Gary R. Hunter, FACSM)
(No relevant relationships reported)

PURPOSE We examined how exercise training-induced changes in the energetic cost of walking affected accelerometer-based metrics during a standardized walking task coupled with indirect calorimetry. **METHODS** 29 breast cancer survivors were evaluated at baseline (M0) and following a 3 month physical activity intervention (M3). Participants were outfitted with a heart rate monitor and hip worn triaxial accelerometer while treadmill walking (0.89 m/s, 0% grade) for 4 minutes. Indirect calorimetry was used to measure steady state oxygen uptake (VO$_2$) and carbon dioxide production, to objectively quantify EE. The highest VO$_2$ and corresponding heart rate over a 30 sec period were used for analyses. Percent of age predicted heart rate max (HRmax) was calculated by dividing steady state HR by the difference of 220-age. Vector magnitude, a composite of three orthogonal planes [mediolateral(x), vertical(y), & anteroposterior(z)] was used to estimate EE. Accelerations from each axis were collected during the walking task. **RESULTS** Consistent with improved fitness, percent of HRmax was decreased by -6.7% ($p<0.01$) during the walking task at M3. The energetic cost of walking, represented by VO$_2$ (mL·kg^{-1}·min^{-1}) was significantly decreased (M0, 10.0±1.4 *vs.* M3, 9.3±1.1; $p<0.01$), which corresponded with a concurrent -6.5% reduction in measured EE. Alternatively, vector magnitude (au) exhibited a significant increase (M0, 40.4±10.3 *vs.* M3, 45.2±13.9; $p<0.05$), that reflected larger (+24%) estimates of EE. Individual axis accelerations revealed there were no differences ($p>0.05$) in the mediolateral (x) or anteroposterior (z) planes of movement at M3. However, indicative of an altered gait, vertical (y) accelerations were significantly increased (M0, 17.8±9.1 *vs.* M3, 23.3±10.2; $p<0.01$). **CONCLUSION** These data suggest accelerometer-based estimates of activity related EE are not sensitive to the improvements in fitness or energetic cost of treadmill walking. Research is needed to determine if changes in muscle-tendon elasticity occurring with exercise training account for the decreased energetic cost of walking and simultaneous

increase in vertical accelerations. The divergence between actual EE and accelerometer based estimates of EE may contribute to erroneous inferences concerning free-living physical activity.

The Test-retest Reliability And Exercise-driven Changes Of UCH-L1 In Healthy, Recreationally Active College Students

Grant H. Cabell[1], Elizabeth F. Teel[2], Erik D. Hanson[1], Jason P. Mihalik[1], Kevin M. Guskiewicz, FACSM[1]. [1]The University of North Carolina at Chapel Hill, Chapel Hill, NC. [2]McGill University, Montreal, QC, Canada.
(No relevant relationships reported)

Concussions are common in sports, yet remain difficult to diagnose since truly objective assessments are lacking. Blood biomarkers are a potential solution to this problem. A biomarker must be sensitive and specific to head injury before it can be further studied as a clinically useful diagnostic for sport-related concussion (SRC). It must be stable over time, and remain unchanged by other factors including acute exercise. **PURPOSE:** To investigate the test-retest reliability and acute exercise effect on a novel head injury biomarker, Ubiquitin C-Terminal Hydrolase-L1 (UCH-L1) in healthy subjects such that findings could assist with interpretation of findings in acutely injured athletes. **METHODS:** Recreationally active (>30 min activity 3 days/week) college students (n=27, males=14, age=21± 2.3 yrs) completed a maximal cycle ergometer exercise test during two assessment sessions 10-14 days apart. Blood samples were collected within 10 minutes before and after each test. UCH-L1 values were determined through sandwich enzyme linked immunosorbent assays (ELISA) run in triplicate. Intraclass correlation coefficients (ICC) and 80% reliable change indices (RCI) examined the test-retest reliability of UCH-L1. A 2 (sex) x 2 (pre/post) mixed model ANOVA analyzed the acute exercise effect on UCH-L1 levels. **RESULTS:** UCH-L1 was moderately reliable in the entire cohort (ICC$_{2,k}$=0.505, 80% RCI=107.0 pg/ml). Males had excellent reliability (ICC$_{2,k}$=0.895, 80% RCI=44.4 pg/ml), while females had poor reliability (ICC$_{2,k}$=0.094, 80% RCI=138.8 pg/ml). No significant effects of acute exercise (F$_{1,25}$=0.002, p=0.966), sex (F$_{1,25}$=3.981, p=0.057), or sex by exercise interaction (F$_{1,25}$=1.108, p=0.303) on UCH-L1 values were found. **CONCLUSIONS:** UCH-L1 may have potential to be clinically useful in males. The high reliability and negligible effect of exercise suggest the biomarker remains stable in healthy males and is unaffected by acute exercise. Thus, changes may be attributed to external factors known to affect the biomarker such as head trauma. Conversely, the low reliability and wide RCI suggests UCH-L1 use in females should be limited. Further investigation of sex differences in reliability of UCH-L1 and feasible methods of sideline biomarker analysis are needed in hopes of improving SRC detection and identification.

Effects of Body Position and Electrode Type on the Reliability of Bioimpedance Spectroscopy

Michael Lane[1], Lee A. Doernte[1], April M. Spears[1], Ryan M. Bean[1], Jordan R. Moon[2]. [1]Eastern Kentucky University, Richmond, KY. [2]Impedimed, Inc., Carlsbad, CA.
Reported Relationships: M. Lane: Contracted Research - Including Principle Investigator; I am conducting funded research by a manufacturer of BIS technology..

PURPOSE: To compare multiple BIS measurements taken using the traditional approach (gel-backed wet electrodes and subject supine) to BIS measurements taken when subjects are standing or seated using fixed metal electrodes and determine the reliability of each method. **METHODS**: Twenty-five subjects (m=10/f=15) participated in the study (22 +/- 3 years, 171.5 +/- 12.0 cm, 70.9 +/- 13.6 kg). Four (whole body right side) measurements each were taken for sitting with metal electrodes (SiM), standing with metal electrodes (StM), and supine with gel-backed electrodes (SuG). Data was analyzed comparing the two back-to-back measurements both before and after repositioning as well as measurements taken before repositioning to measurements taken after repositioning (pre-to-post). **RESULTS**: Both back-to-back and pre-to-post analysis revealed all methods to be highly reliable (ICC > 0.98, %CV < 2.32). Back-to-back measurements resulted in more reliable R0 and Rinf data compared to pre-to-post repositioning data for SiM, StM, and SuG (ICC > 0.87, SEM < 6.72 Ohms), compared to pre-to-post data for SiM, StM, and SuG (ICC > 0.987, %CV < 2.32, SEM < 13.33 Ohms). SuG produced the most reliable back-to-back measurements (SuG: ICC =1.00, %CV < 0.34, SEM < 1.48 Ohms, SiM/StM: ICC > 0.995, %CV < 0.97, SEM < 6.72 Ohms) but had the largest reliability errors from pre-to-post compared to SiM and StM (SuG: ICC > 0.986, %CV < 2.32, SEM < 13.33 Ohms, SiM/StM: ICC > 0.991, %CV < 1.51, SEM < 10.29 Ohms). Similar results were observed when comparing SiM to StM for both back-to-back and pre-to-post measurements. **CONCLUSIONS**: Sitting with metal electrodes, standing with metal electrodes, and lying supine with gel-backed electrodes all appear to produce

reliable and repeatable BIS measurements (R0 and Rinf). Gel-backed electrodes appear to produce greater variability when measurements are taken after re-applying the electrodes compared to re-positioning with metal electrodes. Yet, back-to-back measurements have slightly greater variability with metal electrodes compared to gel-backed electrodes. BIS measurements that require tracking of changes over time appear to be more reliable when using metal electrodes over gel-backed electrodes.

Pulmonary Testing and Exercise-Induced Bronchoconstriction in Collegiate Baseball Players

Matthew J. Garver[1], Molly A. Jennings[1], Dustin W. Davis[1], Brian J. Hughes[1], Steve Burns[1], Taylor K. Dinyer[2], Alex Rickard[1], Justin L. Colf[1], Jenna L. Carducci[1], Anna L. Blazer[1], Laura A. Wilson[1], Dave M. Burnett[3]. [1]University of Central Missouri, Warrensburg, MO. [2]University of Kentucky, Lexington, KY. [3]University of Kansas Medical Center, Kansas City, KS.
(No relevant relationships reported)

Testing for pulmonary conditions such as asthma and exercise-induced bronchoconstriction (EIB) is often overlooked in collegiate athletes, despite the fact that they may have profound effects on performance and health. Asthma is a chronic condition, while EIB is a transient narrowing of the airways activated by strenuous exercise. **PURPOSE**: The purpose of this analysis was to investigate the prevalence of asthma, undiagnosed asthma, and EIB in collegiate baseball players. **METHODS**: Participants with asthma were noted and removed from the EIB provocation protocol. The protocol commenced with maximal forced spirometry. Participants were encouraged to achieve a six-second plateau, and spirometry values were collected in duplicate. Participants failing to achieve a baseline forced expiratory volume (FEV)1 of at least 70% of the predicted value were removed from ongoing testing. Those passing the baseline spirometry screening proceeded to a single bout of exercise on a treadmill. In stepped fashion, participants progressed to an intensity matching 80-90% of age-predicted maximal heart rate. Exercise intensity was confirmed with ventilation (35*FEV1*0.5 and 35*FEV1*0.6). Participants maintained target intensity for four minutes. Immediately post-exercise, participants resumed a seated position. Maximal forced spirometry efforts were repeated at 2, 5, 10, 15, and 20-min time points. A fall in FEV1 >10% from baseline was considered positive for EIB. **RESULTS**: Thirty athletes (age: 20.3+1.9 yr, height: 184.2+6.4 cm, and weight 86.5+8.8 kg) volunteered for testing. One (3.33%) had been previously diagnosed with asthma. At baseline, two participants (6.67%) failed to obtain 70% of predicted FEV1 values (labeled as potentially undiagnosed asthma and removed from ongoing testing). A total of 27 participants completed the EIB provocation protocol. Five (16.7% of cohort) failed to obtain 90% of their pre-exercise FEV1 value (an indication of EIB) at one of the post-test time points. The mean drop among those failing was 30.5% with all values being reviewed by a registered respiratory therapist. **CONCLUSIONS**: The prevalence of pulmonary conditions in athletes may be masked by a lack of testing. It would seem prudent to test athletes for these conditions and create treatment plans.

3358   Board #227   June 2 9:30 AM - 11:00 AM

Decreased Aerobic Efficiency in Pediatric and Young Patients with Sickle Cell Disease : Race Comparison

Sandra K. Knecht, Wayne A. Mays, Malloree C. Rice, Andrea L. Grzeszczak, Adam W. Powell, Clifford Chin, Punam Malik, Tarek Alsaied. Cincinnati Children's Hospital, Cincinnati, OH.
(No relevant relationships reported)

PURPOSE: To compare the differences in aerobic efficiency between pediatric and young Sickle Cell patients (SS) and African American (NAA) and Caucasian (NC) controls. **METHODS:** We evaluated 14 SS patients, NAA and NC age, gender and size matched using a Ramp Cycle Ergometry protocol. Oxygen consumption (absolute and indexed), carbon dioxide production, expiratory minute volume (VE), respiratory exchange ratio (RER), systolic blood pressure (SBP) and heart rate (HR) were obtained at all stages. The VE/VO$_2$ (VO2Eq) and VE/VCO$_2$ (VCO2Eq) equivalents, oxygen consumption uptake efficiency slope (OUES), VE/VCO2 slope (Slope) and oxygen pulse (O2Pulse) were calculated at anaerobic threshold (AT) and maximal exercise (Max). **RESULTS:** There was no difference in SBP between SS, NAA and NC groups. Max RER was significantly elevated in SS. Indexed Max oxygen consumption (IMVO2) was significantly deceased in SS. O2Pulse and OUES were significantly decreased in SS at AT and Max. Slope, VO2Eq and VCO2Eq at Max were significantly elevated in SS. The HR at AT was significantly elevated in NAA compared to SS at AT.

SATURDAY, JUNE 2, 2018

	SS AT	SS Max	NAA AT	NAA Max	NC AT	NC Max
HR (BPM)	149 ± 19	186 ± 10	162 ± 14*	186 ± 11	157 ± 20	186 ± 14
O2Pulse (cc/bpm)	6.7 ± 2.4	7.4 ± 2.7	9.0 ± 2.4**	10.5 ± 2.9**	9.8 ± 3.3**	11.4 ± 3.9**
OUES	1653 ± 497	1455 ± 487	2186 ± 647*	2204 ± 534**	2416 ± 673**	2334 ± 626**
Slope	24 ± 6	29 ± 6	22 ± 4	25 ± 3*	21 ± 4	25 ± 3*
VO2Eq	27 ± 5	40 ± 6	26 ± 5	31 ± 5**	24 ± 3	31 ± 5**
VCO2Eq	27 ± 5	30 ± 5	25 ± 5	27 ± 3*	24 ± 3	27 ± 3*
RER		1.33 ± 0.18		1.17 ± 0.05**		1.18 ± 0.08**
IMVO2 (cc/min/kg)	18 ± 4	24 ± 6	24 ± 6**	32 ± 7**	25 ± 5**	35 ± 8**
SS vs NAA, SS vs NC: *p<0.05, ** p<0.01						

DISCUSSION: The SS showed similar responses in SBP and HR compared to control groups. The SS group showed decreased aerobic efficiency reflected by an increased VE/VO2Eq, VE/VCO2Eq and Slope with a decrease in OUES and O2Pulse. The effect was a decreased aerobic capacity reflected in the decreased IMVO2 in SS.
CONCLUSION: These data suggest a major determinant for the decreased aerobic capacity in sickle cell is related to a decreased aerobic efficiency and decrease oxygen carrying capacity. The data does not support significant racial differences.

Comparison Of Estimated And Achieved Metabolic Equivalents In Children With Severe Burns

Christian Tapking, David N. Herndon, Ludwik K. Branski, Oscar E. Suman, FACSM. *Shriners Hospital for Children-Galveston and University of Texas Medical Branch at Galveston, Galveston, TX.*
(No relevant relationships reported)

We measure peak oxygen consumption (VO_2 peak) in children with severe burns via indirect calorimetry. When we can't measure VO_2 peak, we estimate it using the Cooper equation (CEq). In addition, a pharmacological agent sometimes used in burns to decrease hypermetabolism is propranolol.
PURPOSE: It is unknown, how propranolol affects the prediction of VO_2 peak using CEq. Therefore, we compare predictive and measured VO_2 peak and metabolic equivalents (METS) in children with severe burns.
METHODS: Children with severe burns were randomly assigned to receive propranolol or no drug during their hospital stay. At discharge, patients underwent a treadmill exercise test using the Bruce protocol. VO_2 peak and METS were measured and compared to predicted values using CEq (male: VO_2 peak = (43.6 x height (cm) - 4547.1)/weight (kg)); female: VO_2 peak = (22.5 x height (cm) - 1837.8)/weight (kg)). Values are means +/- SD.
RESULTS: We studied 99 children with burns with admit dates between March 1990 and November 2015; with 46 children receiving propranolol and 53 receiving no drug. Mean age at burn was 12±4 years in the propranolol group and 12±3 years in the control group (p = 0.512). Height was 150±18 cm and 148±17 cm (p = 0.571); total body surface area burned was 44±12 % and 49±12 %, respectively (p = 0.072). Measured VO_2 peak (25.1 ± 5.6 mL/min/kg vs. 22.1 ± 4.9 mL/min/kg, p = 0.005) and METS (7.2 ± 1.6 vs. 6.3 ± 1.4, p = 0.004) were significantly higher in the propranolol group. However, the actual values were lower than the predicted values, with the propranolol group being closer to predicted values (R^2 propranolol: 0.24, R^2 control: 0.13).
CONCLUSIONS: This study indicates that patients receiving propranolol can achieve higher VO_2 peak and METS at discharge. However, estimated VO_2 peak and METS using CEq may need to be re-evaluated considering additional factors such as age, gender and body mass index.

Correlation Between Self-reported Physical Activity And Objective Measurement In Children With Cardiac Disease

Jessica S. Hall, Chaitanya Panchangam, Kelli M. Teson, Suma Goudar, Brian Birnbaum, Lindsey Malloy-Walton, Jami Gross-Toalson, Girish Shirali, Anitha Parthiban, David A. White. *Children's Mercy Hospital, Kansas City, MO.*
(No relevant relationships reported)

Children with significant cardiac disease (SCD) have lower levels of physical activity compared to population norms. Few studies have compared objective measures of physical activity (O-PA) to subjective measures of physical activity (S-PA) in children and adolescents with and without SCD.**PURPOSE**: To examine the relationship between S-PA and O-PA in children and adolescents with and without SCD. **METHODS**: Children and adolescents with SCD (n=22; 70% single ventricle physiology, 12% pulmonary hypertension, 27% heart failure) and age and gender matched healthy controls were recruited (Total n=56; mean age 12.5 ± 2.6 years old; 39.3% female). All subjects wore a tri-axial accelerometer over their non-dominant hip for 7 days. The Evenson cutpoints for moderate-to-vigorous PA (MVPA) were applied. A minimum of 3 days with 10 hours of wear time was necessary to be included in the analysis (1 subject excluded due to inadequate wear time). Past year S-PA, in hours/week and MET hours/week, was assessed using the interviewer administered Modifiable Activity Questionnaire for Children or Adolescents (MAQ-C or MAQ-A, respectively). Past 7-day physical activity was assessed with the Physical Activity Questionnaire for Children or Adolescents (PAQ-C or PAQ-A, respectively). Relationships between the MAQ-C/A, PAQ-C/A, and the accelerometer results were assessed using Partial correlations controlled for accelerometer wear time. **RESULTS**: Significant positive relationships were found between the self-reported PAQ-C/A and O- PA in SCD within all intensities of PA (Sedentary r=-0.516, p=0.004; Light r=0.552, p=0.002; Moderate r=0.615, p<0.001; Vigorous r=0.368, p=0.046; MVPA r=0.598, p<0.001). Significant positive relationships were also found between the PAQ-C/A and O-PA in the control group with moderate PA (r=0.503; p=0.024) and MVPA (r=0.493; p=0.027). In the SCD group, there were no significant relationship of O-PA with MAQ hours/week or MAQ MET hours/week. In the control group, youth had significant positive relationships in sedentary PA and MAQ hours/week (r= -0.435, p=0.049) and MAQ MET hours/week (r= -0.450, p=0.041). **CONCLUSIONS**: The self-reported PAQ-C/A had the strongest relationship with O-PA in the SCD group. The PAQ-C/A may be a reliable tool to assess PA in children and adolescents with SCD.

3361   Board #230   June 2 9:30 AM - 11:00 AM

Effects Of A Therapeutic Exercise Program In Children With Non-cf Bronchiectasis: A Randomised Controlled Trial

Barbara E. Joschtel[1], Sjaan R. Gomersall[1], Sean Tweedy[1], Helen L. Petsky[2], Anne B. Chang[3], Stewart G. Trost[3]. *[1]University of Queensland, Brisbane, Australia. [2]Griffith University, Brisbane, Australia. [3]Queensland University of Technology, Brisbane, Australia.*
(No relevant relationships reported)

Non-cystic fibrosis (non-CF) bronchiectasis is a major contributor to respiratory morbidity in children and youth. Current guidelines for this patient group recommend regular exercise to improve clinical outcomes including cardiovascular fitness and quality of life. However, no study has yet evaluated the effects of exercise therapy in children with non-CF bronchiectasis. **PURPOSE:** To evaluate the effect of a 7-week movement program on fundamental movement skill (FMS) proficiency, cardiorespiratory fitness, perceived movement competence, and health-related quality of life (HR-QoL) in children with non-CF bronchiectasis. **METHODS:** Children (n = 21) investigated, mean age 7.1 ± SD 2.3 years with non-CF bronchiectasis were randomly allocated to an exercise or control group. The program consisted of 7 weekly sessions plus home exercises. Each 60-minute session consisted of 6 different developmentally appropriate games, each targeting a specific FMS. The TGMD 2 was used to assess FMS; cardiovascular fitness was assessed measuring % change in exercising heart rate (HR); perceived competence was evaluated by the athletic competence subscale from Harter's Self-Perception Profile for children. HR-QoL was assessed with the PedsQL and parental cough-specific quality of life (PCQOL). A two-way ANOVA was used to assess the effects of the program. Data were analysed according to the intention to treat principle. **RESULTS:** Average HR during sessions was 137 ± 12 bpm. There was a significant group x time interaction for both FMS subgroups, locomotor ($F_{(1,19)}$ = 7.6, p = 0.01) and object control skills ($F_{(1,19)}$ = 8.3, p = 0.01). The exercise group exhibited improvements in both locomotor (pre 29 ± 2.0,

post 35.2 ± 2.2) and object control (pre 27.0 ± 2.0, post 35.5 ± 2.2), while the control group showed minimal changes. The associated effect sizes (Cohen's d = 1.2 and 1.3, respectively) indicated a large effect on FMS. The program improved cardiovascular fitness (5.9% decline in Delta HR) with an effect size commensurate with that reported for asthmatic children completing exercise training (d = 0.5). There were no significant changes in perceived competence and HR-QoL. **CONCLUSION:** A 7-week movement program increases FMS proficiency in children with non-CF bronchiectasis and has a moderate positive effect on cardiovascular fitness.

Predictors Of Insulin Resistance In Obese Adolescents

Armando Cocca[1], Michaela Cocca[1], Grethel Ramirez Siqueiros[2], Oswaldo Ceballos Gurrola[3]. *[1]Texas A&M University San Antonio, San Antonio, TX. [2]State University of Sonora, Hermosillo, Mexico. [3]Autonomous University of Nuevo Leon, Monterrey, Mexico.*

(No relevant relationships reported)

Obesity is a widespread issue that affects people regardless of age, socioeconomic status, culture, or ethnicity. This issue is commonly associated with metabolic risk factors, inherited genes and family history, as well as with unhealthy behavior such as tobacco or alcohol use. Furthermore, obesity is one of the main causes of early manifestation of chronic diseases, which account for about 70% of yearly mortality indexes worldwide. Insulin resistance (IR) is a key element in the chain of events that lead from early obesity to chronic diseases; therefore, IR screening in high-risk individuals must be under constant screening. The Homeostatic Model Assessment (HOMA) constitutes a reliable indirect method for detecting initial signs of IR presence; however, it requires the use of instruments not always available in areas of low income, where accessibility to medical equipment is limited. For this reason, finding reliable, external predictors of IR may be useful to trigger prompt interventions, or to prevent IR raise, while avoiding the need of special tools. PURPOSE: to evaluate a predictive model of IR in adolescents with obesity. METHODS: Blood samples, anthropometric information, and family history were collected from a sample of 216 obese adolescents, patients at the Children Hospital of the State of Sonora, Mexico. Hierarchical Regressions were performed to establish the predictive power of the parameters of the Metabolic Syndrome, hereditary and family history, as well as of Acanthosis Nigricans. HOMA indexes were calculated from blood glucose and insulin. RESULTS. After controlling age and gender, HOMA was significantly predicted through a model ($F = 12.033$; $R2 = .371$; $p < .001$) that included only Acanthosis Nigricans ($b = .142$; $p = .019$). CONCLUSIONS: Acanthosis Nigricans, which can be easily detected through skin exams, may represent an early indicator of risk of high HOMA, and consequently it can be used as a powerful and relatively easy assessment tool for conditions of insulin resistance in patients with obesity.

3363   Board #232   June 2 9:30 AM - 11:00 AM

Comparison of Body Composition in Severely Burned Children Undergoing Community Based Exercise versus Hospital Based Exercise

Evan Ross[1], Shauna Glover[1], Ashley Ewald[2], David Herndon[1], Oscar E. Suman, FACSM[1]. *[1]UTMB, Galveston, TX. [2]University of Tennessee, Chattanooga, TN.* (Sponsor: Oscar Suman, FACSM)

(No relevant relationships reported)

PURPOSE: Severe burns cause long-term bone and muscle loss. Severely burned children (total body surface area burned = TBSA ≥ 30%) enrolled in either hospital based exercise (HBEx) or community based exercise (CBEx) have been shown to preserve their lean body mass, but the effect of these programs on bone density and fat mass are unknown. **METHODS:** Severely burned children were randomly assigned at admit to HBEx or CBEx for 12 weeks to begin after hospital discharge. Dual energy X-ray absorptiometry (DEXA) scans were performed at the start and end of 12 weeks. Body mass index (BMI), lean mass index (LMI), fat mass index (FMI), percent body fat (%BF), and total body bone mineral density (BMD) were recorded. For BMI, LMI, FMI and BMD, normative percentiles for age and gender were determined. Exercise involved aerobic and progressive resistance exercises. Within and between group comparisons were performed using paired and unpaired Student's t-tests, significance was set at p < 0.05. Values are expressed as mean +/- SD. **RESULTS:** 22 patients received HBEx (14.3 ± 3.1 years, 77% male, TBSA = 55 ± 12%) and 12 patients received CBEx (14.0 ± 3.5 years, 83% male, 52 ± 19% TBSA). For HBEx, mean BMI percentile rose from 51 to 63 (p=0.004), LMI percentile rose from 40 to 54 (p=0.005), and BMD percentile fell from 45 to 32 (p=0.003); FMI percentile rose from 34 to 38 (p=0.36) and %BF did not change (p=0.8). For CBEx, mean LMI percentile rose from 54 to 66 (p=0.002); BMI percentile rose from 67 to 71 (p=0.31), FMI percentile rose from 57 to 63 (p=0.11), BMD percentile fell from 57 to 50 (p=0.22) and %BF fell from 29% to 28% (p=0.72). No between group comparisons were significant. **CONCLUSION:** Participation in CBEx resulted in improvements in LMI percentile

for age and gender without changes in %BF or percentile for BMI, FMI, or BMD. HBEx resulted in percentile improvements in LMI, but a decrease in BMD percentile. These results suggest that HBEx and CBEx are equivalent for maintaining lean mass, but their differential effect on BMD deserves further study. This study was supported in part by the National Institute on Disability, Independent Living, and Rehabilitation Research 90DPBU0003, 90DP0043; the National Institutes of Health R01-HD49071, P50-GM060338, T32-GM8256; the Department of Defense W81XWH-09-2-0194, W81XWH-14-2-0160; and Shriners Hospitals 84080.

BMI versus Body Composition as Measures of Success in a Clinical Pediatric Weight Management Program

Amanda Gier, Philip Khoury, Shelley Kirk, Christopher Kist, Robert Siegel. *Cincinnati Children's Hospital Medical Center, Cincinnati, OH.*

(No relevant relationships reported)

PURPOSE: To determine the proportion of patients that achieve favorable changes in body composition in the absence of improvements in body mass index. **METHODS:** Data from 52 months of clinical visits to a pediatric weight management program were extracted from electronic medical records. Body mass index (BMI) and body composition measurements were collected during clinical care. Height and weight were used to calculate BMI. BMI percentile (BMI%ile) for age and gender was determined. Bioelectrical impedance analyzers were used to measure body fat percentage (PBF). Data were analyzed to determine what proportion of patients had a favorable decrease in PBF despite an increased or unchanged BMI. **RESULTS:** Data were obtained for 1741 patients (943 females, 798 males), ages 4-21 years old, with at least two clinical visits. Initial age (±SD) was 12.2 ± 3.1 years. Initial BMI was 32.8 ± 7.0 kg/m[2]. Initial BMI%ile was 98.6 ± 1.7. Initial PBF was 44.0 ± 6.4%. At follow-up, BMI increased or remained unchanged in 1148 patients (66%). PBF decreased in 928 patients (53%). There was an overall increase in BMI (1.20 ± 3.03 kg/m[2], p<0.0001). However, BMI%ile and PBF decreased (-0.31 ± 1.73, p<0.0001 and -0.66 ± 3.94%, p<0.0001). In patients whose BMI increased or remained unchanged, overall BMI%ile and PBF increased (0.15 ± 0.89, p<0.0001 and 0.55 ± 3.15%, p<0.0001). In males, the increase in PBF was small (1.90 ± 0.06, p=0.7). Of the 779 patients whose BMI increased by 1.0 kg/m[2] or more, 239 (30.1%) had a decrease in PBF. **CONCLUSION:** Results suggest that including body fat percentage as a measure of success may be beneficial in a pediatric clinical weight management program. While patients with stable or increasing BMIs did not improve body composition overall, males demonstrated stabilized body fat percentages. In addition, of those patients whose BMI increased by 1.0 kg/m[2] or more, 30% still demonstrated an improvement in body composition. While this may not be clinically significant for the patient population as a whole, it is a measure of success for a specific subset of patients who otherwise may believe they had done poorly. This may act as a motivator for patients to continue with healthier lifestyle changes. Future research in this area may include examining age cut-offs and gender differences for the usefulness of body composition assessment.

Enhanced Erythrocyte Antioxidant Status Following an 8-Week Aerobic Exercise Training Program in Heavy Drinkers

Athanasios Z. Jamurtas[1], Kalliopi Georgakouli[1], Eirini Manthou[1], Panagiotis Georgoulias[2], Chariklia Deli[1], Yiannis Koutedakis[1], Yannis Theodorakis[1], Ioannis Fatouros[1]. *[1]university Of Thessaly, Department Of Physical Education & Sport Science, Trikala, Greece. [2]university Of Thessaly, Department Of Nuclear Medicine, Trikala, Greece.*

(No relevant relationships reported)

Alcohol-induced oxidative stress is involved in the development and progression of various pathological conditions and diseases whereas exercise training has been shown to improve redox status, thus attenuating oxidative stress-associated disease processes. **PURPOSE:** to evaluate the effect of an exercise training program on blood redox status in heavy drinkers. **METHODS:** Eleven sedentary, heavy drinking men participated in an intervention where they completed an 8-week supervised aerobic training program of moderate intensity. Blood samples were collected before, during (week 4) and after intervention and analyzed for total antioxidant capacity (TAC), thiobarbituric acid reactive substances (TBARS), protein carbonyls (PC), uric acid (UA), bilirubin, reduced glutathione (GSH) and catalase activity. **RESULTS:** Catalase activity increased ($p<0.05$) after 8 weeks (340.7±13.3 U mg/Hb) of intervention compared to week 4 (299.5±18.7 U mg/Hb). GSH increased ($p<0.05$) after 8 weeks of intervention (1.22±0.16 μmol/g Hb) compared to the control condition (1.11 ± 0.17 μmol/g Hb) and to week 4 (1.11 ± 0.15 μmol/g Hb). TAC, UA, bilirubin, TBARS and PC did not significantly change at any time point. **CONCLUSION:** An 8-week aerobic

training program enhanced erythrocyte antioxidant status in heavy drinkers, indicating that aerobic training may attenuate pathological processes caused by alcohol-induced oxidative stress.

(No relevant relationships reported)

Background: An age related loss of muscle mass is frequent among older adults, a phenomenon termed sarcopenia. In order to circumvent this age related phenomenon, nutritional strategies of increased protein intake has been proposed, however studies investigating the effect of long-term habituation to divergent protein intakes are scarce. In this study we wish to examine if divergent levels of protein intake, is reflected in postprandial whole body protein kinetics in older male subjects.
Method: 12 male subjects ages 65-70 were included in a double blinded cross-over study, where each intervention consisted of a 21-day habituation period to either low or high protein intake (0.6-0.8 g/kg body weight (BW) or above 1.5 g/kg BW, respectively) interspersed by at least 60 days. At the end of each habituation period, subjects met in to an experimental trial with a primed, constant infusion of D_8-PHE. A baseline blood sample was taken 90 min after infusion start. Hereafter, intrinsically labeled milk proteins, ^{15}N-phenylalanine (PHE) caseinate and D_5-PHE whey were ingested in a breakfast meal. In the postprandial period blood sample were taken at 30, 60, 90, 120, 150, 180 and 240 min. All blood samples were analyzed for amino acid concentrations and PHE tracer enrichments on LCMSMS system. The gastro-intestinal (GI) absorption rate of the milk-protein derived amino acids was estimated from the appearance rate of the milk protein bound PHE tracers. The whole body protein degradation rate was calculated by subtracting the exogenous PHE appearance from the total PHE rate of appearance.
Results: The absorption rate of PHE from casein protein was elevated in the late postprandial period after being habituated to low protein intake (interaction: P=0.01, N=6). The absorption rate of whey protein and the endogenous rate of PHE appearance (whole body degradation rate) were not affected in the postprandial period by the habituated level of protein intake.
Conclusion: When habituated to a low protein diet preliminary results reveal that the absorption rate of slow digestible dietary protein is enhanced while the whole body protein degradation is not affected in the postprandial phase.

Effect Of An Unhealthy Lipoprotein Distribution On Muscle Protein Synthesis Response To Whey Protein Feeding

Jakob Agergaard[1], Mie C F Zillmer[1], Kenneth Mertz[1], Grith Højfeldt[1], Peter Schjerling[1], Lars Holm[2]. [1]*Institute of Sports Meidicine, Bispebjerg Hospital, Copenhagen, Denmark.* [2]*School of Sport, Exercise and Rehabilitation Sciences, University of Birmingham, Birmingham, United Kingdom.*

(No relevant relationships reported)

Introduction: Sarcopenia can be linked to dyslipidemia. The present study investigated how an unhealthy lipoprotein distribution (LPD) affects the sensing of hyperaminoacidemia and determines causality between LPD and development of resistance towards muscle anabolic stimuli such as whey-protein feeding.
METHODS: APOE-/- mice (n=12 per time-point) that develop an unhealthy LPD were compared to WT-mice (n=12 per time-point). Change in body composition was accessed from 10-20 weeks of age. At 20 weeks of age an acute trial was conducted to compare; muscle protein synthesis (MPS) measured by Puromycin labeling at post-

absorptive basal state and two post-prandial periods; 0-0.5h, and 1.5-2h post whey-protein feeding, and underlying anabolic mechanisms were accessed by RT-qPCR.
RESULTS: From 10-20 weeks of age, the body weight of the APOE-/- mice increased less than the WT-mice (p<0.05), whereas the lean body mass increased equally for the APOE-/- and WT-mice. Surprisingly, whey-protein did not significantly affect MPS in the post-prandial period. At 20 weeks of age, APOE-/- mice had a greater mRNA-expression for SNAT2, CD98, ATF4 and GCN2 compared to WT-mice (P<0.05). The mRNA-expression of Beclin1 was lower in APOE-/- mice compared to WT-mice (P<0.05). SLC38A9 responded to whey-protein feeding with a greater mRNA-expression at 0.5h post-feeding compared to post-absorptive state and 2h post-feeding (P<0.05).
CONCLUSIONS: In contrary to our hypothesis, no difference was seen between WT and APOE-/- mice in the post-prandial MPS. mRNA-expression of targets involved in amino acid sensing, and anabolic and catabolic pathways, indicated that APOE-/- mice were metabolic challenged and possibly amino acid deprived.

The Effects of Protein Type and Added Leucine on Myofibrillar Protein Synthesis Following Concurrent Exercise

Tyler A. Churchward-Venne[1], Philippe J.M. Pinckaers[1], Joey S.J. Smeets[1], Wouter M. Peeters[1], Ian Rollo[2], Luc J.C. van Loon[1]. [1]*Maastricht University, Maastricht, Netherlands.* [2]*Gatorade Sports Science Institute, Leicester, United Kingdom.*

Reported Relationships: T.A. Churchward-Venne: *Contracted Research - Including Principle Investigator; This study was externally funded by GSSI, a division of PepsiCo Inc. Any opinions or scientific interpretations expressed in this manuscript are those of the author and do not necessarily reflect the, position or policy of PepsiCo Inc.*

Protein ingestion increases skeletal muscle protein synthesis (MPS) rates. The effect of protein on MPS rates is enhanced by prior exercise. However, the effect of different types of protein on MPS is unclear and has not been evaluated following concurrent exercise. **PURPOSE:** The objective of this study was to determine the capacity of total milk protein (MILK), whey (WHEY), micellar casein (CASEIN), and soy protein, without (SOY) and with additional leucine (SOY+LEU) to support postprandial myofibrillar protein synthesis (MyoPS) following concurrent exercise. **METHODS:** 72 young recreationally active males participated in this parallel group, double-blind, randomized controlled trial consisting of two arms. In arm #1, 48 subjects (23±0.3 y) ingested 45 g of carbohydrate with either 0 g protein (CHO), or 20 g MILK, WHEY, or CASEIN protein. In arm #2, 36 subjects (23±0.5 y) ingested 45 g of carbohydrate with 20 g WHEY, SOY, or SOY+LEU. A primed continuous infusion of L-[ring-$^{13}C_6$]-phenylalanine with blood and muscle biopsies was applied to evaluate postprandial MyoPS over 360 minutes after exercise. **RESULTS:** In arm #1, MyoPS did not differ between treatments (*P*=0.12) during the postprandial period after exercise (FSR: CHO=0.051±0.003; MILK=0.061±0.003; WHEY=0.056±0.002; CASEIN=0.062±0.005 %/h). When MILK, WHEY, and CASEIN were collapsed into a single group (PROTEIN), protein-carbohydrate co-ingestion resulted in greater MyoPS rates than carbohydrate alone (FSR: PROTEIN=0.060±0.002; CHO=0.051±0.003 %/h; *P*=0.042). In arm #2 MyoPS did not differ between treatments (*P*=0.85) after exercise (FSR: WHEY=0.056±0.002; SOY=0.056±0.004; SOY+LEU=0.058±0.004 %/h). **CONCLUSION:** Total milk protein, whey, and micellar casein (arm #1) do not differ in their capacity to support postprandial MyoPS rates when co-ingested with carbohydrate following concurrent exercise in young males. Similarly, whey and soy protein, irrespective of leucine enrichment of soy (arm #2), do not differ in their capacity to support postprandial MyoPS after concurrent exercise. Co-ingestion of protein with carbohydrate results in greater postprandial MyoPS rates than carbohydrate alone, and may therefore represent a nutritional strategy to support skeletal muscle remodeling following concurrent exercise.

The Effect of Whey Protein Supplementation on the Recovery of Contractile Function following Resistance Training

Robert W. Davies[1], Joseph J. Bass[1], Brian P. Carson[1], Catherine Norton[1], Marta Kozior[1], Matthew S. Brook[2], Daniel J. Wilkinson[2], Philip J. Atherton[2], Ken Smith[2], Philip M. Jakeman[1]. [1]*University of Limerick, Limerick, Ireland.* [2]*University of Nottingham, Nottingham, United Kingdom.*

Reported Relationships: R.W. Davies: *Contracted Research - Including Principle Investigator; Food for Health Ireland, Prof. Philip Jakeman.*

PURPOSE: This study investigated the effect of supplemental whey protein (WP) on acute measures of muscle protein fractional synthetic rate (FSR) and the recovery of skeletal muscle contractile function during repeated bouts of resistance training (RT).
METHODS: Sixteen resistance-trained men (80 [13] kg body mass; 23 [4] y; 2.6 [1.2] y RT experience; mean [SD]) completed the 7-day dietary supplement

intervention study. Subjects were randomly assigned to consume each morning in a double-blind manner either a WP supplement (WP; 0.33 g/kg; n = 8) or an isocaloric, isonitrogenous, non-essential amino acid control (CON; 0.33 g/kg n = 8) with a timed and standardised diet (35 kcal/kg/day; 2 g/kg/day protein). Peak isometric squat force (ISQ) and countermovement jump displacement (CMJ) were used to assess baseline contractile function. Subjects then completed three RT bouts (0.7 1RM back squat; 10 repetitions per set; 0.25 duty cycle; point of exhaustion = 8 [2] sets), every other day. Other activities of daily living did not exceed 3 metabolic equivalents. Repeat measurement of ISQ, CMJ, muscle pain and serum creatine kinase (CK) activity (an index of muscle damage) was taken pre-RT, +24h and +48h post-RT, each bout. Muscle protein FSR was measured between muscle biopsies taken from the vastus lateralis pre- and 5 h post- the first RT intervention using the D(2)O stable isotope tracer technique. The observed changes are reported as the mean [low, high] 90% CI, p-value (P).
RESULTS: A 1.0 [0.7, 1.3] fold increase (P < 0.008) in CK and muscle pain (20 [10, 30] %; P = 0.011) was observed +24h the first RT bout only, confirming an absence of overt muscle damage. An acute loss of ISQ was observed following all RT bouts +24h (-19 [-21, -17] %; P < 0.001) and +48h for ISQ (-19 [-21, -17] %; P < 0.001), and +24h for the CMJ (-7 [-9, -5] %; P < 0.05). Whilst acute FSR was increased for WP over and above the CON (+ 0.275 [0.148, 0.403] %/day; P = 0.07), no discernible difference between WP and CON was observed for any measure of contractile function, pain, or CK (P > 0.493).
CONCLUSIONS: We conclude that, whilst peri-RT supplementation with WP augments muscle protein FSR, further inference of this pro-anabolic effect should not extend to acute (0 to 48 h) recovery of peri-RT muscle contractile function.

Dietary Sodium Restriction Changed Calcitonin, T3, T4, and Urinary Mineral Excretion in Healthy Women

Naho Serizawa[1], Mamoru Nishimuta[1], Naoko Kodama[2], Mieko Shimada[3], Yutaka Yoshitake[4], Nobuko (kay) Hongu, FACSM[5]. [1]Graduate School of Toyo University, Gunma, Japan. [2]Tokyo Shokuryo Dietitian Academy, Tokyo, Japan. [3]Chiba prefecture University of Health Sciences, Chiba, Japan. [4]National Institute of Fitness and Sports in Kanoya, Kagoshima, Japan. [5]University of Arizona, Tucson, AZ.
(No relevant relationships reported)

PURPOSE: The purpose of this study was to examine the relationship between dietary sodium (Na) restriction and levels in hormone and urinary mineral excretion.
METHODS: We used a part of the metabolic balance study (the duration: 21 days) data carried out in 2004. Subjects were 11 healthy women, aged 19-23 yrs. They were divided into two levels of dietary Na groups (G), *i.e.* Na restricted (R) G (n = 5) (NaCl: 6 g/d) and the Control G (n = 6) (NaCl: 12 g/d). Aldosterone (ALD), calcitonin (CT), parathyroid hormone, triiodothyronine (T3) and thyroxine (T4) were measured from the blood samples collected in the fasting morning. The second voided early morning urine (EMU) minerals {Na, potassium (K), calcium (Ca), magnesium (Mg), phosphorus (P) and zinc (Zn)} were also measured.
RESULTS: ALD and CT levels were significantly higher in the Na RG than in the Control G (ALD: 16.5 ± 5.2 *vs.* 11.2 ± 3.4 ng/dL p<0.001, CT: 34.6 ± 14.1 *vs.* 21.7 ± 10.0 pg/mL, p<0.05). T3 and T4 levels were significantly lower in the Na RG than in the Control G (T3: 99.1 ± 22.8 *vs.* 111.1 ± 14.9 ng/dL p<0.05, T4: 6.2 ± 1.3 vs. 6.9 ± 1.1 µg/dL p<0.01). EMU-Na, Ca, Mg, P and Zn of the Na RG concentrations were significantly lower than those of the Control G (Na: 0.7 ± 0.4 *vs.* 1.5 ± 0.8 µmol/kg body weight (BW)/min p<0.001, Ca: 19.3 ± 11.3 *vs.* 33.0 ± 16.6 nmol/kg BW/min p<0.001, Mg: 33.6 ± 10.2 *vs.* 38.9 ± 9.5 nmol/kg BW/min p<0.001, P: 165.0 ± 55.9 *vs.* 193.7 ± 57.4 nmol/kg BW/min p<0.05, Zn: 50.1 ± 12.4 *vs.* 64.1 ± 20.0 pmol/kg BW/min p<0.01), respectively.
CONCLUSION: Our data showed that dietary Na restriction increased calcitonin and decreased both T3 and T4, and decreased minerals in the EMU. It was revealed that dietary Na restriction affects most of EMU-minerals as well as Na. This suggests that Na affected to the metabolism of the other minerals. Further studies are required to confirm the effects of Na restriction on the hormones.

Effects of Olive Oil Phytochemicals and Exercise on Circulatory Leukocytes and Inflammation in Atherosclerotic Rats

Tianou Zhang[1], Tao Liu[1], Yuzi Zhang[1], Jose Amerigo[2], Jing Shao[1], Dongwook Yeo[1], Li Li Ji, FACSM[1]. [1]University of Minnesota-Twin Cities, Minneapolis, MN. [2]International Society for Oleocanthal, Malaga, Spain.
(No relevant relationships reported)

Oleocanthal (Oleo) and Oleacein (Olea) are natural phenolic compounds found in extra-virgin olive oil (EVOO), exerting anti-inflammatory and antioxidant effects. Atherosclerosis, led by arterial plaque deposition, involves increased chronic

inflammation and oxidative stress. **PURPOSE:** The purpose of the study is to evaluate the immuno-regulatory and anti-inflammatory effects of Oleo/Olea supplementation and exercise training in the atherosclerotic rats. **METHODS:** Female Sprague-Dawley rats (age 4-week, n=48) were randomly divided into 4 groups fed an atherogenic diet (C) with added cholesterol (1.25%) and cholic acid (0.5%) for 12 wks. Half of the rats were supplemented with high Oleo/Olea (1000 mg/kg, HO, n=24); the other half with low Oleo/Olea (100 mg/kg, LO, n=24). In each dietary group, half group was trained (T) on treadmill for 12 wks (25m/min, 10% grade for 60 min/day, 5 days/wk), while the other half remained sedentary (S). Two separate groups of rats were fed a chow diet (n=6) and atherogenic diet (n=12), respectively without EVOO or T. Total leukocytes and differential were measured using flow cytometry. Total nitrate/nitrite (NOx) contents were determined by colorimetric assay kit. Data were shown as mean ± SEM and analyzed using two-way ANOVA. **RESULTS:** Leukocytes percentage was higher in HO vs. LO rats (P<0.05), but lowered 32% by T (P<0.05). LO and HO rats showed higher granulocytes percentage than C rats (P<0.05), whereas T suppressed granulocytes in HO by 27% (P<0.05). Neutrophils percentage was increased in HO vs. C and LO rats (P<0.05), but declined by 41% with T (P<0.01). Lymphocytes percentage was decreased in LO and HO rats (P<0.05) and elevated in HO+T by 23% (P<0.05). In addition, T tended to increase monocytes levels in LO rats (0.05<P<0.1). Total NOx levels in EVOO-fed rats were decreased compared to C rats (P<0.05), whereas it was higher in HO-fed vs. LO-fed rats (P<0.05). T tended to decrease NOx in LO but increase NOx in HO rats (P=0.052, interaction effect). **CONCLUSION:** High Oleo/Olea diet increased leukocytes, granulocytes and neutrophils percentage but decreased lymphocytes in sedentary rats, whereas exercise training significantly reversed these trends of immune markers.

Effects Of A Novel Probiotic On Exercise-Induced Gut Permeability and Microbiota in Endurance Athletes

Connery J. Brennan, Christopher L. Axelrod, Deborah Paul, Michaela Hull, John P. Kirwan, FACSM. Cleveland Clinic Lerner Research Institute, Cleveland, OH.
(No relevant relationships reported)

Exercise-induced hyperpermeability of the gastrointestinal (GI) tract contributes to abdominal pain, bloating, and fatigue; symptoms commonly expressed in Inflammatory Bowel Disease, Celiac's Disease, and Type 1 Diabetes. Therapies that can ameliorate the symptoms and conditions are lacking. **Purpose:** To assess the efficacy and feasibility of *Lactobacillus Salivarius* (UCC118) supplementation on GI permeability in healthy humans. **Methods**: In a randomized, double blind crossover study, 7 highly-trained endurance athletes (31 ± 6.11 y, VO$_{2max}$ ≥ 57.3 ± 9.3 ml/kg/min) received 4 weeks of daily probiotic or placebo supplementation. The initial 4 week period was followed by a 4 week washout, followed by an additional 4 weeks of placebo or probiotic supplementation. GI permeability, blood chemistry, and fecal microbiota were assessed before and after each 4 week intervention period. GI permeability was challenged using 2 hours of continuous treadmill running at 60% VO$_{2max}$. After 20 minutes of running, subjects ingested 5 grams of L-rhamnose, sucrose, and lactulose. Urine was collected before, immediately after, and every hour for 5 hours after exercise. GI permeability was measured as sugar recovered in urine as determined by LC-MS/MS. Metagenomic sequencing was performed on fecal samples with Illumina HiSeq 4000 utilizing a 2 x 150 configuration for an average of 120-130M paired end reads per sample. Beta diversity was estimated using Bray-Curtis method to reveal the microbial diversity between pre and post intervention samples. **Results:** Compared to placebo, UCC118 treatment reduced area under the curve for urine (N=5) sucrose (P=0.081) and rhamnose recovery (P=.100). Gut taxonomy sequencing revealed significant changes in 60 bacterial species (P<0.05) after UCC118 supplementation. Additionally, there was an increase in microbial diversity after probiotic use.
Conclusion: The results described herein provide proof of principle that 4 weeks of UCC118 supplementation attenuates exercise-induced intestinal hyperpermeability. Molecular processes are ill-defined, so further investigation is needed to determine associated pathways, protein interactions, and impact of specific bacterial taxa. Study supported by external sponsor.

The Caloric Costs and Metabolic Benefits of Wilderness Hunting in Alaska

Robert H. Coker, FACSM[1], Melynda S. Coker[1], Larry Bartlett[2], Carl J. Murphy[1], Karolina Priebe[1], Timothy Shriver[3], Dale A. Schoeller[3], Brent C. Ruby, FACSM[4]. [1]University of Alaska Fairbanks, Fairbanks, AK. [2]Pristine Ventures, LLC, Fairbanks, AK. [3]University of Wisconsin, Madison, Madison, WI. [4]University of Montana, Missoula, MT.
(No relevant relationships reported)

Epidemiological investigations have supported the healthy benefits of subsistence foods. Surprisingly, the health benefits derived from the nomadic nature of humans during the Paleolithic era have been understudied. Hunting and gathering activity that occurs far from the conveniences of civilization on public land most likely represent

the closest example of this ancient lifestyle that thrived for thousands of years. **PURPOSE:** To determine the energy demands, and changes in body composition and metabolic risk factors in humans during a 12-day wilderness hunting immersion. **METHODS:** Four healthy men (age: 42±1 yr, BMI: 27±2 kg/m²) without any known cardiovascular, neurolological, pulmonary or metabolic pathology were recruited for participation in the study. Total energy expenditure (TEE) was measured using the doubly labeled water method and a written food diary was utilized to estimate total energy intake (TEI). Body composition was measured using dual energy x-ray absorptiometry; cross sectional area of the upper thigh (XT) and intrahepatic lipid (IHL) was measured using magnetic resonance imaging/spectroscopy. Fasted blood samples were collected for the measurement of total cholesterol (TC), high (HDL) and low-density lipoproteins (LDL). Results were analyzed using paired t-tests, presented as means±SEM and considered significant at P<0.05. **RESULTS:** TEE and TEI were 4226±219 kcal/day and 2499±422 kcal/day, respectively, and resulted in a caloric deficit of 1726 kcal/day. There was a decrease in body weight (-3.2±0.2 kg), total fat mass (-3.1±0.1 kg) and visceral fat volume (-261±47 cm³). In contrast, total, leg and arm lean tissue mass and XT were preserved. There was a decrease in IHL (-0.5±0.1 % water peak). Beneficial trends were noted in blood lipids, but two of the four participants did not have their blood samples collected due to conflicts with weather and bush flight schedules. **CONCLUSION:** In the context of a chronic caloric deficit, adipose tissue and IHL decreased without any reduction in lean tissue mass or muscle mass. These alterations may reflect the interactive influence of movement constancy and caloric deficit on the health benefits of the hunter-gatherer lifestyle. Supported by NIH grant UL1GM118991, TL4GM118992, or RL5GM118990 and by a grant from the University of Montana.

The Effects Of Acute Exercise On Npy/AgRP And POMC Neuron Activity In The Mouse Hypothalamus
Wyatt P. Bunner, Brenton T. Laing, Hu Huang. *East Carolina University, Greenville, NC.*
(No relevant relationships reported)

NeuroPeptide Y/Agouti-related peptide (NPY/AgRP) and pro-opiomelanocortin (POMC) neurons are key components of the neuronal circuits that respond to various physiological condition to regulate food intake and energy homeostasis. However, far less is known about how these neurons respond to acute exercise. **PURPOSE:** To determine effects of acute exercise on the activity of AgRP/NPY and POMC neurons in the mouse hypothalamus. **Methods:** NPY-GFP reporter mice were utilized in 3 separate experiments. We randomly assigned cohort 1 (N=6) mice to a treadmill exercise with a speed of 13 M/min and an 8.75% grade for a duration of an hour group or a sedentary group, blood glucose was measured immediately post-exercise. Mice were then intracardially perfused, and their brains were isolated to examine the colocalization of the neuronal activation marker c-FOS and the signaling marker for phosphorylation of extracellular signal-regulated kinases (p-ERK) in NPY-GFP and POMC neurons. In cohort 2 (N=7) food intake was assessed following the same treadmill conditions over a 24-hour period. In the final cohort, (N=5) patch-clamp electrophysiological recordings were used to quantify changes in NPY-GFP neuron firing rate induced by exercise. **Results:** Despite normal glucose levels and food intake after the acute treadmill exercise, c-FOS and p-ERK in NPY/AgRP neurons are significantly increased (p<.05) in the exercised mice compared to the control mice. This result was further confirmed by electrophysiological recording shows that the firing rate was increased in the NPY/AGRP neurons of exercised mice. In contrast, exercise induced c-FOS expression was decreased in the POMC neurons of exercised mice. **Conclusion:** Acute treadmill exercise increases NPY/AgRP neuron activation, whereas POMC neuron activation is decreased. The responsiveness of these neurons to acute exercise is independent from food intake and glucose regulation but might associate with exercise-induced phosphorylation of ERK in the mouse hypothalamus. Supported by East Carolina University start-up fund.

Markers of Non-Functional Overreaching Syndrome During the Race Across America (RAAM): A Case Study
Edward K. Merritt[1], David C. Nieman, FACSM[2], Brian E. Barnett[3], Lauren E. Parrish[4], Kathryn Cardwell[5], Brian R. Toone[6], Arnoud Groen[7], Artyom Pugachev[7]. *[1]Southwestern University, Georgetown, TX. [2]Appalachian State University, North Carolina Research Campus, Kannapolis, NC. [3]Delta State University, Cleveland, MS. [4]University of Kansas, Lawrence, KS. [5]University, Shell Lake, WI. [6]Samford University, Homewood, AL. [7]ProteiQ Biosciences GmbH, Berlin, Germany.*
(No relevant relationships reported)

In a previous study, global proteomics procedures identified blood proteins as potential overreaching and overtraining biomarkers, and a targeted proteomics panel of 21 proteins was developed. **PURPOSE:** To measure targeted blood protein changes in

an athlete competing in RAAM. **METHODS:** The 40-y old male athlete underwent fitness testing 4-wks pre-RAAM and 4-d post-RAAM to determine body composition and aerobic cycling capacity. During RAAM training distress score (TDS) and body mass were measured one and 2 times per day. Power output and heart rate (HR) were continuously measured during cycling. Fingerprick samples for dried blood spot samples (DBS) were obtained 4 wks, 24-h, and 2-h before the start of the race, twice per day of the race (morning/evening), and after 1 and 4 d recovery. Proteins were resolubilized from the DBS and digested with trypsin before targeted proteomics measurements (Multiple Reaction Monitoring) on an Agilent 6400 QqQ LC-MS/MS. Data was processed and analysed using Skyline. **RESULTS:** The athlete completed the 4941-km race in 10.1 d at an average moving speed of 24.5 km/h. He cycled for 20.0 h/d, with 20 h sleep for the duration of the race. Power output was 102.6 ± 8.9 watts with the highest 24-h power in the first and last 24 h (108 vs. 120 watts). TDS was 1 before the start and increased to 30 by the finish. Post-RAAM maximal aerobic capacity was 6.3% lower (61.6 vs. 57.5 mL·kg⁻¹· min⁻¹), and maximal HR declined 5.7% (192 vs. 181 beats/min). No changes in body mass or composition occurred. The % change in blood proteins was calculated using the average of the 2 pre-race samples and 5 samples collected on days 8, 9, and the first day of recovery. The 5 blood proteins from the DBS samples that increased the most during RAAM included complement component C7 (359%), complement C4-B (231%), serum amyloid A-4 protein (210%), inter-alpha-trypsin inhibitor heavy chain H4 (191%), and alpha-1-antitrypsin (188%). **CONCLUSION:** This case study of an ultra-endurance athlete competing in the 2017 RAAM event (4th overall) showed the typical decrease in maximal exercise performance associated with non-functional overreaching. Targeted proteomics procedures from DBS samples showed that the largest increases were measured for immune-related proteins that are involved with complement activation and the acute phase response.

Safety Of Sub-maximal Aerobic Exercise During The Sub-acute Phase Of Recovery Following Sport-related Concussion
Phillip R. Worts[1], Scott O. Burkhart[2], S. Daniel Petty[3], Lynn B. Panton, FACSM[1], Michael J. Ormsbee, FACSM[1], Cathy W. Levenson, FACSM[1], Jeong-Su Kim, FACSM[1]. *[1]Florida State University, Tallahassee, FL. [2]Children's Health Andrews Institue, Plano, TX. [3]Centre Pointe Health and Rehabilitation, Tallahassee, FL.*
(No relevant relationships reported)

Previous research suggests that strict rest for 5 days following a concussion may prolong symptom presentation. Sub-maximal aerobic exercise is an efficacious treatment for post-concussion syndrome but therapeutic aerobic exercise is not well described in sub-acutely concussed patients. **PURPOSE**: To determine if sub-maximal aerobic exercise could be safely performed in the days following a sport-related concussion. **METHODS**: Fifteen participants (16 ± 1.5 years; 9 males; 6 females) were assigned using a randomized block design to a 40% Age-Predicted heart rate (HR)$_{MAX}$ (40HR), 60% Age-Predicted HR$_{MAX}$ (60HR), or seated rest control (CON) group. Participants exercised after their initial evaluation between Day 3 and Day 7 (4 ± 1.2 days) following their concussion. Participants' HR and symptoms were monitored during the treatment. Descriptive statistics and a two-way mixed ANOVA were performed using SPSS 22. **RESULTS**: Fourteen (93%) participants were able to complete the treatment session. There was a significant interaction between group and time on heart rate $F(3.690, 20.297) = 5.163$, $P = 0.006$, partial n² = 0.484. HR was significantly higher in the 60HR group versus the 40HR and CON groups throughout the 20-minute treatment. The range of symptoms provoked during the treatment were: Balance problems +4 to -2; Dizziness 0 to -4; Headache 0 to -3; Fatigue 0 to -2; and Fogginess 0 to -5. **CONCLUSIONS**: To our knowledge, this is the first study to examine aerobic exercise as a therapeutic modality during the sub-acute phase of concussion recovery. The majority of our participants were able to tolerate aerobic exercise within the first 3-7 days following a concussion and also reported a reduction in symptom severity.

Is More Physical Activity Always Better? Constrained vs Additive Total Energy Expenditure Models.
Erik A. Willis[1], Pedro F. Saint-Maurice[1], Herman Pontzer[2], Charles E. Matthews, FACSM[1]. *[1]National Cancer Institute, Bethesda, MD. [2]Hunter College, New York, NY.*
(No relevant relationships reported)

PURPOSE: Strategies for the prevention and treatment of obesity require a better understanding of the association between physical activity (PA) and total energy expenditure (TEE). Current strategies are based on an additive model, where TEE and PA increases in a dose-dependent manner. However, recent evidence suggests a constrained TEE model, where increases TEE plateaus at higher levels of PA as the body adjusts to maintain an equilibrium of TEE through metabolic adaptations. Our aims were to examine the shape of the relationship between PA and TEE and to

assess the role of energy balance status (negative, stable, positive) in this association. **METHODS**: Participants were 642 older adults (50-74 yrs.) participating in the Interactive Diet and Activity Tracking in AARP study. TEE was assessed by doubly labeled water. PA, assessed by accelerometer, was estimated using three methods to calculate total PA: Vertical Axis counts per minute (CPM), Vector Magnitude CPM, and MET-hrs./d (using a machine learning algorithm [Sojourn-3x]). TEE for each subject was adjusted for anthropometric and demographic factors using linear regression. The relationshop between PA and TEE was assessed using linear (i.e., correlations) and non-linear parameters (e.g., nonparametric LOESS regression curves). Percent weight change over a six month period of assessment was calculated as a proxy measurement of energy balance status. **RESULTS**: The difference in TEE between the top and bottom deciles of PA was +376(SD=341) kcal/d in the total sample, +499(SD=347) kcal/d in men, and +229(SD=318.4) kcal/d in women. TEE was positively associated with PA levels estimated by Vertical Axis (r= 0.36; <0.0001), Vector Magnitude (r= 0.39; <0.0001), and MET-hrs./d (r= 0.40; <0.0001). There was no evidence of a plateau in TEE as demonstrated by the LOESS curves or the change in median TEE over PA deciles. Individuals who lost ≥3% of their body weight showed evidence of a plateau in TEE at higher levels of PA. **CONCLUSIONS**: Overall, PA was associated with TEE in a linear dose-dependent manner. For individual who lost weight, TEE was positively correlated with physical activity, but the relationship was stronger over the lower ranges of TEE. This study provides evidence to adopt a dynamic model for estimating energy expenditure as it pertains to obesity.

Associations Of Skeletal Muscle And Appendicular Lean Body Mass With Blood Pressure And Hypertension

Sunyue Ye, Chaonan Zhu, Chen Wei, Da Gan, Shankuan Zhu. *Zhejiang University, Hangzhou, China.*
(No relevant relationships reported)

PURPOSE: Previous studies have shown the negative effects of body fat on blood pressure (BP). However, the associations between skeletal muscle and BP remain unclear. The present study was aimed to investigate the associations of total skeletal muscle (TSM) and appendicular lean body mass (LBM) including leg and arm, with BP and hypertension.
METHODS: Data from 3,130 participants aged 18 to 80 years old were analyzed. Appendicular LBM including leg and arm were obtained from dual-energy X-ray absorptiometry. TSM was calculated based on appendicular LBM. Other LBM indices included TSM, and appendicular, leg and arm LBM divided either by weight, or by squared height. Adjusted multivariate linear or logistic regression models were used to analyze the associations of TSM and appendicular, leg, and arm LBM with BP or hypertension, respectively. To further investigate the associations of regional LBM with BP, arm and leg LBM were put in the linear regression models together, and the Wald test was used to compare the standardized parameter coefficients of arm and leg LBM.
RESULTS: TSM, and appendicular, leg and arm LBM indices were all positively associated with elevated systolic or diastolic BP after controlling for potential confounders including body fat percent and android to gynoid fat ratio, except for appendicular and leg LBM/weight. In addition, higher odds of having hypertension were observed in all TSM and appendicular LBM indices, except for leg LBM/weight. The standardized beta coefficients of arm LBM indices on systolic and diastolic BP were significantly higher than relevant indices of leg LBM, except for arm LBM/height^2 on systolic BP.
CONCLUSIONS: Total skeletal muscle and appendicular LBM especially in arms were positively associated with elevated blood pressure and hypertension, after controlling of potential confounding factors including body fat and fat distribution. Our results suggested that excess skeletal muscle especially in upper extremities may have a negative impact on BP and hypertension. Future longitudinal studies are warranted to confirm our findings.

Optimal Level of Objectively Measured Physical Activity for Long-Term Weight Loss

Danielle M. Ostendorf[1], Janet K. Snell-Bergeon[1], Jan P. Lande[1], Anna E. Baron[1], Angela D. Bryan[2], Sarah J. Schmiege[1], Dawn Comstock[1], Edward L. Melanson, FACSM[1], Victoria A. Catenacci[1]. [1]*University of Colorado Anschutz Medical Campus, Aurora, CO.* [2]*University of Colorado Boulder, Boulder, CO.*
(No relevant relationships reported)

Purpose: Existing physical activity (PA) guidelines for weight management have relied heavily on self-reported PA measures, which are typically overestimated. Our purpose was to determine the optimal level of *objectively* measured PA for sustaining long-term weight loss.
Methods: We conducted a secondary analysis of an 18 month behavioral weight loss trial, which included an exercise prescription of 300 min/wk of moderate-intensity PA. Participants received 6 months of supervised exercise during either months 0-6 or 7-12,

followed by 6 months of unsupervised exercise during either months 7-12 or 12-18. PA was objectively measured with the SenseWear armband; Participants with valid wear time (≥12 hr/d awake time on ≥3 weekdays and ≥1 weekend day) upon completing unsupervised exercise were included in analyses. Sustained bouts (≥10 min) of activity ≥3 METS were converted to moderate-to-vigorous intensity PA (MVPA). Receiver-operating characteristic curve analyses determined the optimal duration of bout MVPA to achieve ≥5% or ≥10% weight loss at 18 months. To identify the optimal cutoff, the Youden index (sensitivity + specificity - 1) and 95% bootstrap percentile confidence intervals were calculated using RStudio (pROC package). A linear mixed effects model examined the association between bout MVPA and weight loss.
Results: Participants included 143 adults (age 39.6±9.4 years, BMI 34.2±4.0 kg/m^2, 87% female); 102 provided an 18-month weight and of these, 82 had valid SenseWear data after completion of unsupervised exercise. The optimal level of bout MVPA upon completion of unsupervised exercise was (median (95% bootstrap CI)) 209 (144-301) min/wk to achieve ≥5% weight loss at 18 months or 267 (108-449) min/wk to achieve ≥10% weight loss at 18 months. There was a dose response relationship between bout MVPA and weight loss. Participants who met 5-9.9% or ≥10% weight loss at 18 months were at mean±SD 270±143 or 316±256 min/wk of bout MVPA upon completion of unsupervised exercise.
Conclusions: Results confirm the importance of high PA levels for sustaining clinically meaningful weight loss. These data validate existing guidelines with objective PA measures and suggest that ~200-300 min/wk of bout MVPA is the optimal duration of PA required to achieve successful long-term weight loss (≥5-10% weight loss at 18 months).

Prevalence Of Rash Suspicious For Tinea Among Minnesota High School Wrestlers -2017-18 Season

Mark A. Berg, William O. Roberts, FACSM. *University of Minnesota, St. Paul, MN.*
(No relevant relationships reported)

PURPOSE: Transmittable skin infections in sport are a concern, especially for wrestlers. We followed a geographically defined group of Minnesota high school wrestlers over the 12-week 2017-18 season to determine the prevalence of rash suspicious for tinea (RST).
METHODS: Nineteen high school wrestling programs in the St Paul area were contacted; 17 agreed to participate. Wrestlers undergo skin inspections prior to each competition throughout the season. Wrestlers identified during skin checks with an RST (raised, red, >5mm diameter, and with dry flaky scale) were recruited.
RESULTS: 39 of 510 wrestlers (7%) developed RST. 34 wrestlers consented to enter the study and had a total of 38 RST's meeting inclusion criteria (2 wrestlers developed 2 separate RST and 1 wrestler developed 3 RST). RST occurred throughout the season, with slightly more at the beginning and near the end. Slightly more RST occurred in middle competition weight categories. The most common site for RST was on the extremities(23 RST), followed by trunk(10), neck(2), face(1), and scalp(1). Empiric topical antifungal treatment had been started by 47% of the wrestlers.
CONCLUSIONS: RST prevalence of 7% was less frequent than found in previously reported wrestling populations. This may be the result of routine skin inspections prior to competition. Empiric topical antifungal treatment is commonly employed. Empiric antifungal treatment may be a prevention strategy that deserves further study.

3381   Board #: 250   June 2 9:30 AM - 11:00 AM

Current Practices of Concussion Management in Primary Care: A Survey

William L. Patterson Jr.[1], Kristine Karlson[2], William Dexter, FACSM[1], Deborah Johnson[2], Christina Holt[1], Ardis Olson[2], Amy Haskins[1]. [1]*Maine Medical Center, Portland, ME.* [2]*Dartmouth Hitchcock, Lebanon, NH.*
(No relevant relationships reported)

PURPOSE: Best practices for sports-related concussions (SRC) are evolving rapidly. We aim to describe the knowledge of standardized diagnostic tools and the current practices in SRC management by primary care providers (PCPs) in Northern New England.
METHODS: We designed an 'action' survey, using REDCap, to query current SRC management by pediatric and family physicians in ME, NH, and VT branches of the Academy of Pediatrics (AP) and Academy of Family Physicians (AFP). An email was sent to providers with a link to a deidentified survey which included questions about demographics and clinical practices. The questions covered: frequency seeing SRC, comfort level managing SRC, awareness of current guidelines and resources, use of imaging, return to school/play, and referral patterns. At the conclusion of the survey, the respondents could view their responses compared with others, and were sent links to current guidelines.
RESULTS: Initial response rate is 16% (preliminary) (111 responses of 688 MEAFP and MEAP members surveyed). Demographics: 43 male, 68 female; mean age: 49.2 years; mean years in practice:18.7. 90% (100/111) have seen a patient with SRC in the past 2 years; however, 79% (88/111) see ≤1 per month. 56% work with ATCs to

---

manage SRC. 61% report moderate or extreme comfort managing SRC. 91% (101/111) are aware at least 1 guideline for SRC, but only 18% (20/111) are aware of the 2016 Berlin consensus statement. 87% appropriately do not order imaging when no focal findings are found initially; but 46% (51/111) are likely to order imaging at 3 weeks even without valid indication. 70% (76/109) generally do not prescribe medications for concussion symptoms. 41% (43/106) appropriately recommend staying out of school for 2 or less days after SRC. 86% (94/109) are aware of return to play (RTP) guidelines and 90% (85/94) demonstrate appropriate management when an athlete fails a step. **CONCLUSIONS**: Clinicians responded well to a survey of current SRC practices, which provided updated clinical guideline tools. Most PCPs manage SRC; however, a majority report seeing ≤1 a month. A large proportion of PCPs do not follow current recommendations for imaging or return to school. Results could help guide future CME for SRC management.

3382   Board #: 251   June 2 9:30 AM - 11:00 AM
Effects of 6 Months Endurance Training on Quality of Life and Work Ability

Hedwig Stenner, Lena Grams, Momme Kück, Julian Eigendorf, Sven Haufe, Uwe Tegtbur, Anette Melk, Andres Hilfiker, Axel Haverich, Meike Stiesch-Scholz. *Institute of Sports Medicine, Hanover, Germany.*
(No relevant relationships reported)

Purpose: In this prospective, randomized controlled study we assessed effects of moderate-intense supervised endurance training on quality of life and work ability in middle-aged sedentary women. **Methods:** We randomized 291 healthy, non-smoking sedentary women (45-65 years) to a 6 months endurance training (EG, 210 min/week) or a wait-list-control (CG, no change of inactive life-style). At baseline and 6-month follow-up we assessed peak oxygen uptake (VO_{2peak}) by cardiopulmonary exercise testing, Work Ability Index (WAI) and quality of life (SF36), both by questionnaires. The metabolic syndrome score (MSS) was calculated using the siMS score. **Results:** At baseline, groups were well matched for anthropometric and cardiovascular parameters. Adherence to endurance training was 207±17 min/ week (98±5%). After intervention, the exercise group improved significantly compared to controls in VO_{2peak} (mean difference: 2.11 ml/min/kg, CI [1.41;2.79], p<0.001) and MSS (mean difference: 0.11 points, CI [0.053;0.175], p<0.001). VO_{2peak} and WAI changes correlated significantly (R=0.201; p=0.002). SF36 improved significantly in the EG compared to the CG for the subscales "Physical Role Functioning" (EG: baseline 83.7±26.5, follow-up 88.1±25.2, CG: 92.4±19.4, 89.7±22.1 respectively; p=0.016), "General Health Perceptions" (EG: baseline 69.3±14.8, 73.6±14.3, CG: 72.5±13.6, 71.8±14.3; p=0.002) and the "Sum Scale Physical" (EG: baseline 50.8±6.5, 52.2±6.3, CG: 52.7±5.7, 52.3±6.4; p=0.040) after exercise training. WAI changed significantly in the EG compared to the CG for "Work Ability In Relation To Demands" (EG: baseline 7.8±1.3, 8.2±1.2, CG: 8.2±1.3, 8.1±1.3, p=0.003), "Number of Current Diseases" (EG: baseline 2.2±1.7, 1.9±1.6, CG: 2.1±1.7, 2.2±1.9, p=0.014) and total score of WAI (EG: baseline 38.3±5.0, 39.8±4.9, CG: 39.4±4.7, 39.3±4.9, p=0.001). **Conclusion:** Our results show that a moderate personalized 6-month endurance training in middle-aged previously sedentary women improved established parameters of cardiovascular function, prevented metabolic syndrome progression, work ability and quality of life.

From the Perspective of Mitophagy: Study the Mechanism of Sustained Aerobic Exercises Alleviate Brain Aging

Wang Lu, Deng Wenqian, Li Xue. *Chengdu Sports Institute, Chengdu, China.*
(No relevant relationships reported)

Our previous work has demonstrated that sustained aerobic exercise could affect the morphology and function of mitochondria, and mitigate the mental functions decline of rats caused by D-gal.
PURPOSE: To investigate whether sustained aerobic exercise could alleviate aged rats' brain aging by influencing mitophagy. This project will aslo study the role of mitophagy in brain aging of aged rats.
METHODS: Twenty-four male Sprague-Dawley rats were randomly assigned into a control group (C, n=12), and a sustained aerobic exercise group (E, n=12). Groups C received conventional feeding for four weeks, and group E received feeding and swimming training for four weeks, 60 min/day, 6 days/week. Firstly, we would analysis the effect of sustained aerobic exercise on spatial learning and memory ability of aged rats. Then, transmission electron microscope were used to observe the mitophagy in loubus fromatis;Some indicators of mitophagy were detected by immunofluorescence, such as HSP60 and LC3-II,HSP60 and LAMP1;at last, index related to the mitophagy (Beclin1, P62 and LC3) were detected by western blotting. The experimental data were reported as means±SE, and *P* values<0.05 were considered significant.
RESULTS: Firstly, sustained aerobic exercise could alleviate rats' brain aging in spatial learning and memory ability. Mitophagy was significantly increasing in loubus fromatis detected by transmission electron microscope and immunofluorescence. According to the western blotting test, Beclin1 (C:0.08±0.02; E:0.63±0.09;

respectively, *P*<0.05) and P62 (C:0.05±0.01; E:0.74±0.11; respectively, *P*<0.05) were significantly elevated after sustained aerobic exercise; LC3-II/ LC3-I (C:0.12±0.03; E:1.25±0.17; respectively, *P*<0.05) was aslo significantly increased. These indicators indicated that mitophagy was increasing after sustained aerobic exercise.
CONCLUSIONS: Results from this study suggest that four weeks of sustained aerobic exercise can improve spatial learning and memory ability of aged rats, by increasing mitophagy in rats' loubus fromatis. Mitophagy is playing a very important role in brain aging of aged rats.

Nurse Amie (Addressing Metastatic Individuals Everyday)

Erica Schleicher[1], Leah Cream[1], Rena Kass[1], Michelle Farnan[1], Xiaochen Zhang[2], Katlynn Mathis[1], Jessica Moyer[1], Kathryn Schmitz, FACSM[1]. *[1]Pennsylvania State University, Hershey, PA. [2]Ohio State University, Columbus, OH.*
(No relevant relationships reported)

About 1 in 8 US women will develop invasive breast cancer in her lifetime. Complications with symptoms include inability to deliver chemotherapy, hospitalizations and survival outcomes. For patients to benefit from pharmacologic interventions, clinicians must be made aware. At present, there is no standard of care system to ensure clinicians are made aware of symptoms.
Purpose: To investigate the feasibility and acceptance of a symptom assessment and management platform for metastatic breast cancer (MBrCa) patients, including exercise.
Methods: Our team developed an interactive symptom assessment and management platform, Nurse AMIE. Patients were provided with a tablet, pedometer, and resistance bands. Nurse AMIE asked a daily question on sleep, fatigue, pain, or distress. Data from the pedometer and daily symptom questions were applied to an algorithm that resulted in a self-management intervention. Interventions included guided relaxation, social support forum, exercise, and music. Systematic symptom assessment and self-management interventions, along with weekly supportive phone calls determined whether self-management could continue or if there was a need to schedule an appointment with the clinician.
Results: 31 MBrCa patients had been consented to use Nurse AMIE. The initial patient adherence rate was 76%. Qualitatively, patient interviews suggest that Nurse AMIE is 'surprisingly easy to use' and the most valued interventions have been the social support forum, exercises, and music. Additionally, patients noted an improvement in fatigue while using the walking intervention. One patient who was only able to ambulate painfully with a walker at baseline now walks over 10,000 steps a day. Thus far, all initial patients have been able to self-manage with no interval visits with clinicians while using Nurse AMIE.
Conclusion: Nurse AMIE is an interactive platform that allows MBrCa patients to successfully self-manage symptoms while providing critical feedback. Overall, the physical activity component of this intervention is particularly well received. Qualitative feedback suggests that clinicians and patients are pleased by this comprehensive and standardized approach to assessing and managing symptoms. Further evaluation will allow us to better understand symptom assessment and management.

3385   Board #: 254   June 2 9:30 AM - 11:00 AM
Interindividual Variability and Adverse Responses to Body Composition with Exercise Training in Adolescents with Obesity

Jeremy J. Walsh[1], Gary Goldfield[1], Glen Kenny[2], Ronald Sigal[3], Steven Doucette[4], Brendon J. Gurd[5]. *[1]Children's Hospital of Eastern Ontario, Ottawa, ON, Canada. [2]University of Ottawa, Ottawa, ON, Canada. [3]University of Calgary, Calgary, AB, Canada. [4]Nova Scotia Health Authority, Halifax, NS, Canada. [5]Queen's University, Kingston, ON, Canada.*
(No relevant relationships reported)

Improved body composition (BC) is an expected outcome in adults undergoing exercise training. However, significant interindividual variability (IIV) has been observed in this response. Further, while some individuals fail to accrue training benefits, others demonstrate adverse responses, which can have implications for clinical exercise prescription. It is unknown if exercise training increases IIV and if it affects adverse response rates beyond what would be expected following a diet-only intervention in adolescents with obesity.
PURPOSE: To examine if exercise training increases IIV in the observed response of BC, and to quantify adverse response rates to training compared to diet-only control in adolescents with obesity. **METHODS**: Post-pubertal boys and girls (n = 143; age 15.5 ±1.4 yrs; BMI = 34.8 ±4.6 kg/m²) were randomly assigned to either a diet-only control group (n = 56), aerobic (n = 35), resistance (n = 23), or combined aerobic/resistance training (n = 29). Supervised exercise training was performed 4 x/week for 6 months. All groups received diet counseling to reduce caloric intake by 250 kcal/day. BC

outcomes were body fat % and lean body mass (LBM) measured via MRI, and waist circumference (WC). IIV was assessed by comparing the standard deviation of the observed change for each variable across control and pooled exercise groups (SD_{IR}). A positive SD_{IR} indicates increased IIV with training. An effect size (ES) was used when the SD_{IR} was positive to characterize the magnitude of effect. Adverse responses were evaluated using a measure of typical error to establish response thresholds and expressed as an aggregated score for all BC outcomes.
RESULTS: All exercise groups displayed a systematic increase in IIV following training for body fat % (SD_{IR} = 1.77, ES = 0.32 [0.06, 0.89]), but not for LBM or WC (SD_{IR} = no effect). Exercise significantly decreased the rate of adverse responses for aggregated measures of BC relative to control (7.4% vs. 20.4%, p<0.05), regardless of training modality.
CONCLUSIONS: Regardless of modality, exercise training does not systematically increase IIV across most BC measures in previously sedentary adolescents with obesity. Rather, exercise creates a positive, uniform shift in BC outcomes, thereby decreasing the rate of adverse responses and increasing positive responses.

Effects of Resistance Training and Doxorubicin on Creatine Transporter and Creatine Kinase Expression in Fast Muscle

Salaheddin Sharif[1], David S. Hydock[1], Mackenzie Twaddell[2], Allison Tigner[2], Meghan Wagner[2], Eric C. Bredahl[2]. [1]*University of Northern Colorado, Greeley, CO.* [2]*Creighton University, Omaha, NE.*
(No relevant relationships reported)

Doxorubicin (DOX) is a potent chemotherapy drug used to treat numerous cancers, but its use is limited due to its toxicities. DOX treatment may lead to skeletal muscle dysfunction which compromises quality of life for cancer patients. It is suggested that DOX inhibits creatine transporter (CreaT) and creatine kinase (CK) expression in cardiac muscle, but little is known as to how it affects CreaT and CK expression in skeletal muscle. Additionally, resistance training has been shown to alleviate DOX-induced skeletal muscle dysfunction (weakness and fatigue), but the effects of resistance training on CreaT and CK expression in DOX-treated skeletal muscle is currently unknown. **PURPOSE**: To investigate the effects of resistance training prior to and during DOX treatment on CreaT and CK expression in the primarily type II, or fast, extensor digitorum longus (EDL) muscle. **METHODS**: Thirty-six male, Sprague- Dawley rats were randomly assigned to one of four groups: sedentary+saline (SSS), sedentary+DOX (SSD), resistance training+saline (RRS), and resistance training+DOX (RRD). The resistance training protocol incorporated a raised cage model where food and water were elevated progressively which provided hindlimb loading 10 weeks prior to DOX injection and during the course of DOX treatment. Animals receiving DOX received 3 mg/kg DOX administered i.p. weekly for 4 weeks (12 mg/kg cumulative) and animals receiving saline received equivalent volumes of 0.9% NaCl as a placebo. Five days following the final DOX or saline injection, EDL muscles were excised, and Western blotting was performed to quantify CreaT and CK expression. **RESULTS**: No significant drug effect or activity x drug interaction was observed for CreaT expression, but a significant activity effect was observed for CreaT expression (p=0.0479). No significant main effects or interaction was observed for CK expression. **CONCLUSIONS**: Resistance training prior to and during weekly DOX administration promoted an increase in CreaT expression suggesting that resistance training may play a role in alleviating DOX-induced skeletal muscle dysfunction by enhancing substrate availability for phosphocreatine synthesis.

Exercise In All Chemotherapy (EnACT) Study: Implementation Of Exercise Oncology In A Clinical Setting

Natasha Burse, Kathleen Sturgeon, Cathy Bryan, Wayne Foo, Katlynn Mathis, Jessica Moyer, Renate Winkels, Joachim Wiskemann, Kathryn Schmitz, FACSM. *Pennsylvania State University, Hershey, PA.*
(No relevant relationships reported)

Purpose: Despite exercise recommendations for cancer patients, exercise counseling is not standard of care in cancer centers across the U.S. Challenges in the field of exercise oncology persist and require strategic approaches to ensure that exercise programming is approached in a manner that is widely acceptable to patients and their clinicians. Therefore, we have conducted an implementation study to assess feasibility, adherence to exercise during chemotherapy, and logistics of operating an exercise intervention program in the infusion suite of a cancer institute.
Methods: The Exercise Medicine Unit at the Penn State Cancer Institute (PSCI) is located in the infusion suite of the PSCI and was opened in the Fall of 2017. Staff screened all patient visits to the PSCI infusion suite for study eligibility criteria: ECOG ≤ 2, absence of absolute contraindications for exercise, solid tumor malignancy, and scheduled to receive chemotherapy. Participants completed surveys (physical activity, barriers to exercise, nutrition, work impairment, and quality of life) and physical function testing at baseline and follow up. An ACSM certified cancer exercise trainer

prescribed a personalized exercise program that has 5 components: aerobic, strength, balance, stretching, and relaxation.
Results: Of 317 patients screened, 42% were eligible (135), and 104 consented (77%) to the EnACT study. Characteristics of the study population include an average age of 59 years, 62% female, and 40% with metastatic disease. The top 3 cancer sites in the study were breast (23%), colorectal (17%), and pancreatic (16%). Adherence to prescribed exercise programming was 82%, n=39 completers. Overall, barriers to being active were decreased, with fewer participants reporting lack of willpower to exercise (42%, baseline; 19% follow up; p=0.02), and fewer citing influence from others as a barrier to exercise (19%, baseline; 3% follow up; p=0.06).
Conclusion: We report our mid-point analysis of the EnACT study. Thus far, the study is clinically feasible with 77% of eligible participants providing consent and an 82% adherence rate. Qualitative assessment with participants and health care professionals are ongoing. Collectively this study will aid in moving evidence based exercise-oncology practice into routine clinical usage.

3388   Board #: 257   June 2 9:30 AM - 11:00 AM
Effect Of 10 Weeks Of Low-load High-repetition Resistance Exercise Training On Human Skeletal Muscle

Chang Hyun Lim[1], Tae Seok Jeong[2], Chang Keun Kim[1]. [1]*Korea National Sport University, Seoul, Korea, Republic of.* [2]*SPIK Sport Medicine Clinic and Performance Center, Seoul, Korea, Republic of.*
(No relevant relationships reported)

Generally, high-load resistance exercise is recommended for increasing muscle mass. However, for the physically weak individuals encountering difficulties in performing high load resistance exercise, such as the elderly, women, and patients in rehabilitation, such exercise may not be effective. Recent research suggests that low-load high-repetition resistance exercise can increase muscle mass effectively, and can also contribute by facilitating mitochondrial metabolism or an adaptive phenomenon of endurance exercise.
PURPOSE: We aimed to investigate skeletal muscle functions, hypertrophy, and mitochondrial metabolism according to load and total work volume of exercise training based on molecular biology and physiological factors.
Methods: We recruited 21 men in their 20s and divided them into three groups, 80FAIL (80%RM set to failure, n=7), 30WM (30%RM and work matched to 80FAIL), and 30FAIL (30%RM set to failure), to perform resistance exercise three times a week for 10 weeks. Isokinetic muscle function test and Wingate test were conducted to assess their muscle function before and 72 hours after the last session. A biopsy of quadriceps femoris was performed to determinate changes in muscle cross-sectional area (CSA), satellite cell activation and mitochondrial metabolism.
Results: After 10 weeks of exercise training, 30FAIL and 80FAIL showed an increase in peak torque, CSA, and satellite cell activation (p<.05). In terms of endurance strength, 30FAIL was the only group that presented a significant increase after the training (p<.001). Furthermore, 30FAIL recorded a significant rise in expression of mitochondrial biosynthesis indicators of COXIV and cytochrome c, fusion proteins (Mfn2, Opa1), fission proteins (Drp1, Fis1), and mitophagy factors (PINK1, Parkin) after the exercise training (p<.05). Overall, 10 weeks of low-load resistance exercise training (set to failure) can activate satellite cells, thereby contributing to increase in CSA and improvement of muscle function.
Conclusion: Low-load high-repetition exercise training can be suggested as an effective method of muscle exercise training to enhance skeletal muscle function and aerobic metabolism at the same time by facilitating mitochondrial metabolism of the skeletal muscle.

Expression Of Markers Of Browning In White Adipose Tissue In Life-long Endurance Trained Athletes

Stefan Markus Reitzner[1], Seraphina Kissling[2], Mark Chapman[1], Carl Johan Sundberg[1]. [1]*Karolinska Institutet, Stockholm, Sweden.* [2]*University of Zürich, Zürich, Switzerland.*
(No relevant relationships reported)

Physical exercise and training results in adaptations in adipose tissue. Such adaptations may in part be mediated through "cross-talk" with skeletal muscle. One of these adaptations potentially relevant to energy metabolism in endurance athletes is the beiging of white adipose tissue (WAT). Beiging is the process by which WAT shows characteristics of brown adipose tissue (BAT), possibly increasing basal metabolic rate. While the process of beiging in rodents and the existence of BAT in humans has been shown previously, it is unknown if and how life-long endurance exercise influences beiging of WAT depots. **Purpose:** To study the influence of life-long training on adipose tissue markers of beiging and metabolic performance, the uncoupling protein 1 (UCP-1), CIDEA and PPAR-γ in white adipose tissue (WAT) in sub-elite athletes. **Methods:** Periumbilical subcutaneous adipose tissue biopsies were collected from 14 life-long trained sub-elite endurance athletes (8 male, 6 female; VO₂max performance over 90th percentile for their age group) and 13 age-matched controls (6 male 7 female). Gene expression was analyzed on extracted RNA. Fold induction

SATURDAY, JUNE 2, 2018

was statistically analyzed by Student's-test. **Results:** UCP-1 gene expression was significantly higher in trained women compared with the control group (p=0.046). No significant difference was found in men when comparing UCP-1 expression (p=0.257). Expression of CIDEA was, again, significantly higher compared with controls (p=0.049), but also in men (p=0.024). Finally, expression of PPAR-γ was significantly higher in trained women (p=0.005). Again no differences were found in men (p=0.924). **Conclusion:** Life-long endurance training results in a higher expression of brown adipose tissue markers in periumbilical WAT in women, in men only in expression of CIDEA, a factory closely associated with metabolic health. Previous results in rodents show a higher susceptibility of females to upregulate BAT markers following β-adrenergic signaling. A similar mechanism might be possible in humans. This effect might also be caused by differences in body fat distribution and functionality, with women having a higher prevalence for BAT.

In-vivo Measurement Of Strain In The Iliotibial Band In Motion
Kuntal Chowdhary. *Oakland University William Beaumont School of Medicine, Rochester, MI.*
(No relevant relationships reported)

PURPOSE: Iliotibial band syndrome (ITBS) is one of the most common overuse leg injuries. Two current theories - friction and compression - attempt to correlate the cause of lateral knee pain to the inflammation of the iliotibial band (ITB). Despite lack of consensus, both theories suggest that strain plays a key role in all potential mechanisms of injury. The purpose of this study is to measure strain in the ITB non-invasively over the skin, as a basis for further evaluation of ITBS as correlated to changing strain rates.
METHODS: Strain was measured using a 'strain measurement apparatus' consisting of strain gauges in a carbon fiber casing. The strain measurement apparatus was placed on biomimetic skin overlying a tendon to obtain an estimated measure of strain upon manipulation of the cords to known forces. The output generated by the apparatus was correlated to the actual strain measured by a load cell placed directly on the tendon. The 'strain measurement apparatus' was manipulated to maximize precision throughout the experimental process. In the second phase of the project, the 'strain measurement apparatus' will be used to measure strain in a porcine leg as a closer approximation of the human ITB.
RESULTS: The first phase of this study demonstrated a correlation between the strain measured by the apparatus and the force applied to the biomimetic tendon, as measured by the load cell. Four trials were run, with the strongest correlations in trials 2 and 3 with correlation coefficients of 0.97 (P<0.0001) and 0.99 (P<0.0001), respectively.
CONCLUSIONS: The results thus far support the hypothesis that strain can be measured in the ITB directly using strain gauges. The efficacy of the strain measurement apparatus will provide a basis for further non-invasive evaluation of the ITB as correlated to ITBS in human models.

Applied Assessment and Interventional Energy And It's Effects In A Clinical Setting
Gerardo Hizon, FACSM, Niluk Senewiratne. *University of California Riverside, Riverside, CA.*
(No relevant relationships reported)

PURPOSE:The purpose of this study is to evaluate interventional electron energy's ability to reduce inflammation and related symptoms such as pain. Inflammation is the underlying factor in many conditions. The origin of inflammation is the cells accumulation of waste product caused by ion channel dysfunction. The performance of neuronal ion channels are regulated by voltage or ligand. Voltage disruption in the membrane affect channel gate function. Minute changes in channel gate function leads to cell dysfunction caused by molecular structure abnormality, the result of free radical based electron instability. Free radicals are active in inflammatory processes in vitro and in vivo. Interventional electron energy modifies ionic flow across cell membranes and may correct cell function. Interventional electron energy is used to reduce cell dysfunction and inflammation by neutralizing free radicals. METHODS:The application of interventional electron energy is used to counteract free radical related molecular, sub-molecular and cell dysfunction causing inflammation. This method includes free radical assessment and interventional electron energy application to affected tissue. Free radical neutralization can be achieved via correction of impaired movements and pathways of affected electrons. This may result in correction to molecular structure leading to ion channel function correction within the cell membrane. This can result in the decrease of inflammation and related conditions. RESULTS:Out of 144 interventional electron applications on inflammation and related pain in in knees, cervical, backs, shoulder, hands and heads, the mean deviation improvement was 4.52. The Average improvement Percentage [(652.699213 (Sum total VAS pain scale pre-treatment)/63.9810606 (Sum total VAS pain scale post-treatment) = 10.20 (Difference in sum totals)] [100 - 10.20 = **89.80% (Average pain reduction)**]
CONCLUSIONS: By integrating analytic and interventional processes , the benefit to the patient is a new accelerated assessment and treatment for rapid reduction of

inflammation and related conditions. The pain reduction %'s in this large population pilot study exceed the pain reduction %'s achieved with standard conservative therapeutic options. These results warrant further study and investigation.

Forced PGC1a1 Expression Improves Oxidative Capacity And Partially Rescues Strength Following Volumetric Muscle Loss Injury
William M. Southern[1], Anna S. Nichenko[1], Anita E. Qualls[1], Amelia Yin[1], Hang Yin[1], Sarah Greising[2], Jarrod A. Call[1].
[1]*University of Georgia, Athens, GA.* [2]*University of Minnesota, Athens, GA.*
(No relevant relationships reported)

Volumetric muscle loss (VML) is characterized by a large volume of muscle tissue being removed from the body due to surgery or severe trauma. The remaining muscle after VML has poor function and unknown adaptive potential during physical rehabilitation. **PURPOSE:** To investigate the metabolic plasticity of the remaining skeletal muscle after VML injury. **METHODS:** VML injury was performed on the gastrocnemius muscle of 8-week old C57BL/6 mice. Study 1: Unilaterally injured VML mice performed voluntary wheel running (WR). Study 2: PGC1a1 (CMV promoter) transfection was performed on control (CON) and bilaterally injured VML mice (VML). Mice were divided into three groups: CON+PGC1a1 overexpression, VML alone, and VML+PGC1a1 overexpression. Four weeks after onset of wheel running (Study 1) or transfection interventions (Study 2), muscle strength and mitochondrial respiratory function (mitoFx) were assessed. **RESULTS:** MitoFx was ~23% greater in the uninjured limb of VML+WR mice compared to VML alone, but mitoFx in the injured limb of VML+WR mice was not different from VML alone, suggesting VML injury prevents metabolic adaptations to exercise (ANOVA P<0.001). To determine if a faulty metabolic signaling cascade (i.e., PGC1a1) was responsible for impaired metabolic adaptation in the VML-injured muscle, direct muscle activation via sciatic nerve electrical stimulation was used to initiate oxidative gene transcription in CON and VML mice. The stimulated muscle in CON mice had ~4 fold greater PGC1a1 gene expression than the unstimulated muscle; however, there was no effect of stimulation on PGC1a1 expression in VML mice (Interaction: P<0.001) suggesting VML injury attenuates oxidative gene regulation. Endogenous PGC1α1 activation pathways were bypassed via forced expression of PGC1a1 in Study 2. Forced expression of PGC1a1 resulted in ~33% and ~31% greater mitoFx in CON+PGC1a1 and VML+PGC1a1 mice, respectively, compared to VML alone (P<0.001), and VML+PGC1a1 mice had 47% greater muscle strength than VML alone (P<0.001). **CONCLUSION:** PGC1a1 activation is the limiting factor impairing metabolic plasticity in VML-injured muscle; and improving oxidative capacity of the remaining muscle after VML injury improves recovery of strength.

Myonuclear Transcriptional Rate Differs in Young versus Mature Mice
Samuel E. Crow, Kevin A. Murach, Vandre C. Figueiredo, John J. McCarthy, Charlotte A. Peterson. *University of Kentucky, Lexington, KY.*
(No relevant relationships reported)

Skeletal muscle fiber hypertrophy occurs in mature mice (>4 months old) in response to synergist ablation overload in the absence of satellite cell-mediated myonuclear accretion, whereas young mice (2 months old) are not able to hypertrophy without satellite cells. We hypothesize that young mice have higher myonuclear transcriptional activity at rest than mature mice due to the demands of developmental muscle fiber growth. Age-related differences in transcriptional rate may in part explain why young mice cannot mount the robust myonuclear transcriptional response required for overload-induced hypertrophy without satellite cells. **Purpose:** To determine whether baseline myonuclear transcription differs between young (2 months) versus mature (5 months) mice. **Methods:** Young and mature mice (n=4 males/group) were pulsed with 5-ethynyl uridine (EU), a modified uridine that incorporates into nascent RNA, via intraperitoneal injection then sacrificed after a 1-hour chase. Myonuclei were defined as DAPI-positive nuclei within the myofiber, delineated by dystrophin immunostaining. EU-labeled nascent RNA was detected histochemically on frozen muscle cross-sections, and myonuclear EU intensity was quantified with semi-automated thresholding software. Muscle fiber cross sectional area (CSA) was quantified via the detection of fiber borders using automated software. **Results:** The number of EU+ myonuclei did not differ between young and mature mice. Mean transcriptional intensity per myonucleus was 10% higher in young versus mature mice, and muscle fiber CSA was 18% smaller (P<0.05). Myonuclear transcriptional rate normalized to muscle fiber size appeared 30% higher in young versus mature mice, but did not reach statistical significance (P=0.07).
Conclusion: Likely due to lower normalized myonuclear transcription relative to young mice, mature mice may possess a transcriptional reserve that allows for hypertrophy in the absence of myonuclear accretion, as previously shown by our

laboratory. The current data indicate that murine developmental age could be an important consideration for hypertrophy experiments. These results will be verified in a larger cohort of mice that will also include females.

Relationships Between Muscular Strength And Body Composition In Adults With Cerebral Palsy

Pooja Pal, Cory E. Low, Rachel L. Christensen, Stephanie V. Rosales, Areum K. Jensen. *San Jose State University, San Jose, CA.*

(No relevant relationships reported)

Cerebral palsy (CP) is a non-progressive and permanent neurological disorder that is characterized by muscular weakness and soft tissue contracture or deformation. Adults with CP develop health risk factors and diseases, such as obesity and cardiovascular diseases, significantly more than the general population. Majority of the research focuses on interventions for children and adolescents with CP, and little is known about long-term health issues among adult CP population. Currently, limited information is available to identify the level of muscular strength in relation to the level of obesity in adults with CP.
Purpose: To determine relationships between muscular strength and body composition in adult individuals with and without CP.
Methods: We studied thirteen adults with and without CP. Leg muscular strength and power at 90, 150, and 210 degrees/sec were measured using Humac Norm isokinetic dynamometer. The range of motion at the knee joint was measured. Forearm muscular strength was measured using a handgrip dynamometer. Body mass index (BMI) from weight and height was calculated to identify the level of obesity.
Results: Compared to healthy control, individuals with CP had significantly lower knee extensor peak torque (11.8±2.3 CP vs. 68±12.5 control, ft-lbs, P<0.05) at 90 degrees/sec, (7.5±0.6 CP vs. 53.2±11.7 control, ft-lbs, P<0.05) at 150 degrees/sec, (7.3±1.1 CP vs. 49.2±9.7 control, ft-lbs, P<0.05) at 210 degrees/sec, lower knee flexor peak torque (6.3±1.6 CP vs. 43.8±7.9 control, ft-lbs, P<0.05) at 90 degrees/sec, (6.00±1.13CP vs. 35.83±6.88 control, ft-lbs, P<0.05) at 150 degrees/sec, (7.33±1.89 CP vs. 35.17±6.47 control, ft-lbs, P<0.05) at 210 degrees/sec. In control group, there was no relationship between BMI and extensor/flexor peak torque. However, there was a significant inverse relationship between BMI and torque in CP group.
Conclusion: These findings suggest that the level of obesity does not appear to influence muscular strength in healthy population. However, individuals with CP exhibit an inverse relationship between muscular strength and the level of obesity.

Alterations in Musculoskeletal Function and Functional Mobility in Adults with Cerebral Palsy

Rachel L. Christensen, Pooja Pal, Cory E. Low, Tiffany N. Raczynski, Areum K. Jensen. *San Jose State University, San Jose, CA.*

(No relevant relationships reported)

Cerebral Palsy (CP) is a type of neurological disorder marked by impaired muscle coordination and related physical disabilities due to damage in the brain before or at birth. Adult individuals with CP are more exposed to higher risk of fall and fracture mainly because of their musculoskeletal abnormalities and dysfunction. The lower state of balance and functional mobility is also related to the higher risk of fall and fracture in the general public, and is improved by gaining muscular strength and power as well as bone mineral density (BMD). To date, no studies have examined the relationship between leg muscular strength, BMD, and balance as a detector of functional mobility in the adult CP population.
Purpose: To determine if there is a relationship between leg muscular strength, BMD, and seated balance in adults with CP.
Methods: We studied 7 adults with CP, and 6 without CP as a control. Dual energy X-ray Absorptiometry (DXA) was used to measure bone mineral content and BMD at the lumbar spine region (L1-4). Muscular strength was assessed by using the Human Norm isokinetic dynamometer to measure peak torque, work, and power of the left leg. The Biodex was used to identify the state of seated balance by performing a limited stability test.
Results: There were no significant differences in BMD of the L1-L4 region between adults with CP and the healthy controls. The CP participants had a significantly lower forward (28.6±5.5 CP vs. 69.5±8.1 control, P<0.05), backward (29.0±10.3 CP vs. 77.5±5.6 control, P<0.05), left (20.8±5.6 CP vs. 72.0±7.7 control, P<0.05), right (28.0±5.6 CP vs. 65.5±5.8 control, P<0.05), and overall (17.2±3.1 CP vs. 61.7±6.3 control, P<0.05) score values in comparison to the control group on the limited stability test. The CP group had a significantly lower knee extensor peak torque (7.3±1.1 CP vs. 49.2±9.7 control, foot-pounds, P<0.05) and knee flexion peak torque (7.3±1.9 CP vs. 35.2±6.5 control, foot-pounds, P<0.05) at 210 degrees/sec. There was a linear relationship between torque and balance for both the CP and control.
Conclusion: Our findings suggest that leg muscular strength appears to influence

seated balance in individuals with CP even though bone strength in the lumbar region is not significantly different compared to controls.

3396   Board #: 265   June 2 9:30 AM - 11:00 AM

Alterations in Skeletal Architecture, Bone Mineral Density, and Muscular Strength in Adults with Cerebral Palsy

Cory E. Low, Pooja Pal, Rachel L. Christensen, Areum K. Jensen. *San Jose State University, San Jose, CA.*

(No relevant relationships reported)

Cerebral Palsy (CP) is a neurological disorder caused by lesions in the brain that affect motor development. It is characterized by impaired motor function and atypical development of musculoskeletal structures and muscular weakness. Individuals with CP develop osteoporosis earlier in their age compared to the general population. Bone weakness has a detrimental effect on the muscular system, which causes the CP population to be more prone to bone fracture and further immobility. To date, it is still uncertain whether structural alterations in the skeletal system in CP population have an influence on bone mineral density (BMD) and muscular strength.
Purpose: To determine relationships between skeletal architecture, BMD, and muscular strength in adults with and without CP.
Methods: We studied 14 participants with and without CP. Dual energy X-ray absorptiometry was used to measure regional BMD and bone mineral content (BMC) at the lumbar spine, proximal femur, and forearm regions. Architectural differences were measured as angles from a center line through the femoral neck to top and bottom of greater trochanter, and lesser trochanter. Leg and forearm muscular strength was assessed by using Humac Norm isokinetic dynamometer, and handgrip dynamometer, respectively, to measure peak torque of the left leg.
Results: Individuals with CP had significantly different skeletal architectural angles presented by the top and bottom of greater trochanter (e.g., top, 56±4 CP vs. 72±3 control, degrees, p<0.05). BMC, BMD, T-scores, and Z-scores were all significantly different in the left femoral neck (e.g., T-score, -2.96 ±0.92 CP vs. -0.89±0.49 control, p<0.05) as well as in the forearm regions (e.g., radius 33%, T-score, 0.48±0.31 CP vs. -0.30±0.18 control, p<0.05). Individuals with CP had significantly lower knee extensor peak torque (e.g., at 90 degree/sec; 11.8±2.3 CP vs. 68.0±12.5 control, foot-pounds, p<0.05). Architectural angles of the femur were closely related to the level of BMD on femoral neck regions and leg muscular strength (p<0.05).
Conclusion: These findings suggest that femoral skeletal architecture (via reduced angles of top and bottom of greater trochanter) has an influence on BMD and muscular strength in adults who have CP.

The Effect Comparison of Foam Rolling with Passive Stretching After High Intensity Training

Yuanpeng Liao, Yu Xia, Minjia Wang. *ChengDu Sports Institute, ChengDu, China.*

(No relevant relationships reported)

PURPOSE: Objectives: To compare the effect of foam rolling (FR) and passive stretching (ST) after high intensity training.
METHODS: 63 male were conclude from college students,which divided into three groups: control group, FR group and ST group. And each group included 21 subjects. All subjects finished a high intensity training session of weight-bearing squat exercise.After the training session, FR group practiced a 6-min foam rolling and ST groups practiced passive stretching. Isometric Peak torque (IPT) were measured with isokinetic system at pre-training, immediately post-training and 24h, 48h after training.
RESULTS:After training, IPT was significantly decreased in all three groups (p<.01**), and there were no significant differences immediately after training. At 24h after training, IPT was significantly increased in FR and ST groups, although there were no significant differences compared with the pre-training result. At 48h after training , compare with the control group, FR and ST group's IPT was significantly increased in the (p<.01**), while there were no significant differences between these two groups; Compared pre-training and 48h post-training, no significant differences were observed in FR group, while there were still significant difference in ST group(p<.01**).
CONCLUSIONS: (1) Foam rolling and passive stretching can relax muscle after high intensity training; (2) Foam rolling practice and passive stretching had possible beneficial effects at 24h and significant improvement at 48h after training; (3) Under the same condition, the effects of foam rolling practice were greater than passive stretching.

SATURDAY, JUNE 2, 2018

The Changes of IPT pre- and post-training (N*M)			
	Control Group	FR group	ST group
Pre- training	207.10±12.78	213.52±8.38	212.51±10.51
Immediately post-training	152.41±9.25**	157.31±7.14**	158.02±9.13**
24h post-training	153.94±9.84**	165.57±8.49**	163.25±8.81**
48h post-training	159.97±10.26**	193.71±7.57**	182.19±9.95****

A Novel Application of Altitude Training Masks and High-Intensity Interval Training to Improve Exercise Performance

Eric M. Hultquist, Haley N. Yohn, Carlo F. Tirso, Mary A. Dunyak, Jacqueline Denning, Erin L. Blaser, Brycen J. Moore, Rachel Beckmann, Joshua G. Woolstenhulme. *The George Washington University, Washington, DC.*
(No relevant relationships reported)

PURPOSE: This study seeks to examine the effects of altitude training masks (ATM, also known as respiratory fitness masks) used solely during recovery periods (low intensity intervals) during high-intensity interval training (HIIT).
METHODS: Participants underwent six weeks of HIIT (3 sessions per week) with each exercise bout consisting of eight, 60-second high-intensity intervals interspersed with eight, 90-second low-intensity recovery intervals. Workloads for the high-intensity intervals were individualized to elicit heart rates within 10 bpm of each participant's maximal heart rate as assessed during a baseline graded exercise test. The low-intensity recovery intervals were prescribed at a fixed workload corresponding to approximately 10% of each participants' baseline maximal oxygen consumption ($\dot{V}O_{2max}$). Participants were assigned via block randomization to either a control group (CG) or a training mask group (TMG) that only wore the ATM during the low-intensity recovery bouts of the HIIT intervention. Participants performed a graded exercise test to volitional exhaustion at both baseline and following the HIIT intervention as well as a vascular occlusion test to assess the tissue saturation index nadir (TSIN) of the gastrocnemius. Outcomes were $\dot{V}O_{2max}$, oxygen consumption at anaerobic threshold (AT), and TSIN.
RESULTS: Twelve participants (7 women; 25.5±4.5 years; BMI: 23.6±1.5 kg/m²) have completed the study to date. $\dot{V}O_{2max}$ increased significantly in the TMG group (40.5±3.6 to 44.5±5.4 ml/kg/min, p=0.03) but not in the CG. TSI was significantly greater in the TMG group (-17.8±7.3 to -28.3±7.3% from baseline, p=0.05) with no significant change in the CG. No change in AT was observed in either group.
CONCLUSIONS: Implementing ATMs only during the low-intensity recovery intervals of HIIT training appears to improve key components of cardiorespiratory function not observed in our standard HIIT training group. These findings demonstrate a novel use of ATMs that has potential to change how ATMs are used by recreational and professional athletes. These results also have implications for the use of ATMs as potential adjunctive modalities for enhancing training effects in rehabilitative settings where improvements in short time periods are desirable.

3399   Board #: 268   June 2 9:30 AM - 11:00 AM

Novel Use of Respiratory Conditioning Masks during High-Intensity Interval Training to Improve Respiratory Function in Healthy Adults

Brycen J. Moore, Erin L. Blaser, Mary A. Dunyak, Carli F. Tirso, Jacqueline Denning, Haley N. Yohn, Eric M. Hultquist, Alison Rieck, Joshua G. Woolstenhulme. *The George Washington University, Washington, D.C.*
(No relevant relationships reported)

PURPOSE : The purpose of this study was to examine the effects of respiratory conditioning masks (RCMs, also known as altitude masks) on lung function when used only during the low-intensity recovery intervals of high-intensity interval training (HIIT).
METHODS : A group of recreationally active healthy adults performed a 6-week HIIT protocol where half of the participants were randomly assigned to wear an RCM during the low-intensity rest intervals (Mask Group), or no mask (Control). Participants performed three HIIT bouts per week, where each bout included eight high-intensity intervals of 60s exercise performed within 10 beats of maximal heart rate for each subject obtained from a baseline graded exercise test to volitional exhaustion. Each high-intensity interval was immediately followed by a 90s low-intensity recovery interval at a work rate corresponding to 10% $\dot{V}O_{2max}$ for each participant at baseline. Pulmonary function testing was also performed at baseline and following a six week intervention period.

RESULTS : 12 subjects (7 women, ages: 25.5±4.55 yrs, BMI: 23.6±1.5 kg/m²) to date completed the study. Expiratory reserve volume was significantly larger in the mask group compared to the control group after training (1.5 ±0.5 vs. 0.8±0.4L, p=0.02). Resting VE/VO₂ (41.8 ±6.9 vs. 28.3±2.7, p=0.001) and VE/VCO₂ (47.3 ±11.6 vs. 35.8±3.9, p=0.04) increased in the mask group compared to controls. In the mask group alone, at peak exercise VE/VCO₂ significantly increased at isowork rates (31.5 ±2.3 to 34.3±3.6, p=0.02) while the respiratory exchange ratio decreased (1.22±0.11 vs. 1.14±0.08, p=0.02). Resting PETO₂ significantly increased in the mask group alone after exercise training (111.7 ±6.5 vs. 115.5±6.1 mmHg, p=0.02). No other changes were observed in forced vital capacity, total lung volume, or maximal inspiratory/expiratory pressures for both groups.
CONCLUSIONS : RCMs worn only during the low-intensity recovery intervals in a 6 week HIIT protocol appear to have a significant effect on select measures of respiratory and ventilatory function. VE/VCO₂ is an indicator of ventilatory drive, and changes in VE/VCO₂ have been shown to have prognostic significance for several clinical populations. Using RCMs is this novel fashion may play a role in modifying ventilatory drive.

3400   Board #: 269   June 2 9:30 AM - 11:00 AM

Feasibly Measuring Sitting And Physical Activity In The Office Using Bluetooth Sensing

Elisabeth A. Winkler[1], Nyssa Hadgraft[2], Takemi Sugiyama[3], Bronwyn Clark[1]. *[1]The University of Queensland, Herston, Australia. [2]Swinburne University, Melbourne, Australia. [3]Australian Catholic University, Melbourne, Australia.*
(No relevant relationships reported)

PURPOSE: The office is a key setting where sitting occurs and is intervened upon. Office-specific behaviour measures may help evaluate workplace intervention components, such as activity-permissive workstations. We tested whether a feasible Bluetooth sensing method can provide valid measures of office time and office-specific activities.
METHODS: Workers from one building (n=29, 72% female, age 23-68 years) wore, for one workday, the activPAL3 on the thigh and the Bluetooth-enabled ActiGraph Link on the wrist and thigh. Location (office/not) was estimated by signal presence/absence at two beacons in the wearer's office, with chest-worn video cameras (MeCam) as the criterion. Accuracy in location classification was assessed (F-scores) and compared (generalized estimating equations) between 60 s and 10s sampling options (i.e., feasible versus high resolution, requiring daily recharging). The validity of 60 s Bluetooth-derived measures of total time spent in the office and in office-specific activities was assessed.
RESULTS: For both the wrist and thigh-worn Link, accurate classification of location (office/not) was obtained, with a significant (p<0.05) but negligible difference between the two sampling options (F-scores were all 0.98). Agreement with the criterion in daily totals showed only small mean differences (-0.2 to +6.1 min) and moderate individual differences (95% agreement limits ±30 min or ±10 min for stepping). Mean absolute percent error was very small for office time and office sitting time (<5%), moderate for standing (17-23%), and high for incidental stepping (30-49%) and purposeful walking (57-86%) due to how little of these occurred.
CONCLUSIONS: The ActiGraph Link worn on the thigh or wrist can be used to validly measure office time and office activity (provided activity is measured validly) with a 60 s Bluetooth setting that facilitates multi-day measurement without recharging. Higher resolution improves accuracy but not to a meaningful degree.

3401   Board #: 270   June 2 9:30 AM - 11:00 AM

Absence of Functional Left Ventricular Adaption With Short-Term Resistance Exercise Training in Young Men

Jason Au[1], Sara Oikawa[1], Robert Morton[1], Stuart Phillips, FACSM[1], Maureen MacDonald[1], Eric Stöhr[2]. *[1]McMaster University, Hamilton, ON, Canada. [2]Columbia University Irving Medical Centre, New York, NY.*
(No relevant relationships reported)

Resistance exercise training (RET) is recognized as a health-positive stimulus, but the significance of remodelling of the left ventricle (LV) evoked by RET remains unclear, in part due to the lack of data on LV functional adaptation that accompanies the structural remodelling. **PURPOSE**: To examine the effects of 12 weeks of RET on LV twist mechanics in healthy men. **METHODS**: Forty, non-athlete men (age: 23±3 years) were randomized into 12 weeks of whole-body higher-repetition RET (20-25 repetitions/set to failure at ~30-50% 1RM; n=13), lower-repetition RET (8-12 repetitions/set to failure at ~75-90% 1RM; n=13), or an active control period (n=14). Standard, and speckle tracking echocardiography were performed at baseline, and following the intervention period. **RESULTS**: Neither 12-week program of RET altered end-diastolic volume, end-systolic volume, or ejection fraction (*P*>0.05). Similarly, RET did not change total LV twist, untwisting rate, twist-to-shortening ratio, untwisting-to-twist ratio, or longitudinal strain (*P*>0.05). **CONCLUSION**: This is the first longitudinal study to assess both LV structure and mechanics after RET in healthy men, suggesting a maintenance of LV structure and mechanics irrespective of loading

condition. These results contrast those reported from endurance exercise training and therefore present important insight into the specific contributions of RET to cardiac adaptation, even with strenuous training efforts. Future studies should directly compare the effects of RET and endurance exercise on the structure and function of the heart, and determine whether combined training regimes exceed a health threshold in patient populations.

Impaired Exercise Capacity In cTnT-delta160E Mice Validates Pre-clinical Model To Assess Exercise Interventions For HCM

Jonathan J. Herrera[1], Kate Szczesniak[1], Sean Louzon[1], Jaime Yob[1], Jil C. Tardiff[2], Sharlene Day[1]. [1]University of Michigan, Ann Arbor, MI. [2]University of Arizona, Tuscon, AZ.

(No relevant relationships reported)

Reduced peak VO_2 in patients with hypertrophic cardiomyopathy (HCM) is a powerful predictor of adverse outcomes, including all-cause mortality and heart transplant. The risk of death or transplant is reduced by 21% for each 1mL/kg/min increase in peak VO_2. A randomized clinical trial conducted by our group demonstrated 16 weeks of moderate intensity exercise training increased peak VO_2 in HCM patients by 6% compared to usual activity. Whether exercise attenuates disease progression is unknown but is a critical question given the lack of disease modifying therapy. This is challenging to address in patients because disease typically progresses slowly and non-linearly over many years. Therefore, we propose a pre-clinical HCM model to determine the effects of exercise on phenotypic emergence and progression. **PURPOSE**: To determine exercise capacity in a cardiac troponin T mutant (cTnT) mouse model of HCM through a graded exercise text (GXT) protocol. **METHODS**: C57Bl/6 non-transgenic (NTG) (n=6 female, n=5 male) and Δ160E cTnT (n=4 female, n=8 male) mice (age 10-12 months) were subjected to a human parallel mouse GXT w/staged increases in inclination (0°-15°) and speed (6m/min up to 30 m/min). Mice were acclimated (4 days, 30 min day) and tested on a metabolic treadmill in a randomized and blinded fashion at UM Nutrition Obesity Research Center. Test was terminated when mouse remained in contact w/shock grid at treadmill rear for 5 sec. Two sample t-tests were used for data analysis. **RESULTS**: Baseline and peak VO_2 were significantly lower in cTnT compared to NTG mice (baseline: 83.12 mL/kg/min ± 2.07 vs 95.58 mL/kg/min ± 3.61; peak: 102.35 mL/kg/min ± 2.04 vs 119.20 mL/kg/min ± 5.57; p<0.01 in both comparisons). Compared to NTG mice, cTnT ran a shorter distance (201.33m ± 6.40 vs 253.81m ± 8.78; p< 0.0001) and for less time (13.25min ± 0.25 vs 15.22min ± 0.31; p< 0.0001). Respiratory exchange ratio and mean body weights were not different between cTnT and NTG mice. **CONCLUSION**: This is the first report of reduced peak VO_2 in a pre-clinical HCM model. These findings mirror reductions in peak VO_2 observed in HCM patients, the magnitude of which is a strong predictor of adverse outcomes. Our observation validates the model as one in which the effects of an exercise intervention on phenotypic conversion and progression can be assessed. Support by UM

The Influence of EMG-based Maximal Voluntary Contraction (MVC_{EMG}) Intensity on Middle Cerebral Artery Velocity

Heehyuk Lee[1], Seongdae Kim[1], Myungjin Oh[2], Ilgyu Jeong[1]. [1]Hannam University, Daejeon, Korea, Republic of. [2]Baekseok University, Cheonan, Korea, Republic of.

(No relevant relationships reported)

It has been established that cerebral blood flow velocity (CBFV) might elevate due to the increase of exercise intensity determined by %VO_2max during a cardiorespiratory exercise test. But, the response of CBFV to EMG-based maximal voluntary contraction (MVC_{EMG}) during Isometric muscle contraction remains unclear. **PURPOSE**: To evaluate the influence and adaptability as the intensity index of MVC_{EMG} on middle cerebral artery velocity (MCA V_{mean}) during isometric strength type exercise. **METHODS**: Fourteen healthy male (24.1±1.4yrs) were asked to perform the 45° knee extension isometric contraction during 60 seconds. All participants performed three times in random order the isometric exercise of 100%, 80% and 60% MVC determined by root mean square (RMS) of EMG at right rectus femoris m. with a week interval. Each participant was asked to conduct and maintain the predetermined exact intensity of %MVC confirming the figures on a monitor. MCA V_{mean} was measured at rest, during exercise, immediately after exercise, 30 seconds recovery, 60 seconds recovery and 2 minutes recovery using transcranial-Doppler sonography. All data were analyzed using two-way ANOVA (3 intensities x 6 times) with repeated measures. **RESULTS**: MCA V_{mean} in 80% MVC_{EMG} was significantly higher than MCA V_{mean} in 60% MVC_{EMG} (110±19 vs. 89±19 cm/s, p<0.05) immediately after exercise. MCA V_{mean} in 100% MVC_{EMG} was significantly higher than MCA V_{mean} at 60% MVC_{EMG} in 30 second recovery (97±14 vs. 77±10 cm/s, p<0.05) and 60 seconds recovery (97±16 vs. 73±12 cm/s, p<0.05). Heart rate in 100% MVC_{EMG} was significantly higher than in 80%, 60% MVC_{EMG} at immediately after exercise (128±26 vs. 106±15, 97±10 beats/

min, p<0.01) and at 30 seconds recovery (102±18 vs. 87±12, 80±9 beats/min, p<0.05). **CONCLUSIONS**: These results suggest that the increase of isometric exercise intensity up to ~ 80% of MVC_{EMG} might induce the elevation of MCA V_{mean}.

Muscle Afferent Blockade Improves Endurance Exercise Performance When O_2 Transport To Locomotor Muscles Is Preserved

Thomas J. Hureau[1], Joshua C. Weavil[2], Taylor S. Thurston[2], Hsuan-Yu Wan[2], Jayson R. Gifford[2], Jacob E. Jessop[2], Michael J. Buys[2], Russell S. Richardson[2], Markus Amann[2]. [1]University of Strasbourg, Strasbourg, France. [2]University of Utah, Salt Lake City, UT.

(No relevant relationships reported)

PURPOSE: During high intensity whole body endurance exercise, feedback from group III/IV locomotor muscle afferents restricts neural drive to the legs while, simultaneously, optimizing peripheral O_2 transport. We attenuated feedback from these sensory neurons to investigate their limiting effects on endurance exercise performance while controlling for locomotor muscle O_2 transport. **METHODS**: Eight healthy men (VO_{2max}: 55±6 ml/min/kg) performed 5 km cycling time trials (TT) under control conditions and with lumbar intrathecal fentanyl impairing neural feedback from the lower limbs. To assure similar arterial oxygenation, O_2 content (C_aO_2) was raised by breathing 100% O_2 during the control (HYP_C) and the fentanyl (HYP_F) TT. The TT was also performed in normoxia with intact afferent feedback (NORM). After each TT, subjects performed a short, constant-load cycling bout at the mean power output achieved during the preceding TT while common femoral artery blood flow (Q_L) was quantified using Doppler ultrasound. Leg O_2 transport was calculated as the product of C_aO_2 and Q_L. Using supramaximal electrical femoral nerve stimulation, peripheral and central fatigue were quantified via pre- to post-exercise changes in quadriceps twitch force (ΔQ_{tw}) and voluntary activation (ΔVA). **RESULTS**: Both Q_L (~16 ml/W/min) and C_aO_2 (~24 ml O_2/dl) were similar at the mean power output achieved during HYP_C and HYP_F ($P > 0.6$), but significantly different from NORM (18 ± 4 ml/W/min and 22 ± 1 ml O_2/dl). Importantly, leg O_2 transport was similar between HYP_C and HYP_F (~0.36 ml O_2/W/min; $P = 0.6$) and significantly greater than NORM (0.33 ± 0.05 ml O_2/W/min). Although mean power output was augmented during HYP_C compared to NORM (287 ± 57 W and 261 ± 38 W, $P < 0.05$), ΔQ_{tw} was similar between trials (~40%). Interestingly, HYP_F further increased mean power output (309 ± 17 W) and improved time trial performance (3.3 ± 0.9%) compared to HYP_C ($P < 0.05$). This was associated with a greater ΔQ_{tw} (54 ± 9%), but a similar ΔVA (~4%) in HYP_F compared to HYP_C. **CONCLUSIONS**: Group III/IV muscle afferent feedback restricts endurance exercise performance and limits the development of peripheral fatigue. However, to expose the performance limiting aspect of these sensory neurons during whole body exercise, their impact on convective O_2 transport needs to be controlled.

Highly Cushioned Shoes Increase Leg Stiffness And Amplify Impact Loads During Running

Juha-Pekka Kulmala[1], Jukka Kosonen[2], Jussi Nurminen[3], Janne Avela[2]. [1]Harvard University, Cambridge, MA. [2]University of Jyväskylä, Jyväskylä, Finland. [3]Helsinki University Hospital, Helsinki, Finland.

(No relevant relationships reported)

Shoe cushioning represents a standard way to manage impact loading and consequent injuries due to running. However, although modern shoes have become increasingly cushioned, running injuries have not decreased. The probable, but poorly understood explanation for this counterintuitive is that shoes with additional cushion have only limited ability to attenuate impacts during running, even though they can significantly reduce impact loads *in vitro* mechanical tests. **PURPOSE**: The aim of this study was to investigate why shoes with additional cushion provide little or no reduction to the impact loads during running. **METHODS**: Ground reaction forces (GRF) and the spring-like leg mechanics were examined among 12 healthy men while running at 4.0 m/s with a rearfoot striking pattern using normal (NORM, Brooks Ghost 6) and maximalist (MAX) cushion shoes (Hoka One One). We determined and compared vertical GRF impact peak (VIP) and average vertical loading rate (AVLR), as well as leg stiffness and leg compression between shoe conditions. **RESULTS**: GRF parameters illustrating the hardness of the impact showed significantly greater values when running with MAX shoes, as compared to running with NORM shoes (VIP (p = 0.001) and AVLR (p = 0.038) were 10.7% and 12.3% greater in the MAX shoe, respectively). The analysis of the spring-like leg function revealed that during running with MAX shoes runner's leg became stiffer (p = 0.012) and compresses less (p = 0.006) when compared to running with NORM shoes. **CONCLUSIONS**: The present findings suggest that increased landing stiffness may

be responsible for opposing the impact attenuation effect of extra shoe cushioning during running. In fact, highly cushioned MAX shoes can even amplify impact loading during running, which thus may increase the risk of impact-related running injuries.

Mean (SD) data for the normal (NORM) and maximalist (MAX) shoe.

	NORM shoe	MAX shoe	*t*-test
Spring-like leg mechanics			
Leg stiffness (kN/m^{-1})	26.1 (7.1)	27.9 (8.2)	0.012*
Leg compression (cm)	8.3 (1.3)	8.0 (1.4)	0.006**
Impact loading			
Vertical GRF impact peak (BW)	2.01 (0.32)	2.25 (0.32)	0.001***
Vertical GRF loading rate (BW/s)	59.0 (15.2)	67.3 (14.6)	0.038*

Quantifying Head Impact Dynamics In Community Level Australian Rules Football

Alan Pearce. *La Trobe University, Melbourne, Australia.*

Research from elite contact sports is suggesting an athlete may incur hundreds of repetitive head impacts over one season. However, the majority of studies to date have focused on elite level athletes. To date, little investigation has focussed on non-elite sports, particularly in Australia where the majority of sport is played at the community level where little attention is given to those players who may experience significant head trauma. This is the first study to present head impact data in community level football. **PURPOSE**: To quantify head impact data over a season of Australian Rules football (ARF) played at the community club level. **METHODS**: Twenty-five male players (mean age 24.9 ± 5.2 years) from one ARF club participated in 20 home and away matches in the regular season. During matches, head impact data was collected using individually fitted instrumented mouth guards (Nexus A9, Impact Technologies, Australia). Data was sampled at 1000 Hz, with a 500 Hz bandwidth. If the mouthguard exceeded the pre-determined 10 g linear acceleration threshold 100 milliseconds (ms) of data (10 ms pre-trigger and 90 ms post-trigger) were recorded to the on-board memory for later downloading. Outcome measures included mean impact number, mean peak linear and peak rotational acceleration, and injury severity profiles for linear (ISP$_{linear}$) and rotational (ISP$_{rotational}$) accelerations. **RESULTS**: A total of 2810 impacts were recorded. Individual players experienced an average of 162 ± 40.5 impacts over the course of the season resulting in mean of 8 ± 11 impacts per-player per match. Linear accelerations ranged from 10 g to a peak of 176 g; with a mean, media and 95th percentile value of 33 g, 25 g, and 76 g respectively. Rotational accelerations ranged from 87 rad/s^2 to a peak of 19831 rad/s^{2,} with a mean, median, and 95th percentile value of 4004 rad/s^2 , 3109 rad/s^2 , and 9593 rad/s^2 respectively. The ISP$_{linear}$ profiles showed 86.6% were mild severity, 12.7% were moderate severity, and 0.7% were severe. The ISP$_{rotational}$ profiles showed 69%, 19.8%, and 11.2% were mild, moderate and severe respectively. **CONCLUSIONS**: This novel study provides data to better inform medical personnel in the identification and evaluation of at-risk players for concussion at non-elite community level ARF.
